With a block distribution, *blocks* of contiguous array elements are distributed onto each processor [8], as shown in Fig. 1a. Given an array A of 100 elements block distributed onto four processors, the first processor would receive elements $A[0], A[1], \dots, A[24]$, the second processor would receive elements $A[25], A[26], \dots, A[49]$, and so forth. This distribution can be defined more formally. Given the $U_P + 1$ processors onto which an array dimension is distributed, the

Data Distribution. Fig. 2 Examples of replicated, cyclic, and block-cyclic distributions. (a) The layout of a replicated array A on four processors. (b) The layout of a cyclically distributed array A on four processors. (c) The layout of a block-cyclically distributed array A on four processors

number of elements on each processor (i.e., the block size for each processor) is $B_s = \lceil \frac{U_A+1}{U_p+1} \rceil$. Processor p_j will get the j th block, and thus the lowest element of A on p_j is $L_{A_d, p_j} = j \cdot B_s$. The highest element on p_j will be one less than the start of the block on the next processor, or $(j+1) \cdot B_s - 1$. To ensure that only elements in the declared array are distributed, the upper bound on p_j must be less than the maximum element in the array, and thus $U_{A_d, p_j} = \min(U_{A_d}, (j+1) \cdot B_s - 1)$. To determine what processor p_j contains, or owns, some element $e = A[\sigma_{A_d}(I)]$, it is only necessary to determine which

block of length B_s the element is in. The block containing element e is $\lfloor \frac{e+1}{B_s} \rfloor$. Finally, $\Delta_{A_d}(e) = L_{A_d, p_j} \leq e \leq U_{A_d, p_j}$.

Cyclic Distribution

With a cyclic distribution, elements of the array are distributed in a round-robin fashion as shown in Fig. 2b. Each processor p_j receives elements

$$A[j], A[j + U_p + 1], A[j + 2 \cdot (U_p + 1)], \dots \\ A[j + U_{A_d, p_j} \cdot (U_p + 1)],$$

where U_{A_d, p_j} , the number of elements distributed to processor p_j , is $\lceil \frac{U_A+1-j}{U_p+1} \rceil$. An affine function describing the elements of A that reside on some p_j is $\Delta_{A_d}(p_j) = (U_p + 1) \cdot (k - 1) + j, 1 \leq k \leq \lceil \frac{U_A+1-j}{U_p+1} \rceil$. The processor that owns element $A[\sigma_{A_d}(I)]$ is given by $\sigma_{A_d}(I) \bmod (U_p + 1)$.

Block-Cyclic

The block-cyclic (or *cyclic(Bs)*) distribution combines features of both block and cyclic distributions. Whereas the cyclic distribution (which is a block-cyclic distribution with $B_s = 1$) spreads single elements of an array across the processors in a round-robin fashion, the block-cyclic distribution spreads blocks of contiguous array elements across the processor grid. With block-cyclic, B_s is the programmer specified size of a block, and $num_{Bs} = \lceil \frac{U_A+1}{B_s} \rceil$ is the number of blocks in the array. To find the elements contained by processor p_j , it is necessary to first find the blocks that are contained by p_j . A processor p_j contains $num_{Bs, p_j} = \lceil \frac{num_{Bs}-j}{U_p+1} \rceil$ blocks. Note that the formula for the number of blocks is similar to that for the number of elements on a processor with the cyclic distribution. Number the b blocks as $1, 2, \dots, num_{Bs, p_j}$. Then the first element in block b of array A_d is $L_{A_d, b, p_j} = B_s \cdot j + B_s \cdot (U_p + 1) \cdot (b - 1)$. Thus, the set of doubles

$$\{ [max(L_{A_d}, L_{A_d, b, p_j}) : min(L_{A_d}, L_{A_d, b, p_j} + Bs - 1)] | \\ 0 \leq b \leq num_{Bs, p_j} \}$$

describe the elements of the A on processor p_j .

The elements contained on a processor p_j for the replicated, cyclic, and block distributions can be described as an affine function in one variable because the distance between the e 'th and $e + 1$ 'th element of an array residing on p_j , in the global space of A , is constant and independent of the value of e . For block-cyclic, this

is not true – if elements e and $e + 1$ are within a block, the distance between them is one, and if e and $e + 1$ are in different blocks, the distance is at least $(U_P + 1) \cdot Bs$. This means that the distribution cannot be described as an affine function in one variable, a situation that caused much difficulty in handling block cyclic distributions in HPF [5, 9] in the early 1990s. However, once it is realized that the distribution can be described as an affine function in two variables [7, 10, 12], it is possible to manipulate these distributions as described above. One variable, b , moves from block to block, and the other, e , traverses the elements within a block.

Distributing Data Along Multiple Dimensions

The distribution of multidimensional array A onto multidimensional processor grid P is now described. There exist three cases: (1) the array rank is greater than the processor rank; (2) the array and processor rank are equal; and (3) the processor rank is greater than the array rank.

In the first case, D_P dimensions of the array are distributed onto the processor grid, and $D_P - D_A$ dimensions are replicated, as shown in Fig. 3a. In the second case shown in Fig. 3b, $D_A = D_P$ dimensions of the array are distributed onto the processor grid. Figure 3b shows array rows (columns) distributed onto processor rows (columns), and Fig. 3c shows array columns (rows) distributed onto processor rows (columns). In the third case, D_A dimensions of the array are distributed onto D_P dimensions of the processor grid, and the distributed array is spread (replicated) across the remaining $D_P - D_A$ dimensions of the processor grid, as seen in Fig. 3d.

The computations required for determining what elements along a dimension a processor might own can be computed independently for every dimension. Given an element of an array, it resides on a processor if the index for that element along every dimension of the array resides on the processor.

Trade-Offs of Different Distributions

When a value is needed on every processor, and the computation of the value costs significantly less than communicating it (e.g., via a *broadcast* or complicated point-to-point messaging), the best solution is often to compute the value on every processor. This requires replicating the data across the processors.

a	A[0:3, 0:24]	A[4:7, 0:24]	A[8:11, 0:24]	A[12:15, 0:24]
	A[0:3, 0:3]	A[4:7, 0:3]	A[8:11, 0:3]	A[12:15, 0:3]
	A[0:3, 4:7]	A[4:7, 4:7]	A[8:11, 4:7]	A[12:15, 4:7]
	A[0:3, 8:11]	A[4:7, 8:11]	A[8:11, 8:11]	A[12:15, 8:11]

	A[0:3]	A[4:7]	A[8:11]	A[12:15]
	A[0:3]	A[4:7]	A[8:11]	A[12:15]
d	A[0:3]	A[4:7]	A[8:11]	A[12:15]

Data Distribution. Fig. 3 Examples of multidimensional distributions. (a) Distribution of an array onto a processor grid with fewer dimensions. (b) Distribution of an array onto a processor grid with the same number of dimensions. (c) Distribution of rows (columns) of an array onto columns (rows) of a processor grid. (d) Distribution of an array onto a processor grid with a larger number of dimensions

A cyclic distribution is often used in situations where the amount of work being done on each processor may change from iteration to iteration, as is the case with triangular loops and some of sparse matrices. Using a cyclic distribution spreads consecutive iterations across the processors and leads to better load balancing at the cost of increased communication when adjacent array elements (in the global space) are needed. A block distribution can lead to a greater load imbalance but less communication. The block-cyclic distribution is a hybrid of the two with the benefits of both at the cost of more complex code to access elements of the array and to determine loop bounds.

Iteration Space Partitioning

After data has been distributed onto processors, it is necessary to partition, or shrink, the iteration space of loops that execute on each processor to only access the elements of the array that are owned by the processor. To partition the iteration space for a processor p_j , information is needed about the distribution, original loop bounds, and the subscript that is accessing the array. For the distribution, the information required is the first and last elements of the array that are distributed

onto the processor (U_{A,p_j}, L_{A,p_j}) , the block-size B_s , the number of processors $(U_p + 1)$, the affine function Δ describing elements of A that are present on a processor, and the type of the distribution. For simplicity, the present discussion will restrict itself to subscript expressions that are affine functions in one variable, i , i.e., $e = \sigma(i)$. This restriction is later lifted, and the general case of multiple references in a loop is also discussed.

Partitioning on Subscript Expressions in a Single Variable

Partitioning the loop bounds logically proceeds in two steps. First, the bounds are initially shrunk to encompass the range of elements that are owned by the processor. Next, the elements resident on a processor that are accessed by the subscript are identified, and the range of the index variable is modified to only access those elements.

Initial bounds partitioning. The initial partitioning gives lower and upper bounds of the loop index i on processor p_j for some reference $A[\sigma(I)]$ as

$$L_{i,p_j,\sigma}^{\text{init}} = \max(L_i, \min(\sigma^{-1}(L_{A,p_j}), \sigma^{-1}(U_{A,p_j})))$$

and

$$U_{i,p_j,\sigma}^{\text{init}} = \min(U_i, \max(\sigma^{-1}(L_{A,p_j}), \sigma^{-1}(U_{A,p_j}))),$$

respectively. The function σ^{-1} is the inverse of the subscript function, i.e., $e = \sigma(\sigma^{-1}(e))$. Thus the lower bound of the partitioned loop i must be at least as great as the least of the lower and upper bounds of the original loop. Moreover, for a monotonically increasing subscript value, it should be no less than the value needed to access the lowest numbered element of the array partition owned by the processor. The explanation of the expression for monotonically decreasing subscript values and for the initial loop upper bound is similar.

Finding elements on p_j accessed by $\sigma(i)$. The technique above is not sufficient to find the bounds of the loop. Why this is true can be seen in the example of Fig. 2a. In the example, some processors only contain odd elements of A, and some only contain even elements. If the array is accessed with $\sigma(i) = 2 \cdot i$, the processors containing only odd elements of A will not access any elements.

To determine precisely which elements are accessed, it is necessary to intersect the set of elements accessed by the subscript for each reference, as specified by σ and

the bounds computed above, and the list of elements on the processor, specified by Δ and its bounds. This is done by solving the Diophantine equation $\sigma = \Delta$. If there is no solution to the equation, then no elements of A accessed by the subscript are owned by the processor. If there exist solutions, then for each variable x_1, x_2, \dots, x_n there is a parametric equation $x = \kappa_1 + \kappa_2 \cdot t$ [1]. For block and cyclic distributions, the variable i used in $\sigma(i)$ is the loop index, and the variable (k for cyclic, b for block) for Δ specifies the different elements. Solving $L_{i,p_j,\sigma}^{\text{init}} \leq \kappa_1 + \kappa_2 \cdot t \leq U_{i,p_j,\sigma}^{\text{init}}$ gives the range of the t needed to generate the needed values of the x that corresponds to the index variable i . Plugging these values of t into the formula above gives the range of i values, and therefore the bounds of i for the loop on each processor.

For block-cyclic distributions, the same technique is used, but the Δ function has two unknowns, and consequently the i loop must be logically replaced by a pair of nested loops that iterate over the elements of the array.

Partitioning on Subscript Expressions in Many Variables

It is often the case that a subscript function will be a function of two or more index variables in a loop nest. Consider a loop nest of depth n , and the analysis of a subscript expression

$$\begin{aligned} \sigma(I) &= c_1 \cdot i_1 + c_2 \cdot i_2 + \dots + c_{q-1} \cdot i_{q-1} \\ &\quad + c_q \cdot i_q + c_{q+1} \cdot i_{q+1} + \dots c_n \cdot i_n + c_0 \end{aligned}$$

to partition the bounds of the i_q loop. At runtime, when the i_q loop begins to execute, values of the i_1, i_2, \dots, i_{q-1} loop indices are known, and the sum of products of these and their coefficients can be folded into the constant c_0 , giving $c'_0 = c_0 + \sum_{j=1}^{q-1} c_j \cdot i_j$. For the index variables i_{q+1}, \dots, i_n , the maximum and minimum values of the function

$$\sigma'(i_{q+1}, \dots, i_n) = c_{q+1} \cdot i_{q+1} + \dots c_n \cdot i_n$$

in the iteration space of the i_{q+1}, \dots, i_n index variables can be found. The minimum and maximum values that σ' can have are found for each processor by evaluating it at upper and lower bounds of the iteration space on that processor, and intersecting it with the array elements owned by the processor. Once these bounds are determined, the lower bound can replace the terms

i_{q+1}, \dots, i_n in σ to find the lower bound as described in section “Partitioning on Subscripts Expressions in Single Variables”, and the upper bound can be used to replace the terms to find the upper bound.

Finding Iteration Spaces for Loops with Multiple References

Let $L_{A_1,i}, L_{A_2,i}, \dots, L_{A_r,i}$ be the lower bounds on i for the r array references, $U_{A_1,i}, U_{A_2,i}, \dots, U_{A_r,i}$ be the upper bounds, and $S_{A_1,i}, S_{A_2,i}, \dots, S_{A_r,i}$ be the strides. (The strides result from the solutions of the parametric equations described in section “Partitioning on Subscripts Expressions in Single Variables”.) The final iteration space must contain all of the iterations needed by all of the references. Thus, the lower bound of the resulting loop is $\max(L_i, \min(L_{A_1,i}, L_{A_2,i}, \dots, L_{A_r,i}))$, the upper bound is $\min(U_i, \max(U_{A_1,i}, U_{A_2,i}, \dots, U_{A_r,i}))$, and the stride is $\gcd(S_{A_1,i}, S_{A_2,i}, \dots, S_{A_r,i})$. Because the iteration space contains, in general, more iterations than needed by any single reference, each computed reference must be guarded by an *if* statement that checks if the current value of i is within the upper and lower bound for that reference, and if the stride is a divisor of the stride for a reference, as shown in Fig. 4.

Communication Sets

If cross-iteration dependences exist in the program, communication among processors is necessary to transfer data that is needed by processor p_r but is owned by another processor p_s . With the bounds of the partitioned loop on some processor p_r , the elements of a read array reference accessed by p_r can be determined and expressed as an affine function. The affine function describing the read elements is simply the subscript expression σ for the reference, bounded by the upper and lower bounds of the partitioned loop. By intersecting this affine function with the affine functions Δ describing elements of the array owned by each processor, the elements that must be sent from each processor to other processors can be determined. This intersection is the solution of the Diophantine equation $\sigma = \Delta$.

Naively, this intersection must be performed by every processor. However, compiler analyses can determine communication patterns for pairs of references [3, 8]. These patterns will often limit the number of processors for which communication sets must be computed.

```

for (i = max(L_A, min(L_{A_1,i}, L_{A_2,i}, ..., L_{A_r,i})),
      i ≤ min(max(U_{A_1,i}, U_{A_2,i}, ..., U_{A_r,i})),
      i+ = gcd(S_{A_1,i}, S_{A_2,i}, ..., S_{A_r,i}) {
  if (i ∈ max(L_A, L_{A_1,i}) : min(U_A, U_{A_1,i}) : S_{A_1}) {
    A_1 = ...
  }
  if (i ∈ max(L_A, L_{A_2,i}) : min(U_A, U_{A_2,i}) : S_{A_2}) {
    A_2 = ...
  }
  ...
  if (i ∈ max(L_A, L_{A_r,i}) : min(U_A, U_{A_r,i}) : S_{A_r}) {
    A_r = ...
  }
}

```

Data Flow Computer Architecture

JACK B. DENNIS

Massachusetts Institute of Technology, Cambridge, MA, USA

Definition

Data Flow Computer Architecture is the study of special and general purpose computer designs in which performance of an operation on data is triggered by the presence of data items.

Discussion

Introduction

This article discusses several forms of data flow architecture that have been studied in university research groups and industrial laboratories beginning around 1974 [8]. The architectures covered all use some form of data flow graph programming model to enable the exploitation of parallelism.

In its original form, data flow architecture envisioned single instructions operating on individual data elements, integers or floating point numbers for example, as the units of computation, and this has characterized most of the design proposals and projects. Other designs have used blocks of instructions or modules of code as the independently executed unit.

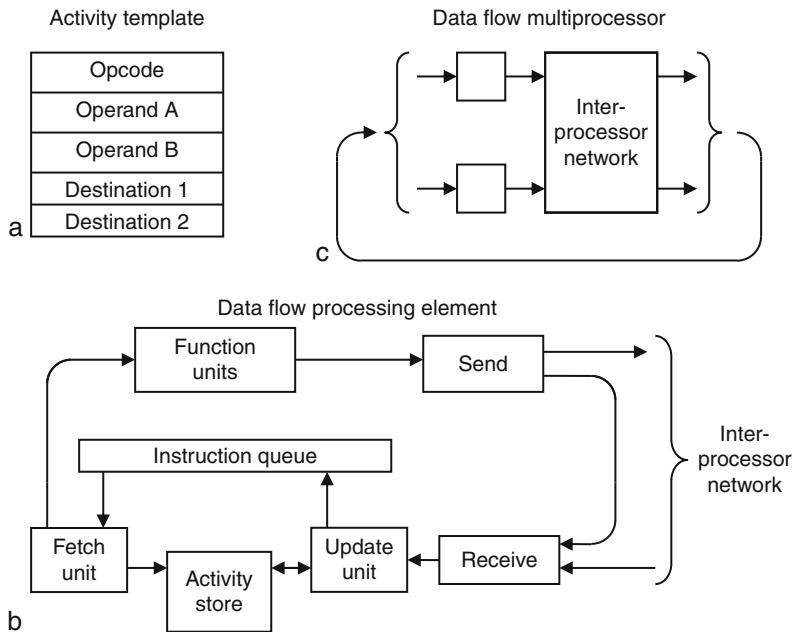

Two major lines of development of data flow architecture have been pursued. In *static* data flow machines, the hardware holds a single unchanging representation of a data flow graph loaded prior to program execution. In *dynamic* data flow, means are incorporated so that computation proceeds as though copies of a data flow graph were generated during program execution, providing direct support of arbitrarily nested function activations. A general form of dynamic data flow also permits many instances of a loop body to have effectively separate data flow representations for each cycle of loop execution so that overlapped execution may occur.

The following sections discuss static and dynamic data flow architecture, then data structures in data flow computers, and multithreading architectures inspired by data flow principles.

Static Data Flow Architecture

The basic scheme of a static data flow multiprocessor is illustrated in Fig. 1. A data flow program is stored in the machine as a collection of Activity Templates divided among the several processing elements and held in the Activity Store of each. The operand fields of Activity Templates are placeholders for operand values expected as results of executing other instructions; destination fields specify the target Activity Template, which may reside locally or in a remote processor, and the role that the result plays at the target. The Instruction Queue contains Activity Store addresses of instructions, for which operands needed for execution have been placed in the corresponding Activity Template, and delivers them to the Fetch Unit. In turn, the Fetch Unit accesses the completed Activity Template and forwards it to a Function Unit appropriate for the requested operation. When a result is obtained, the Function Unit constructs one or more Result Packets, each consisting of a copy of the result value and one destination address from the Activity Template, and passes these to the Send Unit. The Send Unit either directs the packet through the Interprocessor Network to the Update Unit of a remote processing element, or delivers the packet to the local Update Unit through the Receive Unit. The Update Unit enters the result in an operand field of the target Activity Template, and checks whether all needed operands are present. If so, it enters the address of the Activity Template in the Instruction Queue. Conditional and iteration program elements may be implemented using relational instructions that produce Boolean control packets; the Update Unit may use such a control value to choose which of two operands a Function Unit should use. Reference [9] gives details of one proposal.

Although implementations of static data flow have a variety of forms, the circular pipeline structure evident in Fig. 1 is a common feature, and supports the continuous processing of several instructions simultaneously. Static data flow concepts are well-suited to signal processing applications and to scientific computation using linear algebra methods, especially when array sizes are known at the start of computation. Several industrial

Data Flow Computer Architecture. Fig. 1 Scheme of a static data flow multiprocessor

projects have constructed static data flow processors, and the principles have found use in signal processing applications.

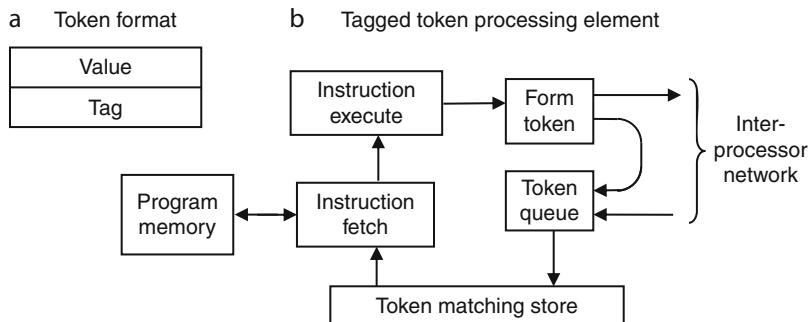

Dynamic Data Flow Architecture

In a dynamic data flow computer, the values passed between actors of a data flow program graph are tagged to indicate which instance of a variable is represented. To handle arbitrary nests of function calls and unknown loop iteration counts, the number of distinct value instances existing in any snapshot of an ongoing computation is unknown until after the computation has begun. Hence, the information in the tag of a value cannot be coded in the structure of the (finite) graph. The tag of a value must define to which function activation the value pertains, and to which cycle within each nested loop of the function body the value applies. The semantics of an execution model known as the *unraveling interpreter* were published in 1977 [1, 12] and supplied the initial impetus for dynamic data flow.

Figure 2 shows the general scheme of a dynamic data flow multiprocessor. The dynamic data flow scheme has similarities to the static scheme: tokens carrying data values flow in a circular pipeline structure. Differences

lie in the way instructions are stored and activated. In dynamic data flow, operands cannot be held with the instruction that operates on them. Instead, a special component, called the Token Matching Store, is used to hold operand values that must wait for a second operand to arrive before an operation on the pair may be performed. Then the Matching Store forwards the pair of values to Instruction Fetch, which accesses the instruction and passes the combination to Instruction Execute. The Form Token unit creates a token using the computed result value, and the operand tag and destination address passed through from Instruction Fetch. Tokens are either entered in the local Token Queue or dispatched to a remote processor according to their tag values.

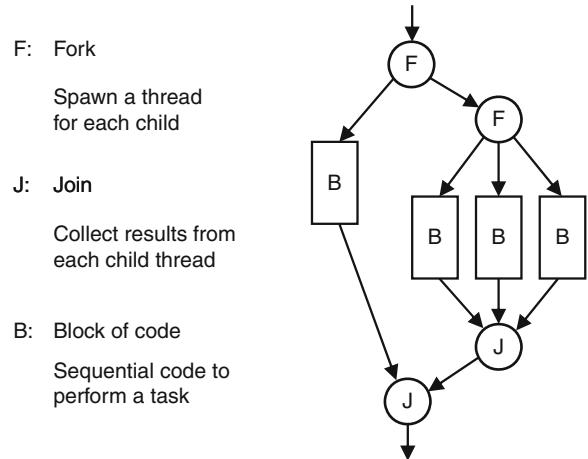

A pioneering implementation of dynamic data flow was built at Manchester University, England [13], and it used a hardware associative memory for the Token Matching Store. Several variations on the scheme of Fig. 2 have been developed at research institutions, some with industrial support. The variations are mainly concerned with replacing the associative memory used in the Manchester University machine with innovative schemes that are substantially more cost-effective.

Data Flow Computer Architecture. Fig. 2 Scheme of a dynamic data flow multiprocessor

Data Structures in Data Flow

Performing computations involving structured data such as arrays of values presents a challenge for data flow architecture because it seems wasteful to carry a complete data structure from a producer actor to a consumer. On the other hand, if the data structure is held separately from the data flow graph, then hazards can arise from races between conflicting memory operations. One solution to this quandary is to use special data structures known as *I-Structures* for which a single write order sets a value and several synchronized reads may safely access it [2]. Other approaches involve partial *copy-on-write* operations, and special data parallel treatment of array construction operations.

Data Flow Computer Architecture. Fig. 3 Multithread tasking scheme inspired by data flow concepts

Data Flow Ideas in Multithreading

Several workers familiar with data flow principles have employed data flow concepts in the construction of systems able to multithread large numbers of concurrent activities with a guarantee of determinate execution. The principles used are illustrated in Fig. 3, where the links indicate flow of control (threads). Here four code blocks are arranged to execute concurrently through the use of **fork** and **join** operators. It is expected that a computer system will schedule threads to execute the code blocks as short sequential program segments. In execution, the code blocks may have internal variables, but all shared data is read-only. At a **fork** operator, the parent thread makes specific data objects accessible to each child task. At a **join**-operator result values produced by each child are combined and made available to the continuation thread. Several variations of this scheme have been implemented for shared-memory multiprocessor systems, and provide a guarantee of determinate

behavior so long as the restriction of code segments to read-only shared data is honored.

Future Prospects

Currently, increased attention is being given to multithread computer architectures inspired by data flow principles to yield higher performance by dynamically scheduling sequences of instructions as independent units of computation [17]. It is known how to build static dataflow computers and streaming processors that can perform well. The extension to data structures and dynamic control structure, such as recursive functions, has remained a challenge for demonstrating levels of performance that would attract widespread interest.

Because dataflow graphs are a determinate representation for parallel programs that do not make essential use of nondeterminacy, it is feasible to build

computers using data flow principles that can provide the user with a guarantee of determinate operation, while achieving highly parallel computation. This was accomplished in the Barton/Davis DDM1 machine [6, 7]. However, reluctance to adopt the functional programming style favored by data flow architecture has limited the prospects for this achievement.

Bibliographic Notes and Further Reading

Data flow computer architecture was inspired by the prospect of using data flow graphs as a programming model, thereby permitting exploitation of parallelism to be readily accomplished. The first proposals for the hardware organization of dataflow computers were published in 1974 [8] and 1975 [9], originating in the Computation Structures Group of MITs Project MAC. The earliest working model of a computer using data flow principles was the DDM1 designed by Al Davis and Robert Barton at the University of Utah, built at the Burroughs Corporation and described in 1978 [6, 7]. It was a very innovative machine, supporting a dynamic programming model including a tree-structured heap for memory objects. It relied on the serial processing of text packets representing instructions and data.

Static data flow architectures were developed as a direct implementation in hardware of the data flow graph program model [8, 9]. Experimental static data flow computers were built by Texas Instruments [4], the ESL division of TRW [16], Hughes [26], and in France [3].

In Japan, NEC conducted two significant static data flow projects. The NEDIPS processor was developed in the Radio division for processing radio astronomy data [24]. The second project developed a data flow processing chip that could be used in cascade to implement signal processing functions and was envisioned to be the basis for an advanced photo copying machine that could scale and rotate digitized images [10, 18]. Many other Japanese manufacturers also built experimental data flow machines; Veen [27] provides details.

The best known early project to build a machine using the tagged token principle was the Manchester University data flow computer that introduced the waiting-matching store [13]. Since then the principle has been developed to introduce more efficient realizations in projects in Japan and at MIT in the USA. The most advanced and successful of these are the Sigma 1 project at the Electrotechnical Laboratory in Japan [14, 15], and the Monsoon project at the MIT Laboratory for Computer Science [20, 21]. These projects have demonstrated the ability of data flow architecture to exploit parallelism in important codes for scientific computation.

Multithreading projects inspired by data flow concepts include the Threaded Abstract Machine [5], and others described in [11]. A recent revival of interest in applying dataflow principles in computer architecture has led to projects at University of Texas, Austin [22] and the University of Washington, Seattle [19].

The 1991 volume edited by Gaudiot and Bic [11] includes chapters written by authors personally involved in many of the data flow research efforts at its time of publication. Good treatments of multithreaded computer architectures and their relation to data flow research may be found in [17]. The papers collected in [25] describe early work on advanced programming models in the context of sequential computers that foresees later work on dynamic data flow. The book by Sharp [23] provides a summary of approaches to data flow computer architecture and includes a good bibliography of early work in the field, and the Veen survey [27] explains details of the many dataflow hardware projects of the late 1970s and 1980s.

Program graphs

Definition

A *data flow graph* is a graph model for computer programs that expresses possibilities for concurrent execution of program parts. In a data flow graph, nodes, called *actors*, represent operations (functions) and predicates to be applied to data objects, and arcs represent channels for data objects to move from a producing actor to a consuming actor. In this way, control and data aspects of a program are represented in one integrated model. When data objects are available at input ports of an actor and certain conditions are satisfied, the actor is said to be *enabled*. Because the set of enabled actors may be chosen to fire simultaneously, or sequentially in any order, data flow models expose much of the

parallelism available in the computation represented, and this parallelism may be exploited in an implementation of the model.

Discussion

Introduction

Although many versions of data flow graphs (DFGs) have been studied in the literature, they share some significant common features.

1. A DFG is a directed graph representation in which an arc is a path over which data are passed from a producing node to a consuming node.
2. Dynamically, a node of a DFG acts (by *firing*, as in a Petri net) by accepting one or more data items from its inputs, performing some computation, and delivering resulting data items to its outputs.
3. Action by a node is triggered by the presence of input data.

The study of data flow graphs has focused mainly on three well-defined formal models: the static data flow model, dynamic data flow, and synchronous data flow. The various models differ in such aspects as how many data items are permitted to occupy an arc, whether actors are permitted to have internal state, and other details.

Basic forms of static DFGs and their properties are described below, including determinacy; this is followed by a discussion of dynamic data flow and the synchronous model. Uses of DFGs are summarized.

Basic Simple DFGs

Figure 1 shows a basic simple static data flow graph, which is an acyclic directed graph (DAG) in which the nodes are drawn as circles and represent *actors* that perform functional operations on a set of input values (possibly empty) to produce a set of one or more output values. The arcs of the graph are called *links*, and convey values from an output port of one actor to an input port of another, or from an input port of the DFG to an actor input, or from an actor output to an output port of the DFG.

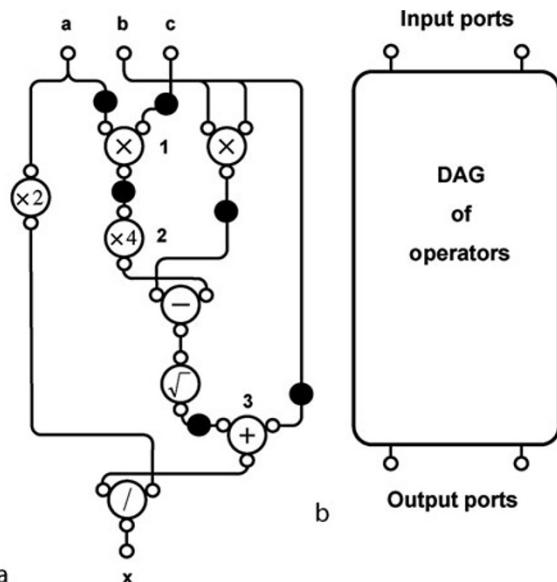

To discuss the semantics of a DFG, it is useful to associate tokens with arcs of the graph. Each token carries a value, which may be a scalar value such as an integer, or, in some studies, a data structure. For most

work with static data flow graphs, links are permitted to hold just one token. For simple static DFGs, each arc holds either a single token or is empty. The firing rule for advancing the state of a DFG is:

Firing rule: An actor of a DFG is *enabled* if a token is present on each input link of the actor, and no token is present on any output link. An enabled actor may be *fired* by removing one token from each input link and placing a token on each output link. The values held by the output tokens are the result of applying the operator of the actor to the set of values held by the input tokens.

Asynchronous firing of actors is permitted, and the time taken for any actor to fire may be arbitrary, so several actors in a DFG may be firing simultaneously. In **Fig. 1**, a state of execution is shown wherein actors 2 and 3 are both enabled and may be chosen to fire in either order, or to fire simultaneously. After actor 2 has fired, actor 1 will be enabled because its output link will then be empty.

The input ports of a DFG may be regarded as special actors that place tokens on the input links of the graph when values are supplied to the ports from the external environment of the DFG. Similarly, output ports make the values held by tokens on output links available to the environment and remove the tokens when the values are taken.

Data Flow Graphs. Fig. 1 Simple static data flow graphs

A DFG is activated by supplying data values at each input port, and terminates when values are available at each output port. A DFG is said to be *well-behaved* if its activity terminates following each presentation of values.

The DFG in Fig. 1a represents the standard formula for computing one of the roots of the second-degree polynomial, $a + bx + cx^2$:

$$x = \frac{b + \sqrt{b^2 - 4ac}}{2a}$$

This DFG is well-behaved, as are all simple static DFGs if their actors have operators that are total functions. Also, simple DFGs can represent pipelined computation, that is, more than one set of input values may be accepted by the DFG before its activity has terminated for the earlier set of input values. The pipelined operation of DGFs is closely related to use of coroutines as a program structure for parallel computing. Some workers with DFGs view each arc as a FIFO queue that can hold either a bounded or unbounded number of value-carrying tokens. This may be shown on the graph by permitting multiple tokens on any arc, with the stipulation that order is preserved: tokens are removed from the arc by a consuming actor in the same order as they were placed by the producing actor.

A simple data flow graph is *determinate*. Determinacy is an important concept in parallel computing. It captures the idea that a system can have repeatable behavior while at the same time being nondeterministic in its operation. The property of being well-behaved guarantees that the value produced at each output port is a fixed composition of the functions defined by the actors of the DFG. Basic simple DFGs are determinate whether or not they are well-behaved.

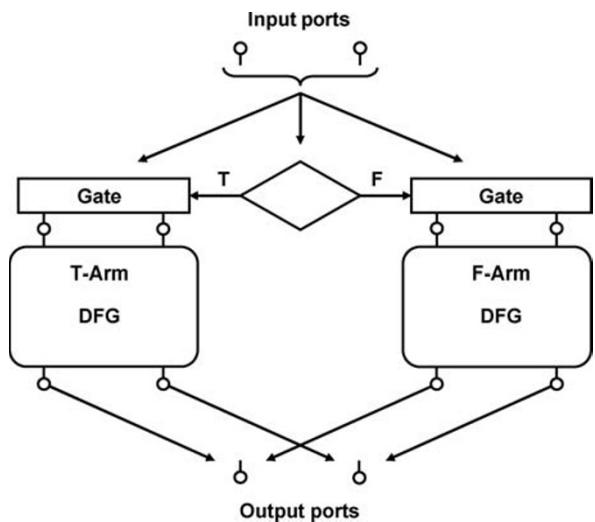

Compound Simple DFGs

A complete system for describing computations requires means for describing conditionals and iteration. In simple DFGs, these features are provided using DFG structures motivated by the principles of structured programming advocated by Dijkstra and Hoare that have had a strong influence on modern programming language design.

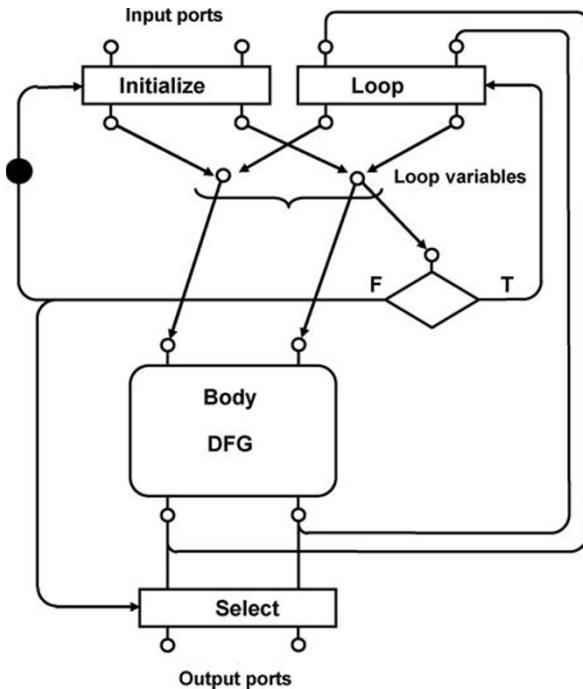

For ease of exposition, the manner of expressing conditional and iteration expressions as DFGs used here

is adapted from their use in several compilers for functional programming languages. Figure 2 illustrates a typical way of representing an *if...then...else* construction as a data flow graph. The diamond-shaped *decider* actor accepts a token carrying a boolean value from one of the input ports and generates *event signals* (tokens) that activate gating structures, shown as rectangular boxes, that select input values for passing to the two component DFGs: the T-Arm activated for a true decision and the F-Arm for false. Any combination of input ports may be selected as inputs to the arm graphs. However, the output ports of the arm graphs must be in one-to-one correspondence with output ports of the conditional graph so that output values are defined for every possible execution. A conditional DFG is determinate, and will be well-behaved if the two arm graphs are well-behaved.

Figure 3 illustrates one way of representing an iterative loop as a data flow graph, in this case a computation of the form **while...do...**. The body of the iteration is represented by a DFG that takes input values from a set of loop variables and produces output values that provide updated definitions for the loop variables. Here, the gating structures serve to provide initial values for the loop variables and then to redefine them from the outputs of the loop body for each cycle. The decider uses the value of a boolean loop variable to control the gating.

Data Flow Graphs. Fig. 2 A conditional DFG

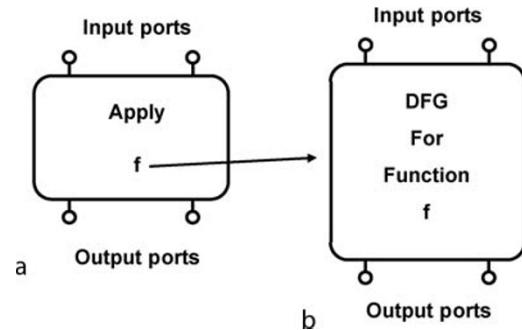

Data Flow Graphs. Fig. 3 Iteration as a data flow graph

Note that the initial state of this graph must have a token carrying an event signal for gating initial values to the loop variables. If the body DFG is well-behaved, then so will the compound DFG, provided the iteration terminates. Note that the compound DFG is determinate even if it might not terminate for some inputs.

The Apply Actor

In comparison with programming languages, the DFG constructions introduced so far are limited. There is no means for expressing function invocation, and no means for building and analyzing data structures. For function invocation, DFGs use the **apply** actor which has the semantics shown in Fig. 4. The Apply actor identifies a separate DFG that defines a computation to be performed whenever the Apply actor is executed. It is executed by copying values from the input ports of the apply actor to the input ports of the specified DFG. When the function body terminates, the values at its output ports are transferred to the output links of the Apply actor.

There are two ways of elaborating the semantics of the Apply actor: by substitution and by using *tagged*

Data Flow Graphs. Fig. 4 The apply actor

(colored) tokens. For substitution, the meaning of a DFG containing apply actors is the simple DFG obtained by copying the specified DFG in place of each apply actor. Of course, this reaches limitations for recursive functions where a potentially unbounded cascade of copying is necessary.

The second approach is to avoid the copying of graphs by permitting multiple tokens with distinct tags to be present on each DFG link. The tags are chosen so that all tokens that carry values associated with a specific activation of a function graph have identical tags. The use of tagged tokens also permits iteration to be represented in a way that permits actors from more than one cycle of an iteration to be active concurrently. The *tagged-token model* of DFG semantics has been the inspiration for at least two projects for building computers using data flow principles, and constitutes the essence of *dynamic data flow*.

An important and useful property of data flow graphs is that they not only express the dependence relations among operations of a computation, but also provide a recipe for execution – how to perform the computation – specifically the firing rule given above. The firing rule specifies a *data-driven* order of performance, that is, each operator acts just when all data it needs have arrived. In this scheme, the firing of an Apply actor, causing execution of the body of the applied function, is delayed until all inputs (function arguments) are present (evaluated). A consequence is that if the applied function does not make use of all of its arguments, unnecessary computation will be performed, and execution of such a program might not terminate if evaluation of an unneeded argument executes an endless loop.

This issue can be avoided by using *demand-driven* evaluation wherein a data flow actor is executed only when its result is needed. It is known how to convert a data flow graph into a new graph for which data-driven execution performs the actors of the original graph exactly as for demand-driven execution.

Data Structures

The simplest way to include data structures in a data flow model is to use **read** and **write** actors that access a memory that is not part of the DFG. The read operation accesses a specified location in the memory, and the write operation updates a memory location with a new value. The drawback of this approach is that the DFG is no longer necessarily determinate because read and write operations for the same memory location may be concurrent in the DFG.

A better way to introduce data structures is by permitting data objects, representing array or record values, to be carried by tokens in a DFG. Three new actor types are added: **create**, **append**, and **select**. The create actor, when fired, produces a null data structure having no components – representing an empty record or an array with no defined elements. The append actor performs the operation

$$\text{object} \leftarrow \text{append } (\text{object}, \text{index}, \text{element})$$

where the object produced has a component named *index* with *element* as its value. (The element could be a structured value such as a row of a matrix or a scalar value.) The object operated on by an append actor may be a null object from a create actor, or a structure from another append actor with one or more defined components. The select actor

$$\text{element} \leftarrow \text{select } (\text{object}, \text{index})$$

yields the component identified by *index* in the data structure represented by *object*. DFGs constructed using the select and append actors have functional (determinate) semantics as in pure Lisp. Other work on data flow models has treated arrays of values as sequences of tokens passed between actors.

Control Flow and Data Flow

A subject of importance for compiler design is the choice of an intermediate representation (IR) on which program transformations may be performed. Data flow

graphs are an attractive IR because they both represent dependence information and provide a complete executable semantics of the computation. Therefore, being able to use this form for programs defined by traditional imperative languages would be highly beneficial. It is straightforward to represent imperative programs by control flow graphs and means for converting control flow representations to data flow graphs are known. Hence, it is feasible to employ data flow graphs as an IR for optimizing transformations in compilers for imperative languages.

Synchronous Data Flow

In the synchronous data flow (SDF) model, arcs of a DFG are permitted to hold multiple tokens, and a generalized form of firing rule is used. Moreover, the firing of actors happens at definite points in time, as if at periodic cycles defined by a system clock. For each actor, the designer of the model may specify a number of tokens required to be present at each input port, how many are removed when the actor fires, and how many tokens are placed on output arcs. These numbers do not change during operation of the model. The links in an SDF model are treated as FIFO buffers, and their sizes, along with the numbers of tokens placed or removed by the firing of nodes must be chosen carefully to avoid deadlock. Conditional constructions and while loops are not permitted in SDFs as these would negate the property that a SDF graph describes a system with a constant rate of operation. The effect of a conditional may be achieved by incorporating the conditional within a node, such that the duration of its firing is invariant. Feedback paths may be present in a SDF graph and are important to represent continuous processes that have internal state using only state-free (functional) operators.

The synchronous data flow (SDF) model is intended as a representation of digital signal processing (DSP) computations that continue in execution for an unbounded time interval, consuming a stream of input data items and producing an output stream. A feature of the SDF model is that DSP systems with components operating at different clock rates can be accurately modeled.

Applications

The early work on data flow models inspired several attempts in universities and industry to build practical

computers embodying data flow concepts. See the article on ►Data Flow Computer Architecture in this encyclopedia. The programming languages Id, Val, Sisal, and Ph are functional programming languages specifically designed to permit natural expression of the parallelism exposed in data flow models. Applications in signal processing include the system modeling tool LabVIEW and work on synthesizing digital signal processing systems, as in the Ptolemy project at UC Berkeley. An important use of data flow graphs is as an intermediate form for programs processed by a compiler written in either a functional or an imperative programming language.

Bibliographic Notes and Further Reading

Precursors to data flow models may be found in simulation models for industrial systems, engineering descriptions of the processing of information packets, especially for communications systems, as reviewed in the survey by Davis and Keller [6]. However, the first works using the data-driven concept as a precise representation for computer programs and systems were published in the 1960s, independently by Karp and Miller at the IBM T. J. Watson Research Center [10], by Rodriguez at MIT [16] and by Duane Adams at Stanford University [1]. These early models were “static” in that they did not embody a natural way of describing arbitrary nests of possibly recursive function definitions. The 1980 paper of Dennis [8] includes an introduction to static DFGs.

The Graph/Heap model for dynamic data flow using colored tokens was described by Dennis in 1974 [7]. The work of Arvind, Gostelow and Plouffe in 1978 [3] formulated the dynamic data flow model in the form of the “unraveling interpreter” using tagged tokens. The semantics of dynamic data flow computations by graph copying was described by Dennis in 1974. The

synchronous data flow model was introduced and its properties studied in the 1987 paper of Edward Lee [11].

In 1982 the IEEE journal *Computer* published a special issue devoted to concepts and research on data flow models [2]. It includes an introduction by editors Tilak Agerwala and Arvind, a paper on data flow languages by William Ackerman, the survey of the data flow program graphs by Alan Davis and Robert Keller, a description of the unraveling interpreter by Arvind and Kim P. Gostelow, and a description of the Manchester tagged token data flow computer by Ian Watson and John Gurd. A “Second Opinion on Data Flow” by Gajski, Padua, Kuck, and Kuhn completes the issue. The book by Sharp [17] provides a later review of the major forms of data flow program models and the types of computer program execution models inspired by them.

Several programming languages have been developed or inspired by data flow concepts, including Val [12], Sisal [13], Lucid [4] and pH [14]. The use of data flow graphs as a program representation in Sisal compilers has been described by Dennis [9] and by Skedzielewski and Glauert [18], although there have been other unreported uses. The expression of demand-driven computations as demand-driven DFGs was described by Pingali and Arvind [15], and the use of DFGs in representing computations written in imperative languages is discussed by Beck, Johnson and Pingali [5].

For a discussion of the influence of data flow concepts on computer architecture and programming languages, see the encyclopedia entries on Data Flow Architecture and Parallel Functional Languages.

Data Mining

AMOL GHOTING

IBM Thomas. J. Watson Research Center, Yorktown Heights, NY, USA

Synonyms

Data analytics; Knowledge discovery

Definition

Data mining, also popularly referred to as knowledge discovery from data, is the automated or convenient extraction of patterns representing knowledge implicitly stored or catchable in large data sets, data warehouses, the Web, and other massive information

repositories or data streams. Parallel data mining refers to the use of parallel computing to reduce time to execute a data-mining algorithm.

Discussion

Introduction

Advances in data collection and storage technologies have allowed organizations to gather, collect, and distribute increasing amounts of data. Spurred by these advances, the field of data mining has emerged, merging ideas from statistics, machine learning, databases, and high performance computing. The main challenge in data mining is to extract knowledge and insight from massive data sets in a fast and efficient manner. This process is iterative in nature and involves a human in the loop. Therefore, to facilitate effective data understanding and knowledge discovery, it is imperative to minimize execution time of a data-mining query. Parallel data mining refers to the use of parallel computing to reduce the time required to execute a data-mining query.

Data mining commonly involves four classes of tasks: association rule mining, classification, clustering, and regression. These classes will be described next together with a brief summary of parallel algorithms for each task.

Association Rule Mining

Association rule mining is a popular method for discovering interesting relations between variables in large databases. Agrawal et al. introduced association rules [4] for discovering patterns involving products in transactional data. An example of transactional data is point-of-sale (POS) data that is produced in supermarkets, which lists the items purchased by each customer during a visit. An association rule found in such data could indicate that if a customer purchased items A and B together, the customer is likely to also purchase item C. An example of an association rule is $(\text{milk}, \text{sugar}) \rightarrow \text{cereal} (90\%)$, which means that if a customer buys milk and sugar together, he or she is likely to also buy cereal 90% of the time. Note that the antecedent of the rule can contain more than two items. Such rules are often used to enable various marketing activities such as promotional pricing and product placements. In addition to the above example from market basket

analysis, association rules are also employed in many other application areas, including web usage mining, intrusion detection, and bioinformatics.

Finding association rules requires determining all frequent patterns in a transactional data set. A post-processing step can then find all association rules using the set of frequent patterns. The frequent pattern mining problem was first formulated by Agrawal et al. [4]. Briefly, the problem description is as follows: Let $I = \{i_1, i_2, \dots, i_n\}$ be a set of n items, and let $D = \{T_1, T_2, \dots, T_m\}$ be a set of m transactions, where each transaction T_i is a subset of I . An itemset $i \subseteq I$ of size k is known as a k -itemset. The *support* of i is $\sum_{j=1}^m (1 : i \subseteq T_j)$, or informally speaking, the number of transactions in D that have i as a subset. The frequent pattern mining problem is to find all $i \in D$ that have *support* greater than a minimum support value, *minsupp*. The frequent pattern mining step is the most time-consuming step in association rule mining, and much work has been done to make it efficient.

Agrawal et al. [2] presented *Apriori*, the first efficient algorithm to solve the frequent pattern mining problem. The *Apriori* algorithm traverses the itemset search space in a breadth-first manner. At level k , candidate itemsets of size k are generated by using frequent itemsets of size $k - 1$. These candidates are then validated against the database (usually by a full scan) to obtain frequent itemsets of size k . *Apriori*-based algorithms speed up the computation by using the anti-monotone property and by keeping some auxiliary state information. The anti-monotone property states that if a size k -itemset is not frequent, then any size $(k + 1)$ -itemset containing it cannot be frequent.

Agrawal and Shafer [3] were the first to address the challenge of frequent pattern mining on shared-nothing architectures, proposing Count Distribution (CD) and Data Distribution (DD). Both CD and DD are parallelizations of the *Apriori* algorithm.

CD reduces execution time by parallelizing the data set scans. The data set is partitioned across all nodes, and each node scans its local data set to obtain frequencies of candidates. The frequency information is then accumulated to determine the global frequencies of the candidate itemsets. Once the global frequencies are obtained, infrequent itemsets are pruned, and each node generates candidates for the next level. Candidate generation is sequential, and not parallel, as each node

generates the same set of candidate itemsets. This process repeats until a level is reached where there are no more candidate itemsets. CD thus reduces the communication between processors at the cost of performing redundant computations (in the form of candidate generation) in parallel. However, it scales poorly as the number of candidates increases.

DD distributes the data set to each node. At the start of each level, each node takes turn broadcasting its local data set to every other node, and each node then generates a mutually disjoint partition of candidates. Furthermore, frequent itemsets are communicated so that each processor can asynchronously generate its share of candidates for the next level. DD overcomes the bottleneck of serial candidate generation by partitioning generation amongst the processors. However, it incurs very high communication overhead when broadcasting the entire data set, which is especially costly in case of large data sets. In their study, the authors find the costs of communication outweigh the improvements to parallel candidate generation. In both CD and DD, processors need to be synchronized at the end of each step, which can potentially cause processors to idle if the data is skewed.

Han et al. [14] proposed Intelligent Data Distribution (IDD) and Hybrid Distribution (HD), which build upon CD and DD. IDD reduces the communication overhead by distributing the data using a ring all-to-all broadcast algorithm. In the original DD algorithm, each node broadcasts its data set, which results in unnecessary communication. Although an improvement, IDD still suffers from the high overhead of transferring the entire data set at each level. The authors noted that a weakness in CD is that the global candidate list may exceed the size of available main memory for a single node. To address this problem while minimizing communication and computation overheads, HD combines the advantages of both the CD and IDD algorithms by dynamically grouping processors and partitioning the candidate set accordingly to maintain good load balance. Each group is large enough to hold the candidate list in main memory and executes the IDD algorithm. Communication across groups is performed as in CD.

Parthasarathy et al. considered the parallelization of the *Apriori* algorithm on shared memory systems [23]. They showed that the hash-based data structures used by *Apriori* during the candidate generation and

counting phases result in poor data locality and false sharing on shared-memory systems. To address these issues, the authors proposed several memory placement techniques to improve performance.

Unlike the above approaches that traverse the search space in a breadth first manner, *Eclat* [28] is an algorithm that traverses the search space in a depth first manner. The algorithm uses itemset clustering techniques to approximate the set of potentially maximal frequent itemsets. A maximal frequent itemset is a frequent itemset that cannot have a frequent superset itemset. Once these sets have been identified, the algorithm makes use of efficient depth-first traversal techniques to generate frequent itemsets contained in each cluster. The advantages of this approach compared with the Apriori-style approaches are improved locality and a natural structure for parallelization – each cluster can be processed independently. The structure of this algorithm naturally lends itself to both shared-memory and distributed-memory parallelizations.

Han et al. proposed the *FPGrowth* [15] algorithm that improves performance through the use of a smart data structure known as the *FP-tree* and by employing a projected data set during the depth-first traversal of the search space. However, while delivering excellent sequential performance, a limitation to parallelizing this algorithm is its reliance on a dynamic, pointer-based data structure and the fact that the data structure can potentially be out-of-core for very large data sets.

Cong et al. [10] proposed a sampling-based framework for parallel itemset mining using FPGrowth on shared-nothing systems. They first selectively sample the transactions by discarding a fraction of the most frequent items from each transaction. Based on the mining time on the reduced data set, the computation is divided into tasks needing roughly the same amount of execution time. In practice, they found that sample mining times were quite representative of actual mining times. Using these timing results, tasks could be assigned to machines statically, while affording excellent load balancing. A drawback of their approach, particularly when mining very large dense data sets is that it assumes that the FP-tree fits in core, and that the data is present on a single central node, which might not be true in many real world scenarios. To address the limitation of the approach by Cong et al., Buehrer et al. presented a parallel algorithm [8] based on FPGrowth –

the salient features of the algorithm include a serialization and merging strategy for computing global trees from local trees, efficient tree pruning for better use of available memory space, and mechanisms to efficiently handle out-of-core data sets and data structures.

Ghoting et al. [12, 13] presented a cache-conscious approach for the effective parallelization of FPGrowth on shared-memory systems. They showed that poor cache performance limits scalability on shared-memory systems and demonstrated that through a careful architecture conscious redesign these bottlenecks can be removed, affording significant improvements. The authors developed smart data placement and computation restructuring techniques to improve both spatial as well as temporal locality during execution.

Classification

Data classification is a supervised learning procedure that given a training data set consisting of data points and their corresponding labels, learns an unknown function that is capable of mapping the input data elements to their corresponding labels based on some characteristic inherent in the input data set. For instance, consider the problem of filtering email spam. Here, one has some representation of an email and a label indicating whether the email is “Spam” or “Non-Spam.” The goal of data classification would be to learn a function that can label an email as “Spam” or “Non-Spam.” This function can then be applied to new data items, in this case, new email messages, to classify them as “Spam” or “Non-Spam.” A variety of data classification algorithms are used in data mining. Examples of classifiers are neural networks (multilayer perceptrons), support vector machines, k-nearest neighbor classifier, naive Bayes, and decision trees. These algorithms differ in the nature of functions they use to approximate the target function. Describing all these algorithms and their parallelizations is beyond the scope of this entry. For many of these algorithms, computation is structured and often specified using linear algebra, allowing for a parallel implementation using popular libraries such as LAPACK [20]. Due to the unstructured nature of its computations, decision trees are described – a family of extremely popular and scalable classifications algorithms.

Decision trees approximate the target function as a tree. Each interior node in this tree corresponds to one

of the input variables; there are edges to children for each of the possible values of that input variable. Each leaf represents a value of the target variable given the values of the input variables represented by the path from the root to that leaf. Decision trees are popular as they can be used to generate a set of classification rules (each path from the root to the leaf represents a classification rule) that are easy to interpret. An example of such a classification rule is : if temperature >90, humidity <70, and outlook = sunshine, then weather is good for playing tennis. A decision tree is typically learnt using a recursive procedure. During each step in this recursion, one determines an (attribute,value) pair that can be best used to split a data set. Here, “best” is defined by how well the (attribute,value) splits the data set into subsets that have similar values on the target label. Finding the best split involves sorting each attribute on its value so as to estimate the distribution of the target label for the potential splits. Starting with the input data set, the process is repeated on each derived subset until it is determined that splitting no longer provides any improvement to the predictions.

SLIQ [21] was one of the first scalable algorithms for decision tree induction. The approach first sorts each attribute in the data set separately. Each attribute is then maintained as a list of sorted values together with the corresponding record identifier. Presorting means that attributes do not need to be sorted through each step in the recursion. The tree is built level-by-level (or bread-first), each level requiring a scan of the input data set. Unfortunately, SLIQ uses a memory-resident data structure that stores the class labels of each record. This data structure limits the size of the data sets SLIQ can handle.

Shafer et al. [24] presented a more memory-efficient version of SLIQ called SPRINT and also gave parallel versions of SPRINT for shared-nothing systems. This algorithm maintains the class label along with the record identifier for each value in the attribute lists. The data set is first partitioned across all processors in a row-wise fashion. Then, a global sort operation is performed at the end of which each processor has an equal and contiguous portion of each attribute list. When determining split points, each processor determines the best split points for all the records that were assigned to it. This is followed by an all-to-all broadcast operation

to determine the best global split point. Once this decision has been made, the attribute lists of the splitting attribute can be partitioned easily. In order to split other lists, a hash table is formed to maintain a mapping of record identifiers to nodes (of the decision tree in the next level), which needs to be communicated to all the other processors from the processor that produced the winning split point. The other processors then use the hash table to split their own attribute lists. The size of this hash table is proportional to the number of records at the current node, which means that for the root of the decision tree, the size of the hash table is proportional to the total number of records in the training set. ScalParC [19] improves on SPRINT by using a distributed hash table that need not be locally constructed and thus eliminates the bottleneck that the hash table presented for SPRINT.

The above mentioned approaches build a decision tree level-by-level and thus exploit data parallelism. However, disjoint sub-trees of a decision tree being independent, an alternative strategy would be to employ task parallelism. It is recognized that data parallelism is more efficient when processing nodes near the root of the tree, while task parallelism is more efficient when processing nodes near the leaf of the tree. This is the basis of the pClouds approach [25] for decision tree construction on shared-nothing systems. Similar strategies have also been utilized for decision tree construction on shared-memory systems [29].

Clustering

Data clustering, or simply clustering, is the assignment of a set of observations into subsets (called clusters) so that observations in the same cluster are similar in some sense. It is a form of unsupervised learning. Data clustering is vastly popular and has several real-world applications. One example is the assignment of customers into segments or groups based on some customer traits (e.g., spending habits) to better understand groups as well as the relationships between groups. Another example is the grouping of web pages into genres to automatically categorize web pages. One of the most important steps in clustering is to define a distance measure between points to measure similarity. The nature of the distance measure dictates the shape of the discovered clusters as well as the quality of the clustering. Clustering algorithms can be roughly

put into three categories – partitional, hierarchical, and density-based algorithms.

Partitional algorithms typically determine all clusters at once. An example of a partitional clustering algorithm is the popular *kMeans* clustering algorithm [16]. Given a data set and the desired number of centers (k), the algorithm first generates k random cluster centers. Next, each point in the data set is assigned to its nearest cluster center, where “nearest” is defined with respect to one of the distance measures. Finally, the new cluster centers are recomputed as the means of the points that were previously assigned to the centers. These steps are repeated until some convergence criterion is met (usually that the cluster centers haven’t changed). The main advantage of the *kMeans* algorithm is that it is easy to implement and parallelize, and thus can be used to process large data sets. Its parallelizations on shared-memory and shared-nothing systems are very similar. The task of assigning data points to one of k centers is the most time-consuming step and is easy to parallelize. Each processor is responsible for assigning a portion of the data points to one of k centers. Each processor maintains arrays for the means of all points and number of points that were assigned to the centers. These arrays are then summed up and used to find new k centers.

Hierarchical algorithms find successive clusters using previously established clusters [17]. These algorithms usually are either agglomerative (“bottom-up”) or divisive (“top-down”). Agglomerative algorithms begin with each data point as a separate cluster and merge them into successively larger clusters. Divisive algorithms begin with the whole data set (as one cluster) and proceed to divide it into successively smaller clusters. Most hierarchical clustering algorithms employ a greedy approach to divide or merge clusters for efficiency reasons, i.e., during each iteration they either divide (“top-down”) or merge (“bottom-up”) clusters that are deemed to provide the best clustering. During each iteration, a distance measure between not just a pair of points but groups of points needs to be defined. Due to a wide range of such possible distance functions, a variety of hierarchical clustering variants exist today. All these algorithms present worse than linear scalability, making hierarchical clustering computationally demanding. The reader can look at the work by Olson [22] for an analysis of parallel hierarchical clustering on various parallel abstraction machines. Due to

the sequential nature of the computations, few practical parallel algorithms for hierarchical clustering exist today.

Density-based clustering algorithms attempt to cluster data points based on their local densities [11]. Such clustering algorithms are capable of discovering clusters with arbitrary shapes. Clusters are groups of points that have dense neighborhoods and are connected in some sense. The primary computation performed in density-based clustering is the nearest neighbor search, and such clustering algorithms have been parallelized on shared-nothing systems by using a distributed index structure [26].

Regression

Regression analysis is used to model the relationship between a target variable and a set of predictor variables. This relationship is expressed as a function that predicts the target variable using the predictor variables as inputs. Regression analysis is widely used for prediction and forecasting. Regression is similar to classification in that both approaches attempt to predict a target variable. Unlike classification, where the target variable is categorical, regression attempts to predict a continuous variable. A variety of regression algorithms are used in data mining. Techniques for classification such as neural networks (multilayer perceptrons) support vector machines, k -nearest neighbors, and decision trees have been adapted to the problem of regression, and their parallelizations are structurally similar. Parametric approaches to regression such as linear regression and logistic regression are often specified using matrix operations, and they can be implemented in parallel using popular libraries such as BLAS [5] and LINPACK [20].

Bibliographic Notes and Further Reading

The earlier portion of this entry concentrated on association rule mining. Over the past decade, a variety of extensions to association rules such as sequential rules and graph patterns have emerged. The reader can look at the book by Zaki and Ho [27] and papers by Buehrer et al. [6] for their parallelizations.

Until this last decade, most data sets that were used in data mining could be processed on a single machine. With the advent of the world wide web and advances

in data collection technologies, institutions are increasingly seeing the need to implement parallel data-mining algorithms, and an emerging research area is that of building infrastructures that are specifically aimed at implementing parallel data mining algorithms. Technologies such as the IBM Parallel Machine Learning Toolbox [18] and the rapidly growing Hadoop Apache project [1] are indicators of this trend.

Another recent research direction in parallel data-mining is that of executing data-mining algorithms on emerging multicore architectures such as the commodity GPU [9] and the STI Cell processor [7]. Due to the nature of these architectures, researchers have targeted data mining algorithms that have structured computation and data access patterns.

Definition

A deadlock is a condition that may happen in a system composed of multiple processes that can access shared resources. A deadlock is said to occur when two or more processes are waiting for each other to release a resource. None of the processes can make any progress.

Discussion

Deadlocks are a problem in parallel computing systems because of the use of software or hardware synchronization resources or locks to provide mutual exclusion for shared data and process coordination.

In general, a deadlock has four necessary conditions:

1. A resource cannot be used by more than one process at a time, commonly called *mutual exclusion*.
2. A process using a resource may request another resource, a *hold and wait* condition.
3. A *no preemption* condition applies to the resources held by a process, and they cannot be released without an action of the process.
4. Two or more processes are waiting for each other to release a resource in a *circular wait* or chain of dependency.

In parallel programming, resources can have many different forms. Some examples are:

1. Memory that must be updated as if by an atomic or indivisible operation
2. Devices like tape drives that can only be used by one process at a time
3. Synchronization primitives that coordinate access to the use of resources
4. Messages that must be sent and received

Example

Consider two sets of memories M1 and M2. If process P1 has exclusive access to the contents of M1 and needs exclusive access to M2 to complete its operations but process P2 has exclusive access to the contents of M2 and needs exclusive access to M1 to complete its own operations, then this is a deadlock. An I/O device like a tape drive may be considered as a substitute for the memory.

In shared memory parallel programming scenarios, semaphores can be used to coordinate access to a resource. Each memory location (or tape drive) would be associated with a semaphore. An operation P() would represent a request to have access to the resource and an operation V() would represent its release. So a program for process P1 might be written:

```
P1: S1.P(); /* get exclusive access to memory M1 */
          /* ... */
S2.P(); /* get exclusive access to memory M2 */
```

```
/* update M1 and M2 */
S2.V();/* release exclusive access to memory M2 */
S1.V();/* release exclusive access to memory M1 */
```

Semaphore S1 is associated with access to M1 and S2 to M2. The value of a semaphore represents whether its associated resource is available. In this case, each semaphore is given an initial value of 1 for its associated memory location. A semaphore value of 0 represents that a process has exclusive access to memory M1. The operation P() decreases the value of a semaphore, while the operation V() increases it. If the semaphore is 0, a P() operation makes the requesting process wait for the semaphore before continuing.

Process P2 is written in a similar manner:

```
P2: S2.P();/* get exclusive access to memory M2 */
S1.P();/* get exclusive access to memory M1 */
/* update M1 and M2 */
S1.V();/* release exclusive access to memory M1 */
S2.V();/* release exclusive access to memory M2. */
```

Then the two processes P1 and P2 deadlock if process P1 executes its first semaphore operation S1.P() and process P2 also executes S2.P().

Coordination of processes can create a deadlock as when process P1 waits for a message from process P2 before sending a message to P2 and process P2 either never sends a message to P1 or P2 waits for a message from P1 first and then sends a message to P1.

Each example satisfies the four deadlock conditions and may be extended to more processes and resources.

Deadlock Detection, Prevention, and Avoidance

The set of four deadlock conditions are necessary and sufficient to create a deadlock. Detecting, prohibiting, or avoiding one of the conditions is thus a basis for deadlock detection, prevention, or avoidance [10]. *Deadlock detection* requires analyzing whether the four conditions apply to a set of processes and resources. *Prevention* ensures that one or more of the conditions cannot hold. *Avoidance* analyzes whether granting a resource request could eventually lead to a deadlock and blocks the process from making that request if such a possibility exists. In turn:

1. Allowing a resource to be used by more than one process at a time removes *mutual exclusion*. Thus,

for example, making memory access read-only eliminates the need for mutual exclusion. Similarly, devices may be shared as in if a tape device is used in append only mode. Non-blocking synchronization primitives may be used that return an error code if a resource is in use. Messages may be sent in asynchronous fashion so that a message receive does not block a process or synchronization primitives.

Programming synchronization and coordination solutions without blocking primitives use “non-blocking synchronization algorithms.” However, such algorithms can suffer from livelock, a similar problem to deadlock in which processes make no progress but are never blocked.

2. The *hold and wait* condition can be eliminated by forcing a process either to acquire all the resources it needs in one operation or to release all the resources it holds when it acquires more resources. Job control in early IBM 360 systems imposed such conditions. In general, this is inefficient as it leads to a process holding more resources than it needs or to an undue number of acquire and release operations.
3. Allowing resources to be removed from a process eliminates the *no preemption* condition. For example, processes often require additional physical memory and virtual memory algorithms allow the physical memory of another process to be released in order to prevent a deadlock arising from memory allocation needs. Another approach often used to preempt a resource is to roll the process holding the resource back to a previous state prior to the time it acquired the resource. This leads to optimistic concurrency control, lock-free, wound-and-wait, and wait-free algorithms for resource allocation. In general, preemption of resources can lead to inefficiencies and thrashing.
4. Ordering the acquisition of resources eliminates the *circular wait* condition and can be implemented in a number of ways. For example, the address of a resource can be used to create an order in which resources are acquired or the resources can be organized into a hierarchy.

As an example above of ordering resources, if the address of M1 is less than M2, then this can be used to impose an ordering on the semaphores such that both

process 1 and process 2 always perform a P.S1 before P.S2. This requires rewriting process P2 as:

```
P2: S1.P();/* get exclusive access to memory M1
    S2.P();/* get exclusive access to memory M2
    /* update M1 and M2
    S2.V();/* release exclusive access to memory M2
    S1.V();/* release exclusive access to memory M1
```

Now, whichever process performs S1.P() first can perform the S2.P() and continue until it can release its access to M1 and M2 and perform S2.V() and S1.V().

Detection

Given an arbitrary parallel program, detecting whether that program will deadlock is undecidable except in very specific circumstances, in the same manner as the halting problem is undecidable. There is much literature concerning the undecidability of deadlocks. Brand and Zafiroplou [2] describe the computational complexity of deadlock detection in communicating state machines, and Gold [8] describes the computational complexity of deadlock avoidance algorithms. However, deadlocks are detectable at runtime. Since the processes involved in a deadlock are waiting, deadlock detection must be performed by a monitoring algorithm that tracks whether the four conditions have been met for the given set of processes and resources. Deadlock detection can be achieved by building a resource allocation graph [12] that represents the state of the system in which a deadlock is observed as a cycle in the graph. Detection algorithms have a runtime complexity of at least $O(M \times N)$ or $O(M^3)$, where M number of resources and N is the number of processes (Holt 1979). Kim and Koh found a complexity of $O(M \times N)$ using trees.

Avoidance

Deadlock detection works well for processes that are already deadlocked. It is possible, under certain restrictions, to determine whether allowing a process to acquire a resource might eventually lead to deadlock. If a deadlock is unavoidable, the process and its request can be suspended pending the release of other resources, leading to a variety of avoidance algorithms.

The banker's algorithm [9] is one such avoidance technique, and it works with a given number of processes and resources, each resource being of a particular type. It imposes the restriction that every process declares the maximum number of resources it might need of a particular type. When a resource is requested, the algorithm determines whether to allocate that resource or suspend the process based on if that allocation will keep the system in a *safe* state.

A safe state is one in which there is some sequence of allocations of resources to processes such that each process can eventually acquire its maximum number of resources needed so that it may complete and release those resources. This algorithm is conservative in that it avoids situations that are unsafe, but may not lead to deadlock. For example, a process may decide not to request its maximum number of resources but the banker's algorithm has no way of accommodating this information.

If it is inexpensive to kill and restart a process, then another avoidance approach is to allow processes to continue until a request is made that will cause a deadlock. Every process is given an age using a timestamp. In the *Wait/Die* algorithm, if the process requesting the resource is older than the process holding the resource, it waits. Otherwise, the process dies. In the *Wound/Wait* algorithm, if the process requesting the resource is younger than the process holding the resource, it waits. Otherwise, the process dies. In both algorithms, the aging scheme ensures that progress is made by preferentially killing the younger process.

Distributed Deadlock

The problems of deadlock extend to distributed systems. The solutions are similar, but require distributed implementations. Distributed deadlock detection solutions decompose the global resource allocation graph into local wait-for graphs that are then combined globally to detect cycles indicating circular wait using graph reduction [3]. An alternative approach to detecting the cycles is to trace the edge of the wait-for graphs from one node to another to determine if it forms a cycle.

Discussion

In practice, deadlocks have not proven to be as difficult an issue as at first thought. The cost of restarting a process or system when a deadlock is discovered is often not too great compared with the cost incurred from an implementation of deadlock prevention or avoidance.

Debugging

CHRISTOF KLAUSECKER, DIETER KRAZLMÜLLER
Ludwig-Maximilians-Universität München, Munich,
Germany

D

Definition

Debugging and testing are integral parts of the software development process, which provides a model for the development of software products from the initial planning to deployment and maintenance. However, debugging and testing are, although closely related, two completely different tasks which must be clearly distinguished. Software testing is used to verify the reliability and functionality of software products and individual components. This is accomplished by checking their adherence to specified requirements, thus allowing an assessment of the quality of software. If any discrepancies occur during the testing phase, debugging is used to track the reasons why the software fails and to correct the mistakes. Concurrency in applications adds additional error sources and effects, making debugging parallel programs a challenging task. As such, parallel program debugging has to deal with increased complexity, large amounts of data, and effects like race conditions and deadlocks.

Discussion

Overview

Debugging of parallel programs is a complex topic. Therefore, Section “Bugs” starts by clarifying the meaning and origin of the term “bug” itself. Section “The Debugging Process” describes a commonly used debugging approach and the difficulties posed by parallel applications. Section “Breakpointing in Parallel Programs” presents the purpose of breakpointing, one of the essential features provided by interactive debuggers, together with different breakpoint types for concurrent programs. Debuggers, that is, the tools commonly used to track down bugs, will be discussed and classified in Sect. “Parallel Debugging Tools”. Current issues and future directions will be presented in Sect. “Future Directions”.

Bugs

A “bug,” which in computing can occur in hardware or software, causes unexpected or unintended behavior that diverges from the product’s specification. A common belief is that the term originated from the finding of a real living bug. While the moth that was found in one of the relays of the Mark II computer [11] may have actually been the first real bug to be found in a computer, the term “bug” was already used at the end of the nineteenth century to describe technical glitches [5].

Definition 1 Bug

A bug is the commonly used term for an error with originally unknown location and reason [18].

According to Definition 1, the location of a bug is typically initially unknown. Its causes are small mistakes, design errors, or hard- and software failures. Their effects, however, can vary greatly in their extent. Bugs crashing a program immediately may seem to be the more severe ones, but they are also more likely to get noticed, and thus usually have a limited life span. The serious bugs are often those having initially only limited effects, or those occurring only sporadically, because they are located in seldom used functions or appear only under special circumstances – for instance only when running a parallel program with a higher number of processes or with specific input data. Such bugs remain undetected for a long time, often until an application is used in production. A product containing bugs is not only annoying for the users, but may also cause consequences such as financial loss and bad publicity for the developer.

While bugs can be avoided to a certain extent by carefully planning and designing using the established software development processes and by practicing good code style, the more complex a program gets, the more likely it is to contain bugs. It is practically impossible to write larger pieces of bug-free code. The reason for this is that software is written by humans, who are likely to make “dumb mistakes” [8]. Parallel programs are especially error-prone since they are often complex due to their concurrent nature and the resulting necessary communication and synchronization steps. As a consequence, software should be tested extensively for unintended behavior and upon detection the causes need to be found and the errors corrected.

The above given definition of a bug stresses the fact that its location is initially unknown, so in order to fix it, it needs to be tracked down first. The process of finding and fixing bugs is called debugging and is usually supported by corresponding tools.

The Debugging Process

As stated before, the best approach is to avoid producing bugs in the first place, which is unfortunately rarely possible. When a programmer encounters bugs, the goal of the debugging process (Definition 2) is to reduce the number of bugs, and consequently make an application execute and behave according to its specification.

Definition 2 Debugging

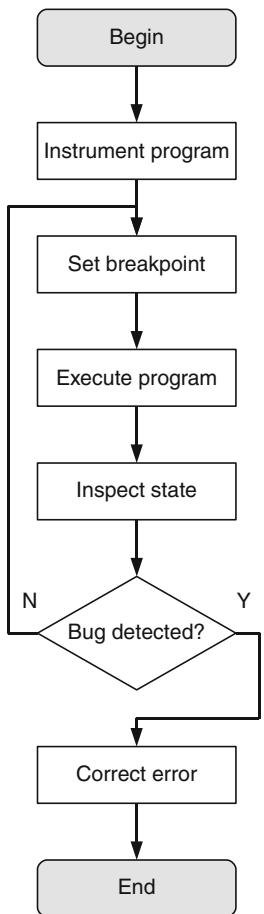

Debugging [22] is the process of locating, analyzing, and correcting suspected errors.

According to the definition of a bug (Definition 1), its location is initially unknown; therefore, to remove it, it needs to be located. In practice approximately 95% of debugging time is spent on locating the origin [25].

The typically applied debugging strategy (in sequential and in parallel case) is the cyclic debugging approach [22] as shown in Fig. 1. The underlying principle is as follows: After a bug has been detected, the developer reruns the program under control of a debugger to narrow down the location of the bug. The same input data is used to reproduce the same faulty behavior. The developer uses breakpoints to stop a program at execution states where the origin of errors is suspected or where additional knowledge about the program’s behavior can be obtained. If the information gathered during a cycle is not enough to isolate the bug, the procedure starts again by setting new breakpoints.

A different approach is reverse debugging, which based on recorded information, enables to execute a target program in reverse to a limited extent. This functionality has been recently introduced in some debuggers [6, 30].

The cyclic debugging approach implies that a program behaves in the same way every time it is executed. While this is often the case for sequential programs, it is not necessarily directly applicable to parallel programs. Due to the introduction of concurrency, a whole new class of problems and error sources appears. The reasons

Debugging. Fig. 1 Cyclic Debugging [16]

why parallel debugging differs from sequential debugging [16] can be summarized as follows:

- **Increased complexity**

Because of the multiple processes or threads involved and the interactions between them, parallel applications can quickly become complex. Therefore, it is hard to understand their behavior and to locate bugs by only using tools which operate on source code level.

- **Amount of debugging data**

The amount of information which accumulates during debugging parallel applications is significantly larger in comparison to sequential applications. Thus, it can get difficult for the programmer to find the proverbial needle in the haystack, especially if haystacks are increasing.

- **Additional anomalous effects**

Due to parallelism and communication, error sources which do not exist in sequential applications are introduced. Those additional anomalous effects include serious problems like deadlocks and nondeterminism, or related events, where concurrent execution of processes and their interaction is involved.

- **Scalability**

When the limit of frequency scaling was reached roughly in the year 2005, a switch from single- to multi-core architectures took place. This development influenced not only the desktop market, but also made high-end parallel computers with higher core counts possible and necessary – a fact posing scalability problems not only for applications, but also for the debugging process and the associated tools (which usually are parallel programs themselves).

A main source of errors in parallel programs is nondeterministic behavior. This poses serious problems for the cyclic debugging approach introduced above, because nondeterministic applications do not necessarily produce the same outcome or execution path for the same input data on repeated runs. This so-called irreproducibility effect sometimes renders reruns of an application to narrow down the location of a bug useless.

There are various reasons for nondeterministic behavior of an application – a common and usually intended source is, for example, a random number generator. An often unintended effect is a race condition. Resulting from varying execution speeds of the parallel processes or network jitter, if two processes send a message to a third one, the outcome can vary depending on which message arrives first.

A possible solution for the elimination of the irreproducibility effect are mechanisms such as instant replay [19]. During a so-called record phase, information from the initial program run, containing ordering information for critical events, is gathered. Afterward, this information is used to replay the previously observed behavior, thus ensuring that the same execution path is used for repeated application runs.

Breakpointing in Parallel Programs

One of the essential functions used during cyclic debugging is breakpointing – the process of setting breakpoints. A breakpoint can be defined as follows:

Definition 3 Breakpoint

A *breakpoint* [31] is a controlled way to force a program to stop its execution. Breakpointing may occur on software interrupt calls, on calls to a program subfunction, or on selected points within the program.

Breakpoints are set intentionally to interrupt a program's execution at a state interesting to the developer. During this interruption, the environment and the state of the application can be arbitrarily inspected and even modified. Furthermore, it is possible to set additional breakpoints for future interruptions.

There are two common types of breakpoints: instruction breakpoints and data breakpoints. The former offer the possibility to interrupt the execution of an application before a specified instruction is reached. The latter, also called watchpoints, allow to stop when a memory address is accessed, or a specified value is assigned to a variable. In other words, instruction breakpoints enable a control-flow-oriented debugging strategy, while watchpoints allow data-oriented debugging [4]. Additionally, some debuggers allow to specify conditions for breakpoints. In the context of breakpointing, a condition is a boolean expression which is evaluated every time the breakpoint is reached. Only if the expression is true the application is stopped. The so-called ignore count is a special case of breakpoint condition, which only stops the application when a

breakpoint has been hit a certain, previously specified, number of times [30].

Setting breakpoints in sequential applications is straightforward: When a breakpoint is reached and the conditions are met, the program is stopped. Afterward, when the programmer finished inspecting and modifying the application's state, the application can be resumed. When it comes to parallel programs consisting of multiple processes, breakpointing gets more complicated since the programmer may want to inspect the state and variables of multiple processes. The question arising is: which of the processes to stop and where.

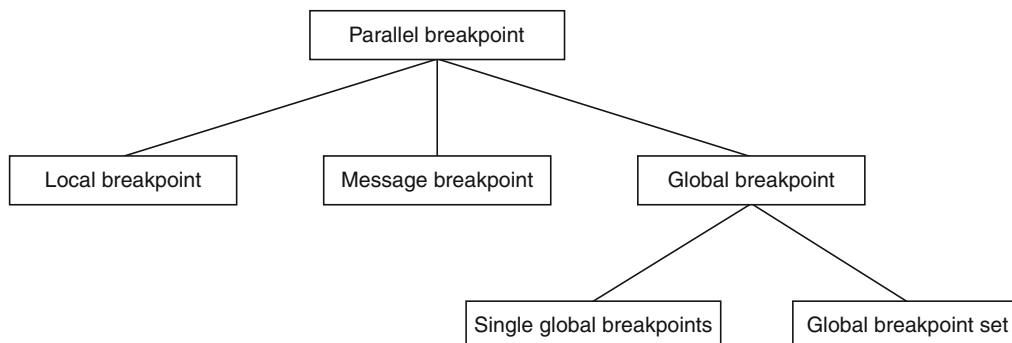

Parallel debuggers typically allow to identify individual processes of a parallel application using numbers reflecting the process number assigned by the parallel runtime environment. Breakpoints for parallel applications can be divided into three main classes (Fig. 2) [10], which can be described as follows:

- **Local breakpoints**

A local breakpoint is only applied to a single process, all other processes are not affected and will continue their execution. This is identical to the sequential case. However, in parallel programs, there are usually relations and dependencies to other processes.

- **Message breakpoints**

A message breakpoint stops all processes involved in a single communication event. In point-to-point communication this typically involves two processes. However, in case of collective operations any number of processes can be part of a message breakpoint.

Debugging. Fig. 2 Classification of parallel breakpoints [10]

- **Global breakpoints**

A global breakpoint involves multiple processes and its classification can be further divided into a single global breakpoint and a global breakpoint set.

- **Single global breakpoint**

A single global breakpoint has exactly one owner process, the respective process on which it was hit. This owner process is stopped at the location or state defined by the breakpoint. The other processes of the parallel application are stopped immediately afterward. They are, however, stopped at undefined states, because of factors like varying execution speed.

- **Global breakpoint set**

In contrast to the single global breakpoint, the global breakpoint set consists of multiple local breakpoints. For this reason, when the global breakpoint is reached, the involved processes are stopped at defined states. However, to accomplish this, each local breakpoint needs to be set at a specific location.

Breakpointing is an important concept in the process of pinpointing the origin of a bug and therefore a central aspect of the debugging process.

Parallel Debugging Tools

While for relatively short and simple programs it may be sufficient to carefully read the code or to insert print statements for locating mistakes, it is not adequate for complex programs like large-scale parallel scientific simulations. As mentioned above parallel applications are not only more error-prone, but locating the error source is also more challenging. For this reason, more sophisticated tools than the so-called printf debugger are required.

There is a variety of tools available for debugging parallel applications. Debugging tools, which intend to provide useful knowledge about a program's execution and the occurring program state changes [34] to the developer, can be divided into three major classes:

- Run-time checking tools
- Program visualization tools
- Traditional debuggers

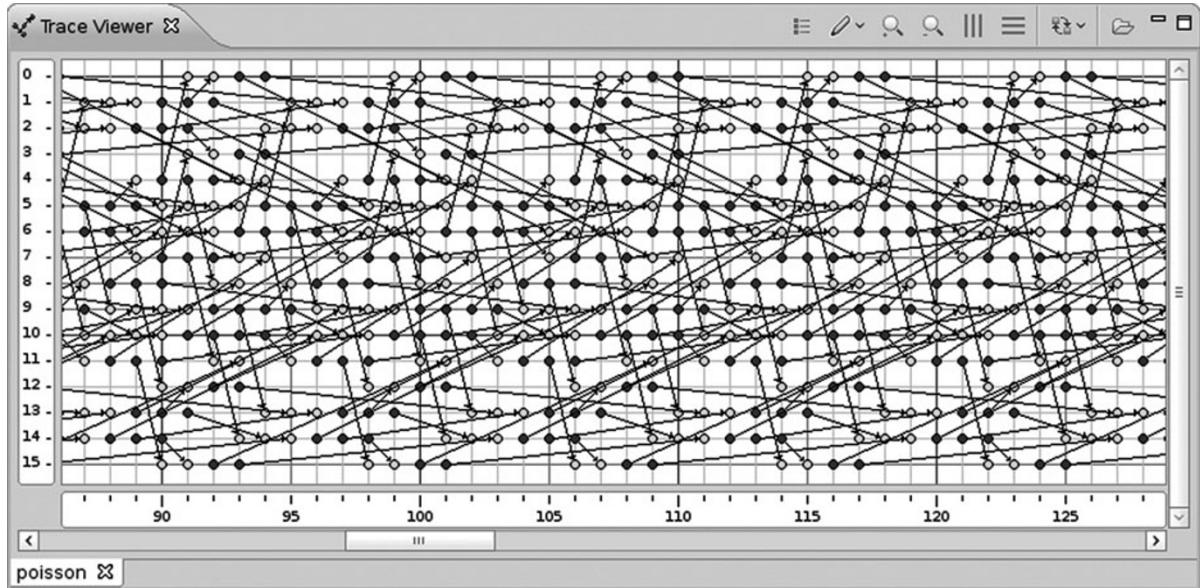

Run-time checking tools provide automated mechanisms to check for errors during the execution of a

program. These tools are typically designed for certain programming interfaces or specific error classes. The used parallel programming interface often adds considerable complexity to the development of concurrent applications. A common example is the Message Passing Interface [23, 24] (MPI), which provides developers with great freedom but also leaves much room for mistakes. As a consequence run-time tools checking the correct usage of MPI have been developed. Prominent examples for this class of tools are Marmot [15], Umpire [33] and their successor MUST [7], which detect invalid arguments for MPI function calls, race conditions, and deadlocks, but also portability issues between different MPI implementations. Another example class of run-time tools are so-called memory checkers. The Intel Parallel Inspector [9] or the Valgrind tool suite [29], help detecting potential memory bugs, like usage of uninitialized memory, memory leaks, and allocation/deallocation errors.

Program visualization tools provide developers with a way to cope with the increased complexity of parallel applications resulting from communication between concurrent processes. Depicting application flow and relations of parallel processes as space-time diagram, like, for instance, the VAMPIR [26] performance analysis tool does, can aid program understanding, and help to detect errors in an application's communication behavior.

The Trace Viewer [12] is a visualization tool based on the space-time diagram and focused on debugging. It implements the event graph paradigm [16], and enables to visualize and analyze communication of message passing programs based on traces [13] recorded during run-time. Figure 3 illustrates the dependencies and the message flow of a parallel message passing program. The vertices represent the events which are located at specific points in time and highlight state changes of a process. The edges represent the continuous transition from one state to another. This includes not only local events, but also the communication flow between processes.

Traditional debuggers are tools allowing to look at and to analyze other programs interactively while they are running [34]. As such, these debuggers support programmers in searching for the reasons for an application's abnormal and unexpected behavior and can be defined as follows:

Debugging. Fig. 3 Event graph visualization [12]

Definition 4 Debugger

A debugger [28] is a tool to help track down, isolate, and remove bugs from software programs.

Rosenberg further proposes several principles a good debugger should at least try to adhere to [28]. These principles can be summarized as following:

- Observing an application with a debugger inevitably changes the debuggee's behavior (sometimes called Heisenberg principle [20]). A debugger, however, should minimize its intrusion on the debuggee.
- The second principle asserts that a debugger must provide truthful information. It is very important that the debugger can be trusted and that it does not lead the programmer into a wrong direction.
- Another prerequisite for a good debugger is that it presents the provided debugging information to the user, together with information where in the execution the program is and how it got there.
- The final principle states the unfortunate fact that debuggers are usually not as technologically advanced as the programmer would need them to be.

The functionality provided by traditional interactive debuggers allow to start and stop an application under their control [34]. Furthermore, it is possible to attach

a debugger to already running applications, but also to disconnect it, thus ending the influence of the debugger on the application. After inspection, the debugger can, on behalf of the user, signal the program to continue, to be aborted, or even to perform a single instruction or execute a source code statement – enabling to trace the execution path of an application. As such, debuggers can be classified into machine-level debuggers and source-level debuggers. As the name already indicates, the former operate on a very low level, providing only assembly information. Source-level debuggers need the debuggee to contain additional symbolic information, hence they are also called symbolic debuggers. This additional information can be added during the compilation of the application, usually by adding a specific compiler flag. Source-level debuggers provide, in addition to the assembly view, means to track the execution progress in the original source code.

Concerning support for parallelism, one needs to distinguish between thread and process level parallelism. While most of today's interactive debuggers support threaded applications, only few provide support for multiple processes. However, there are both open source and commercial debuggers with support for process level parallelism available; for example, MPI programs. The most widespread parallel debuggers include Allinea's DDT [1] and Rogue Wave's Totalview [32],

both commercial products. Well-known open source solutions include the Eclipse Parallel Tools Platform (PTP) [27], and the g-Eclipse [12] debugging functionality. Additionally, several vendor-specific debuggers, usually distributed together with and optimized for certain hardware, are available.

The listed debuggers provide functionality similar to single process debuggers, some of them are actually merely a scalable frontend to multiple instances of a single process debugger, like the popular open source GNU Project Debugger [30] (GDB). Parallel debuggers, however, allow to perform debugging operations like breakpointing, stopping, stepping, and variable and array inspection not only on individual processes or threads but on defined process groups or the whole parallel application. They provide comparison means to analyze differences in the content of variables and in program states between processes of a parallel application.

Parallelizing applications usually requires to partition the data to be processed. Array inspection and visualization tools (Fig. 4) provide useful insight into distributed multidimensional arrays, and assist in the search for data distribution errors [17]. Additionally,

support for filtering and gathering statistical information on data array values, a useful feature for locating bugs in computation, is provided by the aforementioned parallel debuggers.

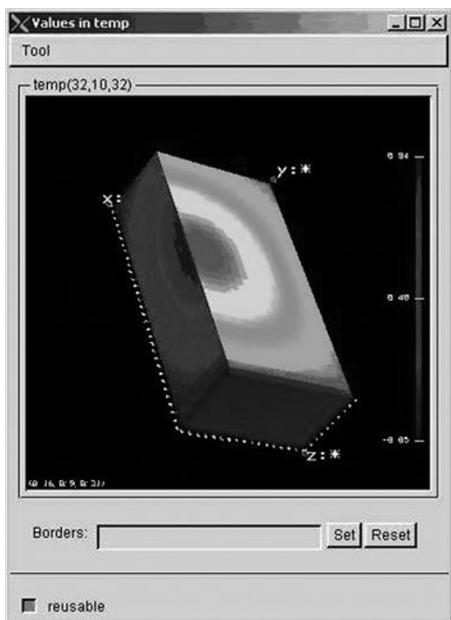

Future Directions

The future of parallel program debugging is clearly connected to the evolution of parallel computing itself. To exploit future computational resources, applications will have to adapt to hierarchical hardware structures, as well as utilize accelerators. Developers will have to incorporate a variety of programming models simultaneously into their applications, and the mixture of these models will make the already demanding task of developing parallel applications even harder and more error-prone. With multi- and many-core architectures coming to the desktop, parallel program debugging will also become more important to a wider audience. Faced with such complexities, debugging will become a major problem, in particular at scale. This poses scalability problems, not only for tools launching and internal communication [21], but also for the analysis and presentation of the debugging information.

Current approaches include using filtering tree-based communication structures [2] for scalable tool communication, however, even if the debugging tools scale, the developer, who has to sift through the data manually, might not. Visualization of program runs with more than a few thousand processes is also not an option without further abstraction techniques, like for instance pattern matching algorithms supporting communication analysis and debugging [14].

Another issue will be that the traditional interactive debugging approach with several reruns is hardly applicable, if not impossible, on large program runs, since it is unmanageable and simply too expensive in terms of time, power, and ultimately money. The Stack Trace Analysis Tool [3] (STAT) tries to address this problem using a lightweight approach for sampling and merging stack traces, with the goal of providing a preselection of processes for further analysis using a traditional interactive debugger.

The focus of future debugging tools must lie on algorithms that automatically analyze the gathered data. Only this will make debugging tools ready for upcoming computing systems by preprocessing and

Debugging. Fig. 4 Array visualization using the MAD environment [17]

abstracting the presented information, assisting and guiding the developer through the error detection and error removal processes.

Microprocessors

Definition

The DEC Alpha was an architecture and line of microprocessors created by Digital Equipment Corporation (DEC). These processors, which began shipping in the early 1990s, were among the most innovative and highest performing of their era. The 64-bit Alpha processors were the successor to DEC's highly successful VAX product line and ran VAX legacy code, though translation, on new incarnations of the company's VMS operating system. Alphas also ran an OSF1-derived version of Unix called Tru64, and Microsoft Windows NT ran natively on the Alphas with support for x86 programs via binary translation.

Background for Alpha

The Alpha architecture arose inside DEC in the late 1980s out of recognized challenges with the company's then-current VAX product line. VAX design projects

were facing difficulties in meeting their schedules and the designs were becoming overly complex for the relatively small DEC design teams. As a result VAX designs, which had had their heyday during the 1980s, were starting to lag behind their competitors on cost and performance. But the VMS operating system and a substantial software ecosystem, which ran on VAXes, were very important to DEC, representing a large customer base and a significant revenue stream.

The VAX architecture had been developed around a philosophy that was premised on code being written in assembly language. In the late 1970s when the VAX architecture was being specified, most large software systems were written in assembly language to achieve adequate efficiency. The VAX instruction set made this easier by having instructions which performed sophisticated operations and provided a universally available set of addressing modes for each operand of the instruction. Improved compilers, however, undermined the assembly language premise on which the VAX was based. In this evolution, the VAX was at a disadvantage because the VAX instructions were over-specified, and it was difficult for compilers to map programming language idioms into the available instructions. Even worse, the VAX instructions provided semantics beyond that needed by the compiler but which had to be paid for in the implementation. This resulted in designs that were more complex and slower than needed.

The VAX architecture with its sophisticated instructions and powerful addressing modes became known as a *complex instruction set computer* or CISC-style architecture. But the 1980s also had seen the beginning of the *reduced instruction set computer* or RISC revolution. RISC architectures were based on the notion that a computer architecture should be good target for compilers by providing exactly the primitive operations that a compiler needs and that also map naturally to simple and efficient hardware implementations. The RISC work was spearheaded by research at IBM, Stanford, and Berkeley, who each developed simple, powerful processor chips quickly. This work led eventually to IBM's PowerPC processors, spawned MIPS as a company, and SPARC as the basis for Sun's computer line.

The attraction of RISC-based architectures was not lost on DEC's engineers. As a result, there were several early RISC projects at DEC. These included Titan,

a RISC-based research project; SAFE, a RISC architecture explored within the development organization; and Prism, which formed a RISC-style architectural basis for an entire software system that was an evolutionary reimplementation of the VMS operating system. DEC also built and marketed systems based on the MIPS architecture. Those systems used MIPS designed chips, but there were MIPS processor designs in flight at DEC when all RISC development efforts were redirected toward Alpha.

A flaw common to all of DEC's initial RISC-style design efforts was that they were not believed to be able to preserve the VAX/VMS-based market, so a task force was formed to address that deficiency. Thus, the primary charter of the Extended VAX, or EVAX, taskforce was to propose a means of modernizing the VAX architecture in a way that preserved the software base in VMS and in DEC's Ultrix (Unix) market. Modernization, of course, implied that it had to gain the efficiency/complexity benefits of the competing RISC architectures and thus this group was often referred to as the RISCy VAX taskforce.

The RISCy VAX taskforce considered a number of design alternatives. Since a key criterion was preserving software compatibility, a number of the alternatives also preserved the VAX architecture directly. For example, one alternative was to have a *heterogeneous design* in which new systems would have a small VAX core running the OS and legacy applications, with a more modern RISC core running performance critical applications, while sharing virtual memory. While such a design preserved compatibility, it added to a RISC design the cost and complexity of a VAX design whose performance would still be a critical component of overall performance.

To mitigate some of the cost of multiple heterogeneous cores, another proposal examined *multi-execution path cores*. In this variation a single core could execute both VAX and RISC instructions by providing two front ends: one interpreting VAX instructions, and another dealing with the new RISC ISA. This was how VAX evolved from the PDP-11, but in that case the microcode complexity was already being paid for, which was something not needed for a pure RISC core.

Some years earlier DEC had already made a simplification of the VAX architecture through the removal some of its most complex operations. This

simplification facilitated the creation of single-chip-microprocessor VAXes. These were the highly successful MicroVAXes. Since reducing the ISA had been successful before, why not try it again?

The *fixed length instruction VAX subset* proposal suggested carefully selecting and implementing only a subset of VAX instructions, all fixed length and with other RISC-like attributes. Note, however, that limiting instructions to only 32-bits (like other RISC architectures) would have resulted in a load with an inadequate 8-bit offset, so a small number of different length instructions were included. Using such a subset architecture, DEC could design a simpler, faster VAX. As with MicroVAX, this scheme dealt well with backward compatibility, but would require some form of emulation for forward compatibility of instructions no longer implemented in hardware. Unfortunately, analysis showed that a number of factors, such as the small architectural register file set and the implementation complexity of multiple instruction sizes, would destine this proposal for subpar performance.

A final hardware solution proposed a hardware unit that would do *hardware instruction translation* of VAX instructions into RISC instructions and then execute those instructions in a pure RISC-style back end. This strategy was approximated in some VAX designs, leaving much of the CISC operations to the front end for simple instructions, while more complex instructions were handled in microcode. Such a scheme was used in the mid-1990s by Intel to implement out-of-order execution in its Pentium Pro processor and has been the basis of many subsequent Intel processors.

After discussing this set of less than perfect hardware solutions to the problem, it was decided to save the hardware of the hardware-based instruction translation scheme and leave it to software to facilitate the migration from VAX to Alpha. Through a combination of interpretation, static and dynamic binary translation, compilation of Macro32 assembly language using a new Macro32 "compiler," and recompiling of higher-level language programs, software would solve the problem. Relegating migration to software freed the architecture team to focus on what they believed to be the best RISC architecture ever without significant legacy constraints.

To make migration to Alpha easier, a few hardware hooks were architected in for VAX support, but

not many. Several were easy to incorporate such as identical protection rings, memory protection codes, and interrupt priority levels. The VAX page size of 512 bytes was already resulting in less efficient page translation and complicated first level cache design, so was a sticky point. Therefore, it was decided to immediately start aligning VAX pages on 8 KB boundaries in the linker two years before Alphas were to start shipping to allow Alpha to be architected with a minimum page size of 8 KB.

Many compatibility issues were also handled with special code called PALcode. A program enters PALcode with a special instruction that dispatches into the entry point for an implementation-specific PALcode routine. PALcode, which looks like regular instructions, but with extra privileges, some implementation-specific instructions, and special registers, could perform special operations needed for various system activities but also could be used to support complex VAX operations. Special instructions could even be used to bracket sequences of operations that were to be executed atomically.

PALcode also provided an easy place to provide various other system functions and implementation-specific functions. This use is similar to Itanium's PAL code.

Alpha Architecture

Like all RISC architectures, the Alpha architecture was designed with a set of simple register-based operations and separate instructions to move memory values to and from the registers. As with many other RISC architectures, the instructions are of a fixed length of 32 bits. Alpha instructions came in just four forms:

- Register-to-register operations
- Memory operations
- Branches
- Dispatches to PALcode

The Alpha instructions were also designed to map efficiently to a hardware implementation and hence were extremely regular. To keep them regular, the operands are in fixed locations. Furthermore, instructions have at most two sources operands and no more than one destination. This greatly simplified the register file, operand tracking tables, and pipeline organization, since there never was a need to access, track, or transport more

than two input values and one output value for an instruction.

A recurring issue related to the two-input/one-output principle was the proposal for adding a Floating Multiply and Add instruction (FMA). FMA allows for more efficient implementation of its constituent operations and saves instruction issues for an operation sequence that occurs frequently in some codes. But FMA also requires a minimum of three sources and a destination. Thus it violated the basic design principles and was left out of the architecture.

With 32-bit instructions, providing a reasonable number of operations and no more than three register operands, the number of architectural registers is restricted to 32. However, by using separate 32-entry register files for integer and floating point instructions, Alpha gained an extra implicit register specifier bit, resulting in a total of 64 architectural registers for computation.

The majority of Alpha architectural state is the 64 integer and floating point registers. Two of these registers, R31 and F31, were hardwired to zero. Thus reads of these registers always returned a zero and writes were ignored. Allowing writes to these registers did, however, allow for special instruction semantics. For example, loads to R31 served as a memory prefetch. Additional architectural state consisted of shadow registers for integer registers that appeared in kernel mode. These saved the costs of explicit register saving by providing some scratch space on entry to kernel routines.

Another piece of architectural state is a floating point mode control register. This register was a compromise that involved saving the use of precious bits in each floating point instruction to specify the mode, e.g., rounding mode, and having library routines inherit a mode from the caller (with unpredictable accuracy results) or check/save/restore the mode (at a significant performance penalty for small routines).

The program counter (PC) is also architectural state, but unlike on the VAX the PC does not appear as a numbered general purpose register. Alphas also have a status register that holds information about such things as the current and previous ring level and interrupt priority level. But in contrast to the VAX the Alpha architecture does not have an explicit register to hold condition codes. This both saves on the bottleneck of having a single register receiving results from many

instructions and preserves the principle that an instruction only reads two registers and writes one register thus simplifying dependency tracking.

Avoid Complex Hardware Features

In a reaction to the complexity of VAX instructions, the Alpha architecture was designed to avoid features that would result in complex hardware. For an operation to be included in the Alpha ISA as an instruction, it had to be shown to occur frequently in important programs, that it could not be done effectively by sequences of other instructions, and that it fit the Alpha model of simple hardware implementation. Integer multiply was debated, but was finally included. Integer divide was found to be a rare operation, often dividing by a constant, equivalent to a handful of shifts and adds, and hence not included.

A significant, and maybe the most controversial decision based on complexity versus frequency of occurrence, was the decision to leave out load and store operations for less than 32-bit values (longwords). This meant that 8-bit values (bytes) and 16-bit values (words) were not accessible except as part of a longword. Stores of a byte required a read, modify, write sequence. The statistics showed byte memory operations to be rare, and that the shifts involved in lining up an individual byte in a 64-bit datapath would slow down loads and stores in general. Byte access can also complicate the implementation of error checking, for example, via ECC. The absence of 8 and 16 bit load/store support turned out to be more costly than had originally been envisioned. The compiler's lack of ability to determine memory aliasing of the bytes being gratuitously read (and re-written) near a byte of interest was a major impediment to code reordering. Thus instructions to load and store both bytes and words were added in the shrink of the second generation Alpha, EV56.

Floating point square root instructions and support for video encoding were added in the third generation Alpha, EV6. Square root was chosen because it was a common operation and could be executed by a small tweak to the floating point divide hardware. Video and multimedia support had emerged as performance-critical applications. A few, simple instructions turned out to make a big difference for performance.

In order to simplify exception handling hardware, arithmetic exceptions are architected to be imprecise in

Alpha. This lets later instructions complete before overflow and underflow conditions are known. To give software the opportunity to rationally respond to such conditions, a barrier instruction was provided that would force instruction issue to wait for all pending exceptions to be resolved. Thus software could achieve the effect of precise exceptions by placing a barrier instruction at the end of an idempotent sequence of instructions that followed any instruction that might cause an exception. This approach simplifies hardware, but does complicate software design. It is interesting to note that with out-of-order execution, register renaming made precise exceptions practically free.

The Alpha design teams also considered hardware support for speculative operations. This tends to create some complexities, mainly around exceptions. But there were some benefits from being able to move operations past branches (control speculation), and to a lesser degree from moving loads past stores (data speculation). Ultimately, it was found that most of these benefits could be achieved without hardware support, but by dealing with spurious exceptions in software. Such a framework was developed in Tru64 UNIX.

Hardware Implementations

The Alpha architecture was implemented in a series of hardware designs. The principal numeric designation for these designs was 21< n >64, where the 21 stood for the twenty-first century (since Alpha was touted to be the architecture for the next 25 years), the 64 indicated that this was a 64-bit architecture and < n > indicated the generation of the design starting with 0.

Internally, the Alpha designs were referred to by code names in the form EV< n >. The EV prosaically stood for Extended VAX, although it has been suggested that EV stood for other more colorful things. The < n > stood for the DEC CMOS process generation, thus EV4 (which was sold as the 21064) was implemented in CMOS4, an 0.7 μ process. When a design was largely remapped into a later process the process generation of the new process was appended to the code name. Thus, EV45 was a shrink (with some design changes) of the EV4 design into the CMOS5 process. Unfortunately, as the goal of having a complete new design in each process generation proved unsustainable, the < n > became simply a monotonically increasing designation of new designs. Still the EV nomenclature conveys more

DEC Alpha. Table 1 Alpha timeline

Year	Processor	Process	Frequency	Features
	EV3	1.0 μ		Software development vehicle
1992	EV4	0.7 μ	200 MHz	Two-wide superscalar
1995	EV5	0.5 μ	350 MHz	Four-wide superscalar
1998	EV6	0.35 μ	600 MHz	Out-of-order, Multimedia
2004	EV7	0.18 μ	1.15 GHz	Integrated system functions
	EV8	0.13 μ	1.8 GHz	Eight-wide superscalar, SMT
	EV9	0.09 μ		Vector processing

information about a design, so this article will typically use it for describing the various Alpha implementations (Table 1).

EV3: Software Development Vehicle

To assist software development and allow exploration of high-speed circuit techniques, a non-commercialized implementation of the Alpha architecture called EV3 was developed. Following the naming convention described above, EV3 was implemented in DEC CMOS3 process, which was a 1.0 μ process. The EV3 design largely matched the first commercially sold Alpha, EV4, but in order to fit in a single chip in the less spacious CMOS3 process, some nonessential functions were left out or reduced in size. For example, floating point operations were emulated in software. The caches were also only 1 KB. EV3 was built into the Alpha Development Unit (ADU), which was available for early software development. EV3 proved very valuable in the successful launch of Alpha as the fastest microprocessor in the industry.

EV4: First Commercially Available Design

The first commercially available Alpha microprocessor was EV4. It was launched at an astonishing clock frequency of 150 MHz, in DEC's CMOS4 0.75 μ process at a time when the industry standard was well below 100 MHz. The functionality, frequency, and overall

performance of EV4 made it an eye opener for the industry. It started an era of rapid improvements in CMOS circuit speed. An updated version of EV4 ran at 200 MHz.

Overall, the software transition from VAX to Alpha went smoothly due to the careful preparation of tools to assist in porting both OS functions and applications. Several systems were designed around EV4, including an Alpha PC, multiple workstations, and low and high end servers.

Both UNIX and VMS were supported. Introducing a 64-bit architecture turned out to be complex. When VAX was introduced as a 32-bit architecture 15 years earlier, the market had clearly outgrown 16 bits. The need for 64 bits was less pressing. DEC decided on a split strategy: 32-bit VMS, and 64-bit UNIX. Pioneering 64 bits was heavy lifting for UNIX, as many applications did not port easily from 32 bits. This had a mixed impact on Alpha as reduced application availability clearly slowed Alpha acceptance. The larger memory footprint due to the increased size of address pointers also had a detrimental impact on some applications. On the other hand, a 64-bit address space proved a valuable asset in some application domains, such as databases, where Alpha did shine. Alpha's pioneering porting efforts also clearly aided today's 64-bit architectures by getting applications ready.

Considering the classic formula that expresses processor performance as a function of frequency of operation, cycles per instruction and number of instructions, the Alpha architecture was most focused on facilitating high-frequency operation with instructions that required few cycles to execute. Designs exhibiting such characteristics were dubbed "speed demons" and the EV4 exhibited these characteristics through a design philosophy of providing speed through high frequency implementation in a simple, relatively shallow pipeline.

Although the EV4 frequency of operation was a function of many components, considerable effort was expended on creating a 64-bit adder that could be cycled as fast as possible and was intended to set the frequency of the design. Thus, other less frequent operations, such as shifts, were allowed to take multiple cycles. Considerable design effort was also expended on the high frequency clocking network to minimize clock skew across the chip – as a consequence approximately half the power of the design went into the clock network.

High frequency operation was also facilitated by avoiding stage-to-stage flow control in the main pipeline. This eliminated complicated cascading stall signals and reduced delay in each stage of the pipeline and thus allowed for more computation logic in each stage.

To control the pipeline, an end-to-end flow control was implemented in which instructions in the early stages of the pipeline always flow systolically and an execution unit stage would notice the need for a stall. But rather than stall the immediately preceding stage of the pipeline the execution unit would redirect the front of the pipeline to stall and buffer up the next few instructions coming down the pipeline and replay them when the stall condition had been resolved. This buffer was referred to as a “skid buffer.”

Since the design of the Alpha architecture and the EV3/4 micro-architecture were designed contemporaneously, a number of micro-architectural considerations entered into the architecture. This included the placement of operand fields in the instruction and assignment of operation codes that were easy to map into a programmable logic array or PLA. The instruction set was also divided into classes that used disjoint sets of function units to facilitate the creation of superscalar designs that could issue multiple instructions simultaneously. Superscalar implementation was also simplified through the absence of a MIPS-style branch delay slot or a VAX-style condition code register.

EV4 was a superscalar design, issuing up to two instructions per cycle. There were no redundant functional units, so the two instructions issued had to be a combination of single load/store, integer, branch, or floating point instructions. The chip had an 8 KB instruction cache and an 8 KB data cache on die, with support for a board level cache.

A challenge in accommodating specific micro-architectural optimizations into the specification of an architecture is the impact such features have on future micro-architectural innovations. The Alpha’s conditional move instruction (CMOV) is an interesting case in this regard.

The CMOV instruction takes a source operand and a condition, and copies the source to the destination if the condition is true. In an in-order design, this seems to fit the two sources and a destination model.

It does, however, have the implicit assumption that the destination register is always physically in the same location. But even in an in-order pipeline the destination *value* of a CMOV is not always in the same place when compared to other arithmetic operations. Therefore CMOV instruction results cannot be bypassed and have a latency greater than that of other simple arithmetic operations.

In an out-of-order pipeline, the assumptions on which the CMOV instruction was premised are even less true. In an out-of-order design with register renaming, the newly assigned destination register does not automatically contain the old value when the condition is false. Thus the old value in effect becomes a third source, violating a key Alpha design principle. This became an issue in EV6 and EV8, the out-of-order Alpha designs. Rather than require costly extra register ports and other changes to the execution pipeline, the CMOV instruction was broken into two separate instructions in the instruction fetch stage.

Despite these implementation challenges the CMOV instruction was found valuable by software. Since the CMOV instruction can be viewed as a specific case of a predicated operation, since a little predication was found to be valuable the team considered adding more predication. At the time, there were several papers published describing significant IPC improvements from predication all instructions. Additional support for predicated operations proposed for inclusion in the architecture. Within the Alpha team, performance studies of such more extensive predication were conducted, but found only negligible benefits beyond what was obtained with the CMOV instruction alone.

Finally, application performance depends on more than just the microprocessor. The system included industry standard memory chips and IO components. The raw execution advantage of EV4 was somewhat diluted by these system components. Not until EV6 did Alpha microprocessors incorporate major advances in memory system, followed by the innovative system design in EV7.

EV45: Compaction of EV4 into .5µ CMOS Technology

Initially, the Alpha design teams maintained a cadence of scaling the previous design into a new process,

followed by a new design in the same process. EV45 was the CMOS5 version of the EV4 design. A similar strategy at Intel is referred to as the Tick-Tock model. EV45 kept the dual issue pipeline of EV4, but the increased size of first level cache from 16 KB and the clock frequency to 275 MHz.

EV5: The Next Generation

EV5 was a major new Alpha design. It was four-wide superscalar, but only if two of these were floating point instructions, an addition and a multiplication. For integer operations, it was two-wide issue. EV5 did relax some of the integer issue rules from EV4, by allowing two load operations or one store through an L1 cache which was implemented as two copies of the data to allow parallel reads. Stores wrote to both copies.

EV5 was an ambitious design. With a total transistor budget of 9.3 million devices, it crammed a lot of functionality into the chip. This was partly made possible by relying on the compiler to schedule code for optimal execution. Multi issue works only when independent instructions are aligned on natural boundaries. Studies showed that more complex issue logic might improve performance in cycles per instruction, but would create tighter timing constraints and make it more difficult for the compiler to schedule for multiple issue. EV5 also relied on the compiler to schedule for resource conflicts. For example, a store followed by a load instruction to the same address in the following cycle causes a replay trap. EV5 took the Alpha philosophy of executing good code very well, while sometimes tripping over legal, but less than optimal code.

EV5 coincided with DEC doing research in VLIW compiler technology. In some ways, it was useful to view EV5 as a VLIW. Having the compiler consider low-level code scheduling had a big impact on performance.

The cache hierarchy was revamped from EV4. The first level caches, I and D, remained at 8 KB each, but they were backed up by an on-die 96 KB, three-way set associative, unified L2 cache. It continued to support an off chip cache as a third level.

EV6: Compacting EV5 into 0.25 μ Technology

The successor, EV56, was possibly the biggest success for the Alpha product line. Re-implementing the EV5

design in the 35 μ CMOS 6 process resulted in a dramatic frequency improvement from 300 to 666 MHz. With the smaller feature size, came smaller die size and lower power, making it easier to manufacture and design into systems. Compilers were getting better at dealing with the idiosyncrasies of the microarchitecture. A fairly major change in EV56 was the addition of byte and word access to memory. This change did not have a negative impact on the cycle time, as had been feared. It had a positive impact on porting application, which often accessed memory in small chunks, and the previously required costly read-modify-write sequences.

EV6: Speed Demon and Brainiac

EV6 was the third major Alpha design. EV6 attempted to maintain the high frequency design of its predecessors. Like EV5, it was superscalar with a peak performance of four instructions per cycle. But the EV6 team aimed to not only preserve those “speed demon” characteristics of the previous designs but also provide sophisticated microarchitectural features of the so-called “brainiacs” of that era.

There were several important microarchitecture features included in EV6. Most striking was the ability to execute instructions out of order. Instructions were fetched, destination registers were renamed, and source registers mapped. They were then placed in an instruction queue, and issued based on when their source operands were ready.

With a deeper pipeline and more operations in flight, the branch predictor became more important. EV6 had a tournament branch predictor, with a global (path history) and local (history of this branch) predictor dueling. A Chooser picked the winner based on the path history. EV6’s branch predictor was far larger and more sophisticated than any of its contemporaries, yet in the design post mortem it was felt that even more size and effort should have been devoted to it.

The complex EV6 branch predictor took multiple cycles to make a prediction and calculate an expected next address. Since the machine needed to fetch a block of instructions each cycle EV6 incorporated a structure referred to as a ‘line predictor’ that could quickly predict a new next instruction block every cycle. This eliminated bubbles in the pipeline waiting for the branch predictor. If the branch predictor disagreed with the

line predictor, then a quick redirect of the front end occurred. Of course, if the branch predictor was found to disagree with the actual instruction during execution then a later redirect of the front end would occur.

EV6 could issue four integer operations in a single cycle, with up to two Load or Store instructions. A remarkable feature was the ability to double pump the first level cache. This allowed for a fully dual ported cache, without bank conflicts. This double pumping mechanism also allowed for reading dirty data out of the cache in the same cycle a block was filled. The virtually indexed cache had a three cycle load to use latency. It was backed up with an off-chip cache with a dedicated interface, eliminating conflicts with traffic to main memory and IO.

To keep the instructions flowing, EV6 relied on speculative execution. It would let issue-ready loads issue before earlier stores, and replay if the addresses conflicted. To prevent future conflicts, a PC-indexed table kept track of past problems and kept loads in order when necessary.

Another interesting issue-related mechanism existed for optimizing the issue of instructions dependent on a value from a load instruction. While the latency of most instructions is deterministic, the latency of a load depends on whether it hits or not. To rendezvous with a hit optimally requires issuing before the machine knows if the load will hit in the first level cache. Since guessing a load is going to hit and having it miss resulted in a costly replay, EV6 had a predictor for the behavior of future loads controlling this load-hit speculation.

The EV6 team set out to combine the raw execution rate of the processor with a matching memory and system interface. EV6 introduced several new instructions to the Alpha architecture. Besides Square Root, and multimedia operations, there were new versions of the memory prefetch instruction, making writes and streaming references more efficient.

For EV6, the Tsunami chipset made big advances in improving memory access. Wide interfaces and point-to-point connections resulted in several Gigabytes per second of memory bandwidth. This design style foreshadowed the link-based systems that followed.

The EV6 design was compacted into new processes: EV67 in 0.25μ , and EV68 in 0.18μ . It was also used as the compute engine in EV7.

EV7: Integrating System Functions

Alpha processors achieved good performance on benchmarks like SPEC, both integer and floating point. In larger applications, some of the processor performance advantage was lost in time spent outside the processor chip itself. With the extra transistors available through the new 0.18μ process, it became practical to integrate the traditional functions of the system chip, such as the memory controller, the network switch, and the network router. In addition, EV7 added a 1.75 MB on die second level cache, and a direct interface to an IO chip. This made for an almost glueless multiprocessor system.

The memory was based on RAMBUS technology, with eight channels connected directly to the CPU chip. This was a further improvement in memory latency and bandwidth, up to 12.8 GB/s. The memory channels could operate in RAID mode, XOR'ing in a redundant channel for high reliability. To keep the caches coherent, there was an in-memory directory which kept track of which cache lines were present in a cache somewhere in the shared memory system. This scheme is relatively simple, but has the drawback of requiring memory bandwidth for directory updates. To reduce this effect, EV7 did not use the directory for local cache accesses. This works very well for programs with good locality. Remote references had to snoop the local cache for possible hits.

The core design itself was an EV6 with only minor changes. The EV7 systems pioneered a new trend in system design. With point-to-point socket connections through high bandwidth links, the performance scaled very well up to 32 sockets with shared, cache coherent memory. This was partly due to a high ratio of memory and link bandwidth (6 GB/s per link) relative to individual socket performance. The plan was to follow up this breakthrough in system design with a new core, EV8, with increased core performance. In practice, the industry trend became multi-core processors, with high aggregate performance, putting pressure on the system functions such as memory and link bandwidth.

EV7 moved the board level cache onto the die. The resulting cache was smaller than the 4 MB cache used in many EV6 systems. Sometimes this impacted performance negatively, but with the higher memory bandwidth and shorter latencies, most applications achieved

good performance improvement with EV7 systems. EV7 showed the importance of overall system design in achieving robust application performance. Even though EV7 entered the market when Alpha investments were being reduced, it had a long product life due to its scalable system design.

EV8: Araña

EV8 was aimed at pushing Alpha processors to ever higher single stream performance. The Alpha architecture goal of enabling superscalar implementations with simple instruction decode and dependence checking would be tested as the EV8 goal was to fortify Alpha's position as the world's highest performing computer architecture. The total transistor budget was now several hundred million transistors and the goal for EV8 was to make good use of them all. The path-finding phase aimed at developing features that would increase the IPC, with relatively little concern for power and area. Performance modeling was aimed at finding the limits for instruction level parallelism. The design could issue eight instructions per cycle, with a wide range of functional units to support an assortment of instruction mixes.

Keeping an eight-wide issue unit busy is a big challenge, which EV8 designers tried hard to meet. The front end could fetch up to 16 instructions per cycle in two chunks of eight aligned instructions, possibly with a taken branch instruction between them. An extensive branch predictor could make up to sixteen predictions in a cycle. A large instruction window tried to feed the functional units with issue ready instructions, usually issued out of order.

One of the messy problems with out-of-order execution results from address conflicts when loads are hoisted above stores. The EV8 team invented the "store set" mechanism, which associated set of loads with sets of potentially conflicting stores, and used the spare register number in the micro-architectural implementation of these operations to encode the dependency.

With performance modeling, it became clear that many interesting applications would not significantly benefit from eight-wide instruction issue. The amount of ILP was just not there, so the architects added "simultaneous multi-threading" (SMT) to the design. Four threads could execute simultaneously in the pipeline,

competing for resources and issue in the same cycle. With multiple threads the instruction window was much more likely to contain issue ready instructions. This was an early implementation of SMT, breaking new ground while solving some interesting problems. A few new instructions were added to support SMT. To keep idling threads from consuming resources, the instruction pair of ARM and QUIESCE set up a memory address to be monitored for updates and allowed a thread to suspend itself while waiting for a write to that location.

With SMT, it became much more practical to utilize CPU resources. Performance scaled well up to four threads. For high IPC applications, there was a dropoff in improvement from three to four threads, but for others, such as transaction processing, the improvement was almost linear with thread count. SMT is an efficient latency hiding technique. While one thread waits for memory, other threads are free to use all the pipeline resources. The extra threads can, of course, put pressure on the shared resources, and will especially increase the cache miss rate due to supporting multiple programs when there is little locality. For EV8, the SMT design became a careful balancing act between multi-threaded performance and the cost of supporting the extra threads in area and power.

There were two principal points in the pipeline with arbitration between threads. Every cycle, a thread selector would pick a thread to fetch instructions from, based on which thread had the fewest instructions active in the early stages of the pipeline. This allowed threads with high IPC to move right along, while allowing slower threads access without clogging up pipeline resources. Another thread selector picked threads for mapping registers based on the register renaming scheme. Once instructions had been mapped, they were put into an instruction issue window shared by all the threads. From there they were selected for issue based on age among issue ready instructions.

While SMT required dedicated architectural register state for each thread, the renaming registers required to fill the instruction pipeline was shared among the four threads. Wherever possible, pipeline structures and caches were shared dynamically between the four threads for optimal throughput performance. Only a few safeguards had to be part of the allocation to prevent

threads from being starved for resources. Overall, SMT proved to more than double through-put performance with less than 10% increase in hardware resources.

EV9: Vectors and Multicore

Although EV8 never shipped, research work was in progress on a variety of successor designs. One alternative, called EV9, was targeted at high-performance technical computing and added an integrated vector unit. Following the naming scheme begun with EV8, which was called araña (spider in Spanish) alluding to both the eight-way issue and SMT threads, EV9 was also called tarantula. The Cray X2 continued this naming tradition with a code name of “black widow.”

Another trajectory examined putting a large number of smaller processors on a ring-based interconnect. This work was pioneered by DEC’s research lab in Palo Alto, code-named Piranha project. The initial design suggested that replacing a single Alpha core optimized for single stream performance with eight simpler cores could improve overall performance on applications such as online transaction processing.

Alpha Systems

Alpha processors were the compute engines in a long array of computer systems. DEC produced systems ranging from PC’s and workstations to high end server systems. TurboLaser was a bus based system with more than 2 GB/s of bus bandwidth used to connect multiple processors with memory and IO. Wildfire was the first link-based system, connecting groups of four processor blocks with a two-level switch interconnect. Marvel was an almost glueless MP system design for EV7 and EV8, using a 2D Torus. The network router and switches were integrated into the processor chips along with the RAMBUS memory controllers.

Alphas were integrated into Cray’s T3D and T3E designs. These systems combined the fast Alpha microprocessor with an external memory system. The nodes were connected with a 3D toroidal mesh network. The ASCI Q system at Los Alamos consisted of a network of a thousand four-socket SMP systems based on 1.25 GHz EV68 processors connected by network switches.

Synonyms

Heterogeneous element processor

Definition

The HEP was a general-purpose shared memory multiprocessor system manufactured by Denelcor, Inc. of Denver, Colorado. Design began in 1973 and a total of six systems were delivered between 1981 and 1985, the year Denelcor closed its doors.

Discussion

Initial Design

The HEP computer system was originally conceived as a digital replacement for the analog computers that were Denelcor's traditional products. The objective was to achieve comparable performance in doing what analog computers do, namely solving nonlinear ordinary differential equations (ODEs). Algorithms for ODEs exhibit only fine-grained parallelism and are poorly suited for vector computation. These characteristics account for the several similarities between the HEP and data flow architectures.

Initially, the HEP was a collection of heterogeneous pipelined functional units connected by a high-speed bus. It was implemented in Schottky TTL logic technology. The planned functional units included an algebraic module that implemented the basic 32-bit floating point operations, a 64-bit wide Runge-Kutta integrator unit, a first-in first-out buffer unit to help data scheduling among the other functional units, a small memory for holding constants, and analog and digital input and output units. A control processor called the *scheduler* explicitly moved data among the several functional units over the 32-bit high-speed bus. Synchronization between the scheduler and the functional units used *full-empty bits* provided with the bus-addressable input and output locations of each functional unit so that the scheduler could stall until both producer and consumer were ready. Later, it was observed that in-place atomic operations could be synchronized with full/empty bits by consuming the old value and then producing a new one.

A prototype of this system was built with funding from BRL, the US Army Ballistics Research Laboratory (now called the Army Research Laboratory) in Aberdeen, Maryland. A follow-on contract with them called for more robust technology, higher performance, and programmability in a high-level language (tacitly assumed to be Fortran). These requirements resulted in major architectural changes.

Process Execution Modules

To improve performance, multi-threaded algebraic modules (renamed Process Execution Modules or PEMs) were designed that could concurrently execute multiple instruction sequences independent of the

scheduler. They had 64-bit data paths throughout and were implemented entirely in 10K series ECL. A PEM had 64 hardware instruction streams (threads) to tolerate both functional unit and synchronization latency. An additional 64 threads were implemented for the operating system. User traps and system calls blocked the trapping thread and started a supervisor thread at the appropriate trap handler entry point. A PEM implemented eight protection domains, one of which was used by the operating system; the rest were made available to run independent user jobs concurrently.

2048 64-bit general-purpose registers, each equipped with a full/empty bit, and 4096 64-bit constant registers were provided in each PEM. Both general register and constant register addresses could be indexed using a per-thread register index or constant index, and were further translated by a pair of base addresses associated with the protection domain to which the thread belonged. There was a limit register as well for general register addresses. Instructions were 64 bits wide and were stored in a dedicated per-PEM program memory with base and limit registers for each protection domain. The integrator and first-in first-out units had been subsumed by the PEMs and disappeared, leaving only the scheduler and input-output functions to be dealt with.

To address the high-level language requirement, advice was sought from a compiler development company, Massachusetts Computer Associates. They recommended replacing the scheduler with a multi-ported shared data memory that all PEMs could access in parallel. Denelcor agreed with this assessment but insisted that all shared data memory locations would need to be equipped with full-empty bits. New PEM instructions would be required, as well as memory base and limit registers per protection domain. Given all the changes to the original HEP design, BRL decided to require a single PEM be built and demonstrated running a high-level language before the shared memory design could begin in earnest.

Register Fortran

The requirement to implement Fortran without data memory was a challenging one. An existing Fortran compiler was modified to use most of the 2048 general

registers of the PEM as shared variables collected into a special *register common* block. Full-empty synchronization was invoked by prefixing the variable name with a currency symbol (\$); this turned stores into produce operations and loads into consumes. Subscripted variable references used the register index and needed a four-instruction sequence for the address computation. Subroutines could be either called or created. The latter would create a hardware thread to run the subroutine, or trap if the number of hardware threads became too close to 64.

Excluding division, the maximum functional unit latency in a PEM was eight 100-ns cycles. Programs for this prototype one-PEM system that did very little synchronization or division exhibited no speed-up above eight hardware threads. Division was not pipelined, but a PEM could have from one to eight divide modules. Division took about 25 cycles. The floating point arithmetic format was compatible with the IBM 360. A few unusual features were provided such as unnormalized add and subtract operations and a loss-of-significance trap.

The PEM hardware was hosted by an Interdata 8/32 minicomputer, which had compatible arithmetic and was responsible for compilation as well as operating system functions. Several papers describe computational experiments with this system for ODEs [10], linear algebra[12], and graph shortest-path problems [5], and the system was demonstrated successfully to BRL in November 1979.

Shared Memory

The multi-threaded PEMs were already able to tolerate both functional unit and synchronization latency. Since functional unit latency was variable, unlike the peripheral processor “barrel” of the CDC 6600 and 7600 systems, the thread issue order was not round-robin but out-of-order, requiring only that the preceding operation of that hardware thread had been completed. Now that the time had come to design a multi-ported shared memory, the natural approach was to extend latency tolerance to the memory system by implementing a fully pipelined packet switched network connected to multiple pipelined memory banks rather than to use the circuit switches then popular in existing systems. Each three-port packet routing

node occupied two circuit boards and could handle a new memory request or response packet every 100 ns on each port. The clock period was 25 ns, and so a packet took four clocks to transit any point in the network.

To make the routers implementable, there was no buffering to accommodate conflicts for output ports; instead, each packet was immediately routed to some output port, which might be the wrong one if there was a routing conflict. This scheme, called “hot-potato” or “pure deflection” routing, was invented by Paul Baran in 1964 for the Internet. The HEP adapted the idea to computer interconnect. A misrouted packet had its priority increased to make it more likely to win future conflicts, and once a packet reached maximum priority, the routing tables were programmed to send these packets an Euler tour of the entire network to guarantee no further conflict losses. Gore-Tex twisted pair cables were used as in the Cray 1, permitting about 3 m of cable between routing nodes. The latency of a routing node and its associated cabling was 50 ns, which meant the graph of the network to be 2-colorable to guarantee correct timing.

The newly designed functional unit that connected the PEM to memory via the network was called the SFU, this abbreviation variously standing for Storage Function Unit or Scheduler Function Unit (since it indeed replaced the original scheduler). Informally, the SFU was fondly known as the Strange Function Unit, chiefly because it functioned in an unusual way. Instead of reporting synchronization failure, e.g., from an attempt to consume an empty memory location, back to the thread scheduling logic so the instruction could be reissued, it would repetitively retry the operation itself. Since a hardware thread would not be allowed to issue its next instruction until the SFU indicated the preceding one was complete, the semantic effect was the same. The major difference was that synchronization consumed a small amount of memory bandwidth and no instruction issue bandwidth at all. If there were enough hardware threads, typically 25–30, executing in parallel and tolerating all latencies, the HEP would steadily execute very close to one instruction per clock per PEM. This made each PEM the rough equivalent of a CDC 7600 or IBM 360/91 and about half the scalar speed of a Cray 1.

Software

The Fortran compiler was modified to address the new memory with little difficulty. The memory full/empty bits were invaluable, and had unexpected uses. Loops were executed in parallel with an arbitrary number of hardware threads by *self-scheduling* [14] the loop iterations: A thread seeking more iterations to execute would consume the iteration counter value, produce a new value incremented by a constant quantum, and then execute the iterations it had just acquired. The programmer wrote something like

```
I = $C  
$C = I + K
```

The quantum K would be chosen big enough to amortize scheduling overhead.

At the end of most loops, it was necessary to make sure all iterations were complete; this was accomplished by having each thread atomically decrement a counter and then wait at another location until the last thread, the one that decremented the counter to zero, freed all the rest. Harry F. Jordan named the underlying abstraction *barrier synchronization* [8] after the barrier used to start horse races because in both cases, all must enter before any may leave. Later, a pattern of pairwise produces and consumes resembling the wiring of an interconnection network was used to scale to larger numbers of threads. This was popularly called the *butterfly barrier*. Loops containing linear recurrences were parallelized in a similar way using parallel cyclic reduction [15] or one of the schemes due to Richard Ladner and Michael Fischer [11].

Harry Jordan developed a set of macros in M4 for automating much of the HEP Fortran programmer’s task including self-scheduling and barrier synchronization. This language extension was called The Force [9] and was the first Single Program, Multiple Data (SPMD) language. It was later implemented for other systems including Flex/32, Encore Multimax, Sequent Balance, Alliant FX series, Cray 2, Cray Y-MP, and Convex C220. IBM research adopted these ideas for the RP3 [4], and they achieved widespread adoption in OpenMP. Argonne National Laboratory wrote their own collection of M4 macros to implement a programming model based on monitors and message passing. This package was simply known as the “Argonne Macros” [2] and

evolved into the P4 and PARMACS languages for both C and Fortran.

The first implementation of the functional language Sisal was done on the HEP by Rodney R. Oldehoeft and his colleagues [1]. Sisal was also implemented on Cray vector processors and on the Manchester Data Flow Machine. The HEP let full/empty bits be used in a way in which loads did not consume but left the memory location full; this permitted a direct implementation of Sisal's single-assignment variables, known as *I-structures* [13] in the data flow community. That community in turn adopted the producer-consumer and atomic update semantics of full/empty bits in the concept of *M-structures* [13].

Parallel divide-and-conquer looked very simple in HEP Fortran but was often not simple at all; the system would run out of memory due to an excess of parallelism and its associated state. This problem was solved by judiciously limiting recursion depth. A much more elegant solution that needed no assist from the programmer was later devised and implemented by Robert H. Halstead in Multilisp [7].

Applications and Customers

There were six HEP machines delivered to customers. The first was a one-PEM system that went to Los Alamos National Laboratory, which was interested in using the system for their nonvector work. Monte Carlo particle simulation was one such application. The problem of parallel random number generation was first solved in using the HEP in addressing this kind of computation [6] and was quickly applied to vector processors as well. Argonne National Laboratory also acquired a one-PEM HEP system and used it for automated reasoning applications. Argonne also taught a summer school in parallel computing, and many students were exposed to HEP programming there.

A system was delivered to Messerschmitt-Bolkow-Blohm (MBB) outside Munich for simulating the flight dynamics of the Tornado fighter in real time. The original mission of the HEP, solving ordinary differential equations, was part of the job. The rest of it involved interfacing to physical hardware, in particular the avionics equipment for controlling the fighter's flight dynamics, the cockpit controls, and the vision system that provided the heads-up display and the view of the adversary aircraft, which in this case were Russian

MIGs. MBB started with one PEM but increased the size of the system to three PEMs during the mid-1980s.

BRL, the US Army Ballistics Research Laboratory that funded HEP development, acquired a four-PEM system around 1982. Their applications included not only physical simulations but also ray-tracing for rendering three-dimensional computer-aided design files. The application that resulted from this work was named BRL-CAD [3]. BRL was also a pioneer in using the Unix operating system for high-performance computing and strongly encouraged Denelcor to port Unix to the HEP. The resulting system, HEP/UPX, was delivered in early 1985. It was based on AT&T System 3 Unix, ran symmetrically on all PEMs, and was highly parallel internally. Another four-PEM system was delivered to the US Department of Defense, and a one-PEM system was delivered to Shoko Ltd. in Japan. Both of these systems were acquired for evaluation of the general potential of the HEP architecture for parallel computing.

Dense Linear System Solvers

BERNARD PHILIPPE¹, AHMED SAMEH²

¹Campus de Beaulieu, Rennes, France

²Purdue University, West Lafayette, IN, USA

Synonyms

Cholesky factorization; Direct schemes; Gaussian elimination; Linear equations solvers

Definition

A **dense system** is given by

$$Ax = f, \quad (1)$$

where $A \in \mathbb{R}^{n \times n}$ and $b \in \mathbb{R}^n$, with A having relatively very few zero elements.

Discussion

These are direct schemes based on block-Gaussian elimination with partial pivoting, for nonsymmetric

systems, and based on the block-Cholesky factorization for symmetric positive definite systems or symmetric indefinite systems. They take advantage of parallel architectures exclusively through efficient implementation of vector and matrix primitives on such computing platforms. In fact, most ScaLAPACK [1] procedures are generated by replacing the BLAS in the corresponding LAPACK procedures by their parallel counterparts PBLAS.

Nonsymmetric Systems

Consider first the nonsymmetric system $Ax = f$ where $A \in \mathbb{R}^{n \times n}$ is nonsingular. For the sake of illustration, let $n = 3k$ where k is the chosen block size. The first step in the procedure is to obtain the LU-factorization of the leading k columns with partial pivoting using the classical unblocked Gaussian elimination scheme, for example, see [6]. Thus if,

$$P_1 * A = \begin{pmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{pmatrix} \quad (2)$$

in which P_1 is the permutation matrix affecting the partial pivoting in the LU-factorization of the first k columns of A , then

$$\begin{pmatrix} A_{11} \\ A_{21} \\ A_{31} \end{pmatrix} = \begin{pmatrix} L_{11} \\ L_{21} \\ L_{31} \end{pmatrix} * U_{11}, \quad (3)$$

where L_{11} and U_{11} are $k \times k$ unit lower triangular, and upper triangular matrices, respectively. The remainder of the first block row of the upper triangular factor of A is obtained by solving a triangular system with multiple right-hand sides,

$$L_{11}(U_{12}, U_{13}) = (A_{12}, A_{13}) \quad (4)$$

using the BLAS-3 primitive DTRSM. Setting

$$\begin{pmatrix} A_{22} & A_{23} \\ A_{32} & A_{33} \end{pmatrix} := \begin{pmatrix} A_{22} & A_{23} \\ A_{32} & A_{33} \end{pmatrix} - \begin{pmatrix} L_{21} \\ L_{31} \end{pmatrix} (U_{12}, U_{13}), \quad (5)$$

which is obtained via the rank-k update BLAS-3 primitive DGEMM, the matrix $P_1 * A$ may be expressed as

$$2P_1 * A = \begin{pmatrix} L_{11} & 0 & 0 \\ L_{21} & I & 0 \\ L_{31} & 0 & I \end{pmatrix} \begin{pmatrix} U_{11} & U_{12} & U_{13} \\ 0 & A_{22} & A_{23} \\ 0 & A_{32} & A_{33} \end{pmatrix}. \quad (6)$$

One is now ready to obtain the unblocked LU-factorization of the leading k columns of the lower principal submatrix of order k less, that is, of order $n - k$,

$$P_2 \begin{pmatrix} A_{22} \\ A_{32} \end{pmatrix} = \begin{pmatrix} L_{22} \\ L_{32} \end{pmatrix} * U_{22}. \quad (7)$$

Setting

$$\begin{pmatrix} A_{23} \\ A_{33} \end{pmatrix} := P_2 \begin{pmatrix} A_{23} \\ A_{33} \end{pmatrix} * U_{22} \text{ and} \quad (8)$$

$$\begin{pmatrix} L_{21} \\ L_{31} \end{pmatrix} := P_2 \begin{pmatrix} L_{21} \\ L_{31} \end{pmatrix}, \quad (9)$$

one can now obtain the remainder of the second block row of the upper triangular factor of A by solving the triangular systems

$$L_{22}U_{23} = A_{23}, \quad (10)$$

using the corresponding BLAS-3 primitive. Setting

$$A_{33} := A_{33} - L_{32}U_{23}, \quad (11)$$

which is also obtained via BLAS-3, one obtains the factorization

$$\begin{pmatrix} I_k & 0 \\ 0 & P_2 \end{pmatrix} * P_1 * A = \begin{pmatrix} L_{11} & 0 & 0 \\ L_{21} & L_{22} & 0 \\ L_{31} & L_{32} & I \end{pmatrix} \begin{pmatrix} U_{11} & U_{12} & U_{13} \\ 0 & U_{22} & U_{23} \\ 0 & 0 & A_{33} \end{pmatrix}. \quad (12)$$

Now, for $n = 3k$, the last step consists of the unblocked LU-factorization

$$P_3A_{33} = L_{33}U_{33} \quad (13)$$

and setting

$$(L_{31}, L_{32}) := P_3(L_{31}, L_{32}) \quad (14)$$

resulting in the completed LU-factorization of A ,

$$\Pi * A = \begin{pmatrix} L_{11} & 0 & 0 \\ L_{21} & L_{22} & 0 \\ L_{31} & L_{32} & L_{33} \end{pmatrix} \begin{pmatrix} U_{11} & U_{12} & U_{13} \\ 0 & U_{22} & U_{23} \\ 0 & 0 & U_{33} \end{pmatrix} \quad (15)$$

in which the permutation Π is given by

$$\Pi = \begin{pmatrix} I_{2k} & 0 \\ 0 & P_3 \end{pmatrix} \begin{pmatrix} I_k & 0 \\ 0 & P_2 \end{pmatrix} P_1. \quad (16)$$

This scheme is described in many references but the presentation above is closest to that in [4], where it is called the *right-looking algorithm*. It is the scheme implemented in the routines DGETRS of LAPACK and PDGETRS of ScaLAPACK [1].

The solution of $Ax = f$ is then obtained by block-forward and block-backward sweeps using the routines DGETRF of LAPACK and PDGETRF of ScaLAPACK.

Symmetric Positive-Definite Systems

For symmetric positive definite (s.p.d.) systems, one adopts the Cholesky factorization, $A = U^T U$, where U is upper triangular, through a block-oriented algorithm. For the sake of illustration, let A be partitioned as

$$A = \begin{pmatrix} A_{11} & A_{12} & A_{13} \\ A_{12}^T & A_{22} & A_{23} \\ A_{13}^T & A_{23}^T & A_{33} \end{pmatrix}, \quad (17)$$

in which $A_{ij} \in \mathbb{R}^{k \times k}$ with k being the chosen block size.

Step 1:

Obtain the Cholesky factorization of the s.p.d. submatrix A_{11} using the unblocked Cholesky algorithm, using BLAS-1 and BLAS-2, for example, see [6],

$$A_{11} = U_{11}^T U_{11}, \quad (18)$$

where U_{11} is upper triangular of order k .

Step 2:

The remainder of the first block row of U is obtained by solving a triangular system with multiple right-hand

sides (Level-3 of BLAS),

$$U_{11}^T(U_{12}, U_{13}) = (A_{12}, A_{13}). \quad (19)$$

Step 3:

Setting

$$\begin{pmatrix} A_{22} & A_{23} \\ A_{23}^T & A_{33} \end{pmatrix} := \begin{pmatrix} A_{22} & A_{23} \\ A_{23}^T & A_{33} \end{pmatrix} - \begin{pmatrix} U_{12}^T \\ U_{13}^T \end{pmatrix} (U_{12}, U_{13}), \quad (20)$$

which is obtained using the BLAS-3 primitive DGEMM, one has the partial factorization

$$A = \begin{pmatrix} U_{11}^T & 0 & 0 \\ U_{12}^T & I & 0 \\ U_{13}^T & 0 & I \end{pmatrix} \begin{pmatrix} U_{11} & U_{12} & U_{13} \\ 0 & A_{22} & A_{23} \\ 0 & A_{23}^T & A_{33} \end{pmatrix}. \quad (21)$$

Similar to the LU-procedure for nonsymmetric systems, steps 1–3 are repeated twice to complete the block-Cholesky factorization $A = U^T U$ with U being of the form

$$U = \begin{pmatrix} U_{11} & U_{12} & U_{13} \\ 0 & U_{22} & U_{23} \\ 0 & 0 & U_{33} \end{pmatrix}. \quad (22)$$

Again the solution of $Ax = f$ is obtained by block-forward and block-backward sweeps implemented in routines of LAPACK and ScaLAPACK based on Level-3 of BLAS.

Indefinite Symmetric Systems

Unlike the symmetric positive definite case (Cholesky factorization), one needs a pivoting strategy (Bunch–Parlett strategy [2]) for obtaining the factorization $U^T D U$, where U is unit upper triangular and D is block diagonal with $1 - by - 1$ and $2 - by - 2$ diagonal blocks. Aside of the pivoting scheme, and row and column pivoting, the main procedure steps are almost identical to the schemes discussed above.

Other Parallel Algorithms

Variants of the algorithm above include (a) the *left-looking* version of block Gaussian elimination in which

data is accessed only when absolutely needed, for example, for pivoting, and (b) the *Crout algorithm*. Characteristics of these versions are discussed by Dongarra, Duff, Sorensen, and van der Vorst in their survey [4].

The partial pivoting strategy guarantees a sound factorization but it limits the parallel efficiency due to loss of data locality. As a remedy, Gallivan, Plemmons, and Sameh discuss the *pairwise-pivoting* strategy in [5]. An error analysis of *pairwise pivoting* is given by Sorensen in [8]. While the upper bound on the error of the resulting factorization is worse than that of the classical LU-factorization with partial pivoting, extensive numerical experiments show that both factorization schemes yield almost identical solutions of the linear system.

The above block-oriented algorithms are quite robust and realize reasonably high performance on a variety of parallel architectures. In the early days of parallel computing, some work was done regarding the theoretical limit of parallelism inherent in Gaussian elimination. Csanky [3] made use of Leverrier's method [7] to show that a dense system of order n can be solved in $O(\log^2 n)$ parallel arithmetic operations employing $O(n^4)$ processors. Later, Preparata and Sarwate reduced the number of required processors to $O(n^{3.31}/\log^2 n)$ taking advantage of properties of *Newton identities* [7], and using *Strassen's* method for matrix multiplication [9].

Dependence Abstractions

FRANÇOIS IRIGOIN
MINES ParisTech/CRI, Fontainebleau, France

Synonyms

Dependence accuracy; Dependence approximation; Dependence cone; Dependence direction vector; Dependence level; Dependence polyhedron; Exact dependence; Use-def chains

Definition

A data dependence between two computer instructions is due to some value passing or resource conflict. Dependencies usually cannot be known exactly at compile time. They must be modeled and over-approximated with different abstractions to be used statically by compilers and to decide if program transformations and optimizations, such as loop parallelization or locality improvement, can be applied without changing the program results. The characteristics of the dependence abstractions are linked to the program transformations whose legality must be proved. All dependence abstractions defined up to 2010 are families of convex affine sets, but different kinds of restrictions apply to the affine constraints. They are ordered from a less accurate to a most accurate abstraction, and they are all optimal with respect to at least one kind of transformation: the set of legal transformations cannot be increased by increasing the dependence abstraction accuracy.

Discussion

When two statements of a program use and/or define the same memory location, their execution order cannot be modified by the compiler to optimize the execution without modifying the program's result when the semantics of the operations is unknown. This sufficient constraint is known as Bernstein's condition [3] and is

used in all optimizing compilers as use-def chains, as defined by Aho et al. [1]. Let's consider the sequence:

```
S1: x = 2;
S2: y = 3*x+1;
```

The compiler cannot guarantee that the value of y is the same after executing $S1; S2$; or $S2; S1$. This is pretty obvious in a sequence, but $S1$ and $S2$ may be executed many times during the program execution, for instance because they are located in loops. So the compiler has to deal with all instances of Statements $S1$ and $S2$, in all possible execution traces.

Furthermore, the memory locations they access may be computed dynamically when pointers or arrays or function calls are used as in:

```
S1: x[i] = foo(x, y, 2);
S2: y[j] = 3*x[k]+1;
```

Without additional information, it is impossible to decide whether $S2$ could be executed before $S1$. It is unlikely, but the decision hinges on the ranges of Variables i , j , and k and on the behavior of Function foo (See ▶Banerjee's Dependence Test, ▶Dependences, ▶Dependence Analysis, ▶GCD Test, ▶Omega Test).

To sum up, an exact knowledge of statement dependencies depends on the program input and its resulting trace on one hand, and on our ability to specify statically the dynamic statement instances and memory locations accessed on the other. Since the exact dependence information is not computable in general, abstractions must be used to make the problem tractable in a compiler. These abstractions must be over-approximations to over-constrain the program optimizations and to guarantee their legality.

To start with, program inputs are ignored. Then a decision must be made about the representation of statement instances. Finally, a decision must be made about the representation of sets of arcs between statement instances. These decisions must be made according to the program transformations that the compiler implements.

Set Abstractions

Finite sets can be represented exactly in extension, but unbounded sets such as the number of iterations of a loop:

```
for(i=0; i<n; i++) { }
```

can only be represented implicitly via predicates. Different classes of predicates can be used, but Presburger arithmetic is the most powerful framework that is still computable. It subsumes less powerful frameworks such as convex polyhedra, i.e., affine constraints, affine subspaces, i.e., affine equations, and their sub-frameworks obtained by reducing the number of nonzero coefficients in the constraints, e.g., one or two, and/or the magnitude of the coefficients, e.g., $-1, 0$, or 1 . Bounded lists of abstract sets can be used to increase the accuracy of a given framework by providing a limited exact set union.

Sets of Statement Instances

Program parallelization has primarily been focused on loop parallelization because its optimization potential linked to the iteration counts is greater than task, instruction level, and superword level parallelizations.

The scope of interest is then limited to one loop or to a loop nest. Each instance of a statement in the loop body can be known exactly by its iteration vector, whose components are the values of the surrounding loop indices, from the outermost to the innermost one. Note that if some control structure is used within the loop body, some abstract instances may not exist in a real execution trace because some condition is true or false, but the set of abstract instances is greater than the set of effective instances, which is safe for most analyses and transformations. Note also that the nesting depths of two statements $S1$ and $S2$ may be different because all statements appearing within the loop nest do not always have the same nesting loops. The iteration (or instance) vectors i_1 for $S1$ and i_2 for $S2$ may not be comparable. A set abstraction must be chosen to define the sets of instances of each statement.

```

for(i=0; i<n; i++) {
S1:   a[i] = 0.
      for(j=0; j<m; j++) {
S2:     a[i] += b[i][j];
      }
}

```

In some cases, statement instances may be defined exactly over a small piece of source code because all iteration sets are defined exactly and because all conditions are predicates over the iteration vectors. The loop bounds and the test conditions must belong to the chosen set abstraction, e.g., affine constraints and convex sets. Such

pieces of code, which include sequences of loops, are called static control code (See ►Polyhedron Model):

```

for(i=0; i<n; i++) {
S1:   a[i] = 0.;
      for(j=0; j<m; j++) {
        if(i!=j)
          a[i] += b[i][j];
      }
}

```

D

Within a loop nest, two statements $S1$ and $S2$ may appear at different depths and/or may be nested within different loops. Their iteration vectors can be limited to their common nesting loops. Such an iteration vector does not always represent one instance of $S1$ or $S2$, but may represent a whole set of them:

```

for(i=0; i<n; i++) {
  for(j=0; j<m1; j++) {
    a[i][j] = 0.;
    for(j=0; j<m2; j++) {
      b[i][j];
    }
}

```

Here $S1$ and $S2$ have only one common loop, the i loop. Abstract instances of $S1$ or $S2$ represented by i contain each a set, possibly empty, of effective instances controlled by the j loops.

When all statements in a loop body appear at the same depth, the loop nest is said to be perfectly nested and statement instances are accurately represented by the loop-nest iteration vector, at least when the loop bounds are compatible with the set abstraction chosen (See ►Loop Nest Parallelization and ►Unimodular Transformations).

It is sometimes convenient to give a number to each statement and to integrate this number in its iteration vector. Thus, the set of all statement instances is abstracted by a set of vectors, which are easier to handle mathematically than several sets.

To sum up, some set abstraction must be chosen, for instance convex sets, as well as some coding rules to handle sequences, tests, and loop nesting. Control structures such as goto and exception preclude such instance abstractions and hence loop parallelization and optimization where they occur.

Sets of Dependence Arcs

Basically, Bernstein's conditions for Statements S_1 and S_2 must be checked for every instance pair of S_1 and S_2 . In the compiler, a collecting semantics is used to project the information about statement instances onto source statements. Information about arc instances is built on the abstract instance chosen, usually a vector, using a new arc predicate, i.e., yet another abstract set.

Each instance of S_1 are defined by an integer vector i_1 and a set predicate $P_1(i_1)$. Each instance of S_2 are defined by a vector i_2 and a set predicate $P_2(i_2)$. Dependence arcs between S_1 and S_2 are pairs (i_1, i_2) meeting Conditions $P_1(i_1)$ and $P_2(i_2)$ and some arc dependence condition $A(i_1, i_2)$, where A belongs to some set abstraction.

So the dependence abstraction is built with an instance abstraction and an arc abstraction. Predicates P_1 and P_2 are usually easy to derive from the program internal representation. The dependence predicate A requires some dependence test (See ▶Banerjee's Dependence Test, ▶GCD Test, ▶Omega Test).

Note that the arc set abstraction may be as simple as 0 and 1, empty set and non-empty set. The empty set is modeled by 0, i.e., no instance of S_2 ever depends on any instance of S_1 , and the non-empty sets by 1, i.e., there may exist at least one instance of S_2 that depends on at least one instance of S_1 . Again, a safe over-approximation is used. In case of doubt, a dependence arc is assumed. This safety property must be insured by the dependence test.

Note also that S_1 and S_2 may denote the same statement S , as some instances of S can depend on other instances of S .

Dependence Abstractions

Many dependence abstractions have been defined since the early seventies because there is a relationship between the program transformations applied by a compiler and the necessary accuracy of the dependence information.

In [16], Yang et al. survey the usual dependence abstractions:

- The dependence levels, DL
- The dependence direction vectors, DDV
- The dependence cone, DC

- The dependence polyhedron, DP
- The dependence set D , a.k.a. dependence distance when the dependences are constant
- The dependences between iterations, DI

They have been listed here from the less accurate to the most accurate one.

The dependence between iterations, DI , is the most accurate one and it stands out because the predicate associated is a predicate over two iteration vectors, i_1 and i_2 . It is the most flexible as it includes the modelization of the loops surrounding i_1 , of the loops surrounding i_2 , and of the relationship between i_1 and i_2 . It has been used by Feautrier [4] and Maydan et al. [10] (See ▶Polyhedron Model).

All other dependence abstractions assume that i_1 and i_2 are comparable vectors, i.e., they are related to the same surrounding loops. Since we need to know if i_1 occurred before or after i_2 , i_1 and i_2 can be replaced by the dependence vector d , with $d = i_2 - i_1$. Arcs (i_1, i_2) are replaced by dependence distances d .

D is the exact set of dependence distances. It can be used when its cardinal is bounded because the dependencies are constant. For instance, the loop nest:

```
for (i=0; i<n; i++)
S:   a[i] = a[i-1] + b[i];
```

contains dependences between instances of S and other instances of S . The i instance of S depends on the result of the $i - 1$ instance of S . This was used by Karp [8] for scheduling computations and introduced by Muraoka [11] for loop parallelization (See ▶Parallelization, Automatic). The systolic community also used this representation (See ▶Systolic Arrays).

The dependence polyhedron, DP , is derived from DI , when Predicates P_1 , P_2 , and A are affine, by adding the affine equation $d = i_2 - i_1$ and by projecting i_1 and i_2 .

The dependence cone DC , introduced by Irigoin and Triolet [7], is the transitive closure of DP . So it is a little bit less accurate, but easier to use because its dual representation is simplified. Vertices are transformed into rays, and only rays have to be dealt with.

The dependence direction vector abstraction, defined by Wolfe in [15], is also a convex set, but the acceptable constraints are signed constraints such as $c > 0$ (i.e., $c \geq 1$), $c \geq 0$, $c = 0$, $c < 0$ (i.e., $-c \geq 1$), and $c \leq 0$ (i.e., $-c \geq 0$), where c is any component of the dependence

vector d . As mentioned earlier, this is a special case of affine convex set: the constraints are limited to one variable, the coefficient is either 1 or -1 , and the constant term is either 0 or 1.

The dependence level abstraction used by Allen [2] is even simpler. The only constraints that can be used for the components of d are $c = 0$ and $c \geq 1$.

Other intermediate abstractions include the dependence vector abstraction of Sarkar et al. [13] which adds one-variable equations such as $c = n$, where n is a numerical constant to the dependence direction framework, and the abstraction by Wolf et al. [14] which also extends the dependence direction vector and Sarkar's abstraction by using constant terms different from 0 and 1. This leads to constraints bounding c such as $n_1 \leq c \leq 2$. With $n_1 = n_2$, Sarkar's constraints are obtained and hence the abstraction order.

Note that simpler less accurate abstractions can easily be derived from more complex more accurate ones with simple algebraic transformations. Note also that dependence tests must be developed for each abstraction and that their results depend on the subscript expressions used, on the pointer-based references, and on the procedure calls. Interprocedural dependence testing requires some more abstraction to modelize the effect of procedure calls on the local variables.

Note also that more complex set abstractions such as Presburger arithmetic, implemented by Pugh [12] in the Omega library, and Feautrier's QUAST [4], which uses finite lists to increase the accuracy of the underlying convex affine representation, are not covered here (see ►Polyhedron Model).

Relationships Between Dependence Abstractions and Program Transformations

Initial contributions, such as Karp's [8], Muraoka's [11], and Lamport's [9], were based on exact constant dependences, also called uniform dependences because they do not depend on the iterations. No abstraction of dependence was used, but the applicability is too limited because dependences are not always constant and dependence sets are not finite.

One may wonder why so many different dependence abstractions were introduced over the years. In fact, each of them is linked to a program transformation or to a class of program transformations. So, when a new

transformation is introduced, no dependence approximation might be available that is accurate enough for it and a new one has to be designed.

Yang et al. [16] shows that the dependence level, DL , is the best abstraction for loop reversal and loop parallelization, but dependence direction vectors are necessary to perform loop permutation (a.k.a. loop interchange) successfully. For unimodular loop transformations, for scalable loop tiling (see ►Tiling), and for multidimensional affine scheduling, the dependence cone is the best dependence abstraction. Some transformations require the dependence set D or the dependence polyhedron DP because they rely on the minimal size of a dependence arc. For instance, the odd and even iterations in the following loop can be executed concurrently:

```
for(i=0; i<n; i++) {
    a[i] = a[i-2]+b[i];
}
```

For transformations dealing with sequences of loops and global affine schedules as defined by Feautrier [5, 6], information about the dependence arc, DI , is necessary, although, in the important case of loop fusion, some sufficient dependence information D can be computed a posteriori since the statements $S1$ and $S2$ end up nested in the same loop by definition of the transformation.

Locality transformations, such as privatization or array scalarization, which may require information about the precision of a particular abstraction with respect to the exact information, are not covered here (see ►Parallelization, Automatic).

Future Directions

Dependence abstractions presented here are useful for loop nest transformations. Better information is needed to schedule larger piece of codes, such as sequences of loop nest: the information about the source and sink iterations must be preserved, when possible. This is part of the polyhedron model.

Conclusion

Several abstraction steps must be taken to make dependence analysis useful in an optimizing compiler. These abstraction steps are often overlooked when a particular program transformation and dependence abstraction are introduced, but a quick survey is useful to make

them understandable to newcomers to the automatic parallelization field.

However, when designing an optimizing compiler, it is important to understand the underlying affine base common to all abstractions and the impact of the choice of dependence abstractions on accuracy and computational requirements. The operator complexity is also often used for decision making, although the practical complexity is polynomial for most operations on unrestricted affine convex sets related to dependence analysis.

Bibliographic Notes and Further Reading

The only paper dealing explicitly with the relationships between different dependence abstractions is Yang's [16]. Other papers deal only with one kind of dependence. The latest editions of the textbook by Aho et al. [1] presents several uses of dependences, e.g., scheduling, parallelization and memory allocation.

Definition

One needs a paradigm shift when reasoning about parallel programs. The usual approach, as for instance in denotational semantics, is to consider each statement as a function from memory state to memory state, and to consider two programs as equivalent if they implement the same function. For instance, $x = 0$; $x = x + 1$; and $x = 1$ are deemed equivalent. However, if these two programs are run in parallel with $x = 7$, they may give different results. Similarly, asking whether a statement can be run in parallel with itself does not make sense. However, the statement may be enclosed in a context – for instance, a loop – which causes it to be executed repeatedly. Each repetition is an instance or *operation*, and it makes sense to ask whether all or some of these operations can be executed in parallel.

These considerations motivate the following definitions. A program is a specification for a set of operations. Each operation is executed only once, and must have a unique name. The program must also specify the order in which operations are executed. It is easy to see that a sequential program has a total execution order,

and a parallel program has a partial execution order. In fact, an embarrassingly parallel program, in which everything can be done in parallel, has the empty execution order.

Methods for specifying operations and their execution order differ from one program style to another – loop programs, recursive programs, and functional programs all have different conventions.

Optimizing compilers, and in particular parallelizing compilers, try to transform the source program into an equivalent program that is better adapted to the target architecture, or runs faster, or has more parallelism. The problem is that in general, program equivalence is undecidable. A possible solution is to restrict the class of admissible transformations to a decidable subset. One of the classes of choice consists of *reordering* transformations. The operations of the transformed program are the same as in the source, but they may be executed in a different order (including parallel execution). The necessary information for validating such a transformation is the dependence relation:

Two operations u and v are independent if the programs $u; v$ and $v; u$ give the same results.

One can prove that a sufficient condition for the equivalence of two terminating programs which execute the same operations is that dependent operations are executed in the same order in both programs.

According to this definition, the dependence relation is symmetric. If one of the programs above is the reference program (e.g., if it is the sequential program to be parallelized), one usually orients the dependence relation according to the execution order of the reference program. With this convention, a transformed program is equivalent to the reference program if its execution order is an extension of the dependence relation.

Discussion

Bernstein's Conditions

Deciding if the execution order of two operations can be reversed can be arbitrarily difficult. Bernstein [3] has devised a simple test, which gives a sufficient condition for independence. This test depends only on the memory cells that are accessed by the operations to be tested.

Let $R(u)$ be the set of memory cells that are read by u . Similarly, let $W(u)$ be the set of memory cells which are written by u . Then u and v are independent if the three sets: $R(u) \cap W(v)$, $R(v) \cap W(u)$, and $W(u) \cap W(v)$ are all empty.

Note that in most languages, each operation writes at most one memory cell: $W(u)$ is a singleton. However, there are exceptions: multiple and parallel assignments, vector assignments among others.

Bernstein's conditions reflect a kind of worst-case reasoning. Consider:

$$y = e; \quad y = f;$$

The final value of y is given by the operation that executed last; in this case, this value is the value of f . If the operations are reversed, y will get the value of e , and *in the absence of any information* on the respective values of e and f , one must conclude that the two operations are dependent.

If the dependence relation is computed according to Bernstein's conditions, the above property can be extended in two directions. Firstly, it applies now also to nonterminating programs: one can show that the *history* of each variable (the succession of values it holds during execution) is the same for both programs. Secondly, it also holds if one of the programs has real parallelism. The reason is that two operations that write to the same location are always in dependence (this is the third Bernstein condition) and hence can never be executed in parallel. Hence, two writes to the same memory cell never occur at the same time.

Scalars, Arrays, and Beyond

Computing dependences for scalar variables is easy. The sets R and W above are finite, and computing intersections is trivial. The only real difficulty is caused by *aliasing*, when two distinct identifiers refer to the same memory cell. The detection of aliasing is a difficult problem. However, it is easy to detect cases in which there is no aliasing, for example, among the local variables of a procedure, and to handle all other cases conservatively. Orienting each dependence is easy, at least within linear code (*basic blocks*).

The case of arrays is more problematic. Arrays usually occur in loops, and their subscripts usually differ from one iteration to the next in complex ways. This has lead to the invention of the *polyhedral model* [6, 9], in

which one considers only regular DO loops, and subscripts which are affine functions of the surrounding loop counters and of constant parameters. A function is affine if it is the sum of a linear part and a constant. One may construct a dependence relation among operations (i.e., loop iterations) in the following way. To name an iteration, one may use its *iteration vector*, whose coordinates are the surrounding loop counters, ordered from outside inward. Iterations are ordered according to the lexicographic order of iteration vectors:

$$\vec{i} < \vec{j} \equiv i_1 < j_1 \vee (i_1 = j_1 \wedge i_2 < j_2) \vee \dots \quad (1)$$

where $<$ (read “before”) is the execution order.

Consider two iterations \vec{i} and \vec{j} of some loop nest, and two accesses to the same array, $A[f(\vec{i})]$ and $A[g(\vec{j})]$, one of them at least being a write. f and g are subscript functions, which relate subscripts to the surrounding iteration vectors. To be in dependence, the two iterations must satisfy the following conditions:

- They must access the same array cell: $f(\vec{i}) = g(\vec{j})$.
- They must be legal iterations, that is, each loop counter must be within the corresponding loop bounds, which define the *iteration domains* of the operations.
- The direction of the dependence is given by the execution order $\vec{i} < \vec{j}$.

For programs that fit in the polyhedral model, the subscript equations and the iteration domain constraints are conjunctions of affine equalities or inequalities. According to (1), the ordering constraint can be split in several conjunctions. Hence, the set of iterations in dependence is the union of several disjoint *dependence polyhedra*. Each polyhedron is characterized by the number of equations at the begining of the execution order, the so-called dependence depth, which goes from 0 to the number of loops that enclose both array references. For some authors, the dependence depth (or level) starts at 1 and goes up to infinity. The notation $\vec{i} \delta_p \vec{j}$ is commonly used to state that there is a dependence from iteration \vec{i} to \vec{j} at depth p , that is, the first p coordinates of \vec{i} and \vec{j} are equal.

For more general programs, one has to resort to approximations: a constraint is omitted or approximated if not affine. This has the effect of enlarging the dependence polyhedra, and hence reducing the amount

of parallelism. However, the correctness of the generated program is still guaranteed.

When a program uses pointers, the computation of dependences becomes much more difficult. The reason is that, depending on the source language, a pointer can point anywhere in memory, and that it is very difficult to decide whether two pointers point to the same memory cell. The best that can be done is to associate to each pointer (conservatively) a region in memory, and to decide a dependence when two regions intersect.

Classification

While in Bernstein's conditions the two operations play the same role, the symmetry is broken as soon as the direction of the dependence is taken into account. One usually distinguishes:

- Flow dependences (or true dependences, or Producer/Consumer dependences [PC], or Read after Write hazards [RAW]), in which the write to a memory cell occurs before the read.
- Output dependences (or PP dependences, or WAW hazards) in which both accesses are writes.
- Anti-dependences (or CP dependences, or WAR hazards) in which the read occurs before the write.
- In some contexts (e.g., when discussing program locality), one may consider Consumer/Consumer dependences, which do not constrain parallelization.

If the objective is just to decide which operations can be executed in parallel, all three kinds are equivalent. Differences appear as soon as one considers modifying the source code for increased parallelism. It is easy to see that in a flow dependence, a value which is computed by the first operation is reused later by the second operation. Hence, a flow dependence corresponds to the naming of an intermediate result, is intrinsic to the code algorithm, and cannot be removed except by modifying it. In contrast, an output dependence simply indicates that a memory cell is reused when the value it holds becomes useless. Such a dependence can be removed simply by using two distinct cells for the two values. Lastly, in a correct program, where all memory cells are defined before being used, removing output dependences has the side effect of removing anti-dependences.

It can even be shown that some of the flow dependences are spurious. Let us consider a memory cell and an operation v that reads it. There may be many writes to this cell. Intuitively, the only one on which v really depends is the last one u which is executed before v . The dependence from u to v is a *direct dependence*. If the source program is sufficiently regular, direct dependences can be computed using linear programming tools [5]. It is, however, difficult to find conservative approximations for more general programs.

Dependence Tests

Early automatic parallelizers were concerned only with the existence or nonexistence of dependences. For instance, to decide that a loop is parallel, one has only to show that there are no dependences between its iterations, that is, all related dependence polyhedra are empty.

Since dependences occur between a pair of statements, it follows that the number of dependences increases more or less as the square of the size of the program. Hence, the scientists of the 1970s initiated a quest for fast but approximate *dependence tests*. One may, for instance, observe that some of the dependence constraints are linear equations whose unknowns, the loop counters, are integers. Such an equation can have solutions only if the gcd of the unknown's coefficients divides the constant term. This observation is the basis of the very fast *gcd test*.

The Banerjee test [2] is based on the observation that in many cases, when solving an equation $f(x) = 0$, one knows a lower bound a and an upper bound b for x , which come, most of the time, from loop bounds. Now, the equation has solutions only if $f(a)$ and $f(b)$ are of opposite signs. The approximation comes from the observation that the eventual solution is not necessarily integral, hence the idea of coupling the gcd and Banerjee test, for increased precision. This idea can be extended in the following way: the inequalities of the problem dictate that x belongs to some polyhedron, and the condition for the existence of a solution is that the maximum of f over this polyhedron be positive, and the minimum be negative. Now the extrema of an affine function over a polyhedron are located at some of its vertices. Hence, one has only to test the sign of f at a finite set of points. This is especially efficient if the vertices are in evidence.

Many other tests were invented with the aim of handling systems of equations instead of a single equation. For instance, in the Lambda test [10] the Banerjee test is applied to well chosen linear combinations of equations. If the answer is negative, then the original system has no solution.

However, it was realized around 1990 that the question of the emptiness of the dependence polyhedron can be solved using classical linear programming algorithms. This approach was originally deemed too costly, but with improved algorithms and a 1,000-fold increase in processing power (Moore's law), the argument has lost its strength.

One possibility is to use the Fourier–Motzkin algorithm [12], in which the unknowns of the problem are eliminated by combining the inequalities that define the dependence polyhedron, until one obtains numerical inequalities, which can be decided by inspection. Programming the Fourier–Motzkin algorithm is quite simple, but its complexity is doubly exponential, which is not critical since dependence testing problems are usually small. The standard Fourier–Motzkin algorithm finds rational solutions or proves that none exists. An extension, the Omega test [11], considers only integral solutions. Other extensions are the I test [8] and the Power test [13].

Another possibility is to use the Simplex algorithm, which is more complex, but which runs most often in time proportional to the third power of the number of inequalities, and hence scales better for large problems. The algorithm can also be extended to the integer case using Gomory cuts, and can even solve parametric problems [4].

Dependence Approximations

Early parallelization algorithms (e.g., deciding if a loop has parallelism) did not need a precise knowledge of dependence polyhedra. Just testing them for emptiness was enough. As the sophistication of parallelization algorithms increased, more precise descriptions of dependences were needed. All such approximations can be described as supersets of dependence polyhedra. On the relations between dependence approximations and program transformations, see [14].

The simplest approximation consists in ignoring the fact that iteration vectors have integer components. When testing a transformed program for legality, this

may generate false negatives. However, this occurs sufficiently seldom that it is usually ignored.

Dependence Depth

The dependence depth abstraction is a natural byproduct of the decomposition of the lexical order into disjoint polyhedra as in (1). One simply has to record at which depth a dependence occurs, instead of taking the disjunction of the test results for several depths. Knowledge of the dependence depth allows one to decide, in a loop nest, which loop must be kept sequential and which one can be executed in parallel. This information is necessary for the Allen and Kennedy algorithm, which uses loop splitting to find more parallel loops.

Dependence Distances

The dependence distance is the difference between the iteration vectors of two dependent operations. One can define a *distance polyhedron* as:

$$D = \{\vec{d} \mid \exists \vec{i}, \vec{j} : \vec{i} \delta_p \vec{j}, \vec{d} = \vec{j} - \vec{i}\}.$$

A projection algorithm is needed to eliminate the existential quantifiers: one may use the Omega test or parametric integer programming. Observe also that the dependence distance is always lexicopositive.

Computing the distance polyhedron is especially interesting when it reduces to a single constant vector. One says in that case that the dependence is uniform. Many parallelization algorithms are especially simple when the source program has only uniform dependences.

Dependence Direction Vectors

In the presence of nonuniform dependences, one may further abstract the distance polyhedron by considering only the signs of the components of the distance vectors. The components of a Dependence Direction Vector (DDV) are either integers (meaning that the component is constant) or one of the symbols $<$, $>$, \geq , \leq (meaning that the component has the corresponding sign) or $*$, meaning that the component may have an arbitrary sign. DDVs are usually computed by adding the corresponding constraint to the definition of the dependence polyhedron and testing for feasibility. While simpler to compute than the distance polyhedron, DDVs give enough information to check the legality of some transformations, like loop permutation.

Dependence Cones

The dependence cone is simply the cone generated by the dependence distance vectors. The simplest way of computing the dependence cone is to compute first the vertices of the distance polyhedron, d_1, \dots, d_n . The dependence cone is then:

$$C = \left\{ \sum_{k=1}^n \lambda_k d_k \mid \lambda_k \geq 0 \right\}.$$

Knowledge of the dependence cone is especially useful when tiling a loop nest.

Bibliographic Notes and Further Readings

There is a large literature on pointer analysis, which may be useful for program parallelization, albeit its orientation is more toward program verification and safety. A good starting point is [7] (110 references!).

For an attempt at parallelization of recursive programs, see [1].

Definition

Determinacy refers to the property of repeatability. A parallel program is determinate, if all feasible executions of the program, when started on the same input, generate the same result.

Likewise, the result of a non-determinate parallel program can vary for different executions, depending on the timing of different threads. The reason for non-determinacy are race conditions.

Discussion

Introduction

This entry discusses the concept of determinacy in the context of parallel programming. The examples and classification of different kinds of determinacy are adopted from Emrath and Padua [6, Sect. 2]. The discussion focuses on explicitly parallel programs with threads that share memory, although the concepts of determinacy can be generalized to other parallel programming models.

Sequential programs are naturally determinate (Exceptions exist, namely languages that offer a choice operator, where the choice of program-flow is not directly specified by the programmer but chosen by the run-time system; such methods are, for example, embodied in backtracking systems.) If parallel programming is used to accelerate the performance of a sequential program without intention of changing the functional behavior, determinacy is a correctness requirement. In general, however, determinacy is neither a sufficient nor a necessary condition for the correctness of a parallel program.

The determinacy of a program can depend on the program input. An example is given in Fig. 1.

External Determinacy

Determinacy that refers to the repeatability of input-output behavior is called *external determinacy*.

```
int i = read()
if (i != 0)
    cobegin
        i = 1 ||
        i = 2
    coend
endif
print(i)
```

Determinacy. Fig. 1 Determinacy of this program is input-dependent: On input 0, the program will always output 0; for other inputs, the program is non-determinate and may output 1 or 2. The reason for the non-determinacy is the data race among the write accesses to variable *i* in the parallel block

Internal Determinacy

A parallel program is called *internally determinate* if the sequence of intermediate values taken by each shared location is the same in all executions. Figure 2 gives an example.

The notion of *internal determinacy* is stronger than external determinacy, since not only final values but also intermediary values of shared variables are considered. Naturally, programs that are internally determinate are also *externally determinate*.

Internal determinacy does not imply that the overall shared state of the program is transformed in a predetermined sequence. It may well be that some executions of the example program in Fig. 2 initialize variables at lower indices first, while other executions initialize variables in some other order.

Internal determinacy is however not required to achieve *external determinacy*. Figure 3 gives an example.

The internal non-determinacy in Fig. 3 is due to the race conditions among concurrent iterations of the second loop when accessing the critical section. The order in which different iterations enter the critical section is

```
int[] arr = new arr[N]
doall (i <- 0 to N-1)
    arr[i] = i + 1
enddoall
```

Determinacy. Fig. 2 Internal determinacy: The sequence of states for each shared variable *arr[i]* is the same in all executions, that is, irrespective of the timing of parallel iterations. Every execution transits the state of location *arr[i]* from its initial value to value *i+1*

```
int[] arr = new arr[N]
int sum = 0
doall (i <- 0 to N-1)
    arr[i] = i + 1
enddoall
doall (i <- 0 to N-1)
    critical
        sum += arr[i]
    endcritical
enddoall
```

Determinacy. Fig. 3 External determinacy but internal non-determinacy: The sequence of intermediate values of variable *sum* can differ in different executions. However, the final value of all shared variables is always the same

not predetermined. There is no data race however, since simultaneous updates of variable *sum* cannot occur.

External determinacy arises here, since the integer addition performed on the shared integer variable *sum* is commutative and associative.

Benefits: Internal non-determinacy can be exploited to accelerate parallel collective reduction and scan operations [10].

Debugging: Internal non-determinacy complicates debugging since a programmer may observe different sequences of operations and intermediate values of shared variables in different program executions.

Associative Non-Determinacy

A computer represents real numbers typically as floating point values with limited precision. Unlike their mathematical counterpart, operations such as addition may not be generally associative and distributive on the floating point representations.

The program in Fig. 4 seems similar to the programs in Fig. 3: It is internally non-determinate, since the *sum* is computed in some order that is not specified a priori by the program. This program is however not *externally determinate*, since the add operation is computed on the floating point, not the integer domain. The result of this computation may vary slightly across different runs. For some applications, this deviation and thus the external non-determinacy may be acceptable, hence the program could be considered correct.

External non-determinacy that is solely due to the lack of associativity and commutativity of floating point operations is called *associative non-determinacy*.

```
int N = 100000
double sum = 0
doall (i <- 0 to N)
    critical
        sum += 1.0/i
    endcritical
enddoall
```

Determinacy. Fig. 4 Associative non-determinacy: The final value of variable *sum* can vary slightly in different executions due to the non-associativity of floating point numbers

Complete Non-Determinacy

External non-determinacy may occur for reasons other than the special case of associative non-determinacy discussed in the previous paragraph. Programs with such form of external non-determinacy are called *completely non-determinate*.

When executed on a given input, the final state of a completely non-determinate program depends on the timing of threads and their operations on shared variables. An example for such a program is given in Fig. 5.

The non-determinacy is due to a race condition among the write operation to variable *j* in different loop iterations. In this particular case, the race condition is a *data race*, since there could be executions with simultaneous write accesses. But the kind of race is immaterial here. If even the execution of write operations were ordered due to a critical section, the precise order is unspecified in the program and thus the program is *completely non-determinate*.

Analysis of Non-Determinacy

Non-determinacy is caused by race conditions. Hence, tools for race detection are used to analyze cases of non-determinacy. When tool are specialized on the detection of *data races*, they will not be successful to identify causes of non-determinacy since general races that are not data races can also cause non-determinacy.

Determinacy in Other Parallel Programming Models

Non-determinacy may be introduced in any explicitly parallel programming model that is susceptible to race conditions. Besides multithreading with shared memory, these are, for example, task-based programming models such as Intel TBB [4] and also message-passing models such as MPI [7].

```
int N = 100000
int j = 0
doall (i <- 0 to N)
    j = i
enddoall
print(j)
```

Determinacy. Fig. 5 Program that is completely non-determinate

Determinate Parallel Programs

Parallel programs that are completely non-determinate are rarely useful in practice. Hence, programming model have been designed that prevent or at least reduce the risk of creating a parallel programs with undesired non-determinacy.

Autoparallelization: Starting point is a sequential program from which a parallel form is derived automatically. The resulting parallel programs are typically externally determinate.

Autoparallelization may involve the reordering of arithmetic operations. The associativity of arithmetic operations is defined in the language report; in particular, floating point operations may be non-associative. The user of a parallelization tool can typically configure if the parallelization should comply with the non-associativity for floating point operations or if such operations may be reordered. The latter may lead to programs with associative non-determinacy.

Speculative parallelization: Similar to autoparallelization, speculative parallelization avoids non-determinacy by design, however not at compile time, but at run time. A run-time system with support for speculative parallelization detects harmful race condition, and hence sources of non-determinacy [11]. When a possible violation of determinacy is detected, the results of the speculative parallel execution are discarded, followed by a re-execution. An example for a determinate programming model based on speculative parallelization is given in [14].

Programming languages for asynchronous parallel computations: Some parallel programming models are designed to limit the space of permissible programs to deterministic ones. Examples are Kahn Networks [8] and an experimental programming language described by Steele [13]. The key idea of the latter language is to limit the available forms of asynchrony and at the same time to restrict the side effects that each asynchronous computation can have on shared memory. Different models for the validation of side effects are feasible, ranging from purely dynamic to static analysis. Unintended non-determinacy due to race conditions is one of the most frequent errors in parallel programs. Thus, a language-enforced programming discipline to avoid non-determinacy seems to be useful. However, such determinate parallel programming models have not

yet been adopted widely. Possible reasons are that the models restrict the solution space too much, such that common algorithmic or parallel programming idioms cannot be expressed. Moreover, the performance impact due to run-time checking for forbidden side effects is deemed too high or not well understood.

Determinate Parallel Execution

Deterministic replay: *Deterministic replay* is a debugging aid and controlled run-time environment that enables repeating a particular parallel program execution of an otherwise non-determinate parallel program. A debugging methodology for data races using deterministic replay was first conceived and formalized by Choi and Min [3, Sect. 2.4]. They prove that an iterative debugging process of data race detection and replay will result eventually in a program execution that is data-race-free. The process requires a data race detection tool with the following property: If an execution has data races, the tool reports some but not necessarily all races.

Systems that support *deterministic replay*, operate in two phases: First, the *recording phase*, where program input and the synchronization order of a parallel program execution are memorized. Second, the *replay phase*, where recorded information is used by a controlled run-time environment to reproduce the original program execution.

The original and the replayed executions typically correspond to each other at least according to the requirements of internal determinacy, that is, the sequence of values taken by individual variables must be the same in both executions. Such guarantee is typically given by software-based implementations, for example [2]. Some systems are able to maintain a global order of all updates, which is an even stronger notion of correspondence among executions [9].

Computer architectures for determinate parallelism: Recently, computer architectures [5] have been proposed that constrain the possible execution schedules at the level of individual memory operations, or groups of memory operations called chunks. Constraints are such that inter-processor communication becomes determinate. At a programming level, this means, for example, that the order in which a lock is taken by different processors is the same in different executions. Since this architecture permits only one execution timing, it lets

any parallel program, determinate or not, execute in a determinate manner.

Checking Determinacy

Determinacy can be asserted at run time, by validating that an execution is free from race conditions. The property of race freedom is however too strong to be useful, since many correct parallel programs with internal non-determinacy would be flagged as erroneous. Hence, checking determinacy means checking external determinacy while allowing internal non-determinacy.

Burnim and Sen [1] developed a set of program annotations, called *bridge assertions*, to mark blocks of code that should behave externally determinate. These assertions validate external determinacy by relating the functional behavior of such block with observations from previous executions of the same block. The method is capable to describe associative non-determinacy.

An alternative technique is proposed by Sadowsky et al. [12]. Their run-time checker verifies the absence of interference while allowing race conditions due to certain synchronization idioms that are known to preserve determinacy. As in [1], code blocks for which (external) determinacy should be validated have to be specified explicitly.

Deterministic Parallel Java

ROBERT L. BOCCINO, JR.

Carnegie Mellon University, Pittsburgh, PA, USA

Synonyms

DPJ

Definition

Deterministic Parallel Java (DPJ) is a parallel programming language based on Java and developed at the University of Illinois at Urbana-Champaign. DPJ uses a type and effect system to provide deterministic-by-default semantics. “Deterministic” means that for a particular input, a given program always produces the same output, regardless of the parallel schedule chosen. “By default” means that the program is deterministic unless the programmer explicitly requests nondeterministic behavior. DPJ guarantees this semantics at compile time for the programs it can express.

Discussion

Introduction

Many parallel programs are intended to have deterministic behavior. Typically, these programs are *transformative*: they accept some input, do a computation in memory, and produce some output, in contrast to programs such as servers that accept input throughout the computation. There are many examples of deterministic programs in domains such as scientific computing, graphics, multimedia, and artificial intelligence.

A programming model that can guarantee deterministic behavior for such programs has many advantages. Parallel programs become easier to reason about, because a key source of complexity (nondeterministic parallel schedules) has been removed, along with attendant difficulties such as unwanted data races and complex memory models. Testing and debugging are easier because, as in the sequential case, it suffices to test only one schedule per input.

Well-known programming models that guarantee determinism include dataflow, data parallel, and pure functional programming. While these models have the advantages described above, they are restrictive

in that they disallow sharing of mutable data through references. In contrast, widely used imperative languages such as Java that support references to mutable data typically provide no guarantee that a parallel program is deterministic or even race-free.

Deterministic Parallel Java (DPJ) is a Java-based programming language that provides deterministic-by-default semantics for parallel programs, while supporting references to mutable objects. The key feature of DPJ that allows this guarantee is a *type and effect system* that expresses what parts of memory are read and written by different parts of the program, so that parallel tasks can be checked for noninterference. DPJ has first-class support for a fork-join style of parallelism. Specifically, it includes a `foreach` statement for parallel loops and a `cobegin` block for parallel statements, most often used to express parallel recursion. Object-oriented frameworks, discussed below, provide a way to express other forms of parallel control.

The DPJ Effect System

The DPJ effect system [5] allows the programmer to partition the heap into *regions*, and to provide *method effect summaries* stating the effects of methods in terms of accesses (reads and writes) to those regions. The compiler uses simple, intraprocedural analysis to check two things:

1. *Correctness of method summaries.* Every method effect summary includes all the actual effects of the method it summarizes, as well as the effects of any methods overriding that method.
2. *Noninterference.* Any two memory accesses, one from each of two tasks that may run in parallel, do not conflict (i.e., they are both reads, or they operate on disjoint memory).

The programmer can omit the region and effect annotations for sequential code (an ordinary sequential Java program is a correct DPJ program) but must add the annotations to code that is executed in a parallel task.

Regions and Effects

[Figure 1](#) gives a simple example showing the use of regions and effects in DPJ. Line 2 declares region names `First` and `Second`. Lines 3 and 4 place instance fields `first` and `second` in regions `First` and `Second`. The

```

class Pair {
    region First, Second;
    int first in First;
    int second in Second;
    void setFirst(int first) writes First {
        this.first = first;
    }
    void setSecond(int second) writes Second {
        this.second = second;
    }
    void setBoth(int first, int second) {
        cobegin {
            setFirst(first); /* writes First */
            setSecond(second); /* writes Second */
        }
    }
}

```

Deterministic Parallel Java. Fig. 1 Regions and effects in DPJ (DPJ additions to Java are highlighted in bold)

region names have static scope, for example, all `first` fields in any instance of the `Pair` class reside in the same region `Pair.First`. (DPJ uses *region parameters*, explained below, to assign different regions to different object instances.) DPJ also provides *local regions* (declared within a method scope) for expressing effects on objects that do not escape the method.

Lines 5 and 8 illustrate the use of method effect summaries. The summary `writes First` in line 5 states that method `setFirst` writes region `First`, and similarly for `writes Second` in line 8. In general, a method effect summary has the form `reads region-list writes region-list`. If a method has no effect on the heap, it may be annotated `pure`. A method effect summary may be omitted entirely (as in line 11); in this case the compiler infers the most conservative effect (“writes the entire heap”) for the method. This default is generally used only for methods that are never called inside parallel tasks, so it is not important to know their precise effects.

A few simple rules govern the use of method effect summaries. First, all the actual effects of the method must be present in the summary. For example, the only heap effect in the body of `setFirst` is the write to field `first` in line 6, so the summary is correct. If the effect in line 5 were `pure`, the compiler would issue an error. (Line 6 also reads the method parameter `first`. However, method parameters and other local variables

in Java cannot have their addresses taken and never alias. Therefore, effects on such variables are handled automatically by the compiler and are ignored by the programmer-visible effect system.) Second, the summary may be conservative, that is, it may specify more effects than the method actually has. In particular, write effects subsume read effects, so it is permissible (but conservative) to say `writes R` in the summary when the method only reads region `R`. Finally, the effects of an overridden method must include the effects of any overriding method. This rule is similar to how plain Java handles `throws` clauses; it ensures sound reasoning about effects in the presence of polymorphic method dispatch.

Lines 12–15 illustrate the expression of deterministic parallelism. The `cobegin` block (line 12) says to execute each component statement in parallel. The compiler accumulates the effect of each component statement and checks that the effects are pairwise noninterfering. Here, the effect of invoking `setFirst` in line 13 is `writes First` (from the definition of method `setFirst` in line 5); and similarly the effect in line 14 is `writes Second`. Because `First` and `Second` are distinct names, the writes are to disjoint regions, so they are noninterfering. If the effects in lines 13 and 14 were interfering (e.g., they both wrote to the same region), then the compiler would issue a warning.

Region Parameters

DPJ allows classes and methods to be written with *region parameters* that become bound to actual regions when the class is instantiated into a type, or the method is invoked. Figure 2 illustrates the use of class region parameters. Line 1 declares a class `SimpleTree` with one region parameter `P`. Region parameter declarations coexist with Java generic type parameters and use a similar syntax; the keyword `region` distinguishes region parameters from type parameters. Line 3 places the instance field `data` in region `P`. When the class `SimpleTree` is instantiated with a type, and an object of that type is created with `new`, the type specifies the actual region of the storage for `data`, as illustrated in lines 4–5.

The compiler computes effects on fields by using the region specified in the class, after substituting actual regions for formal region parameters. This is illustrated

in lines 8–9. The effect of line 8 is `writes Left`, as shown, because the write is to field `left.data`. Line 3 says that `data` is in region `P`, and line 4 says that the type of `left` has `P = Left`. (There is also a read of field `left` in region `Left`, but this read is subsumed by the effect `writes Left`.) Similarly, the effect of line 9 is `writes Right`. Because `Left` and `Right` are distinct regions, the `cobegin` statement in lines 7–10 is legal. The DPJ type system ensures that this kind of reasoning is sound: for example, it is a type error to attempt to assign a reference of type `SimpleTree<Left>` to a variable of type `SimpleTree<Right>`.

Region parameters can have *disjointness constraints*. For example, `<region P1, P2 | P1 # P2>` declares two parameters `P1` and `P2` and constrains them to be disjoint. The compiler uses the constraint to check noninterference in parallel code that uses the parameters. If the disjointness constraint is not satisfied by the actual region arguments at the point where a class is instantiated or a method is invoked, the compiler issues a warning.

Region Path Lists (RPLs) and Nested Effects

In deterministic parallel computations, it is often essential to express a *nesting* relationship among regions. For example, to do a parallel update traversal on a binary tree, one must specify effects on “the left subtree” or “the right subtree.” A natural way to do this is to put a nesting structure on the regions that mirrors the nesting structure of the tree. DPJ represents this kind of nesting structure using *region path lists*, or RPLs.

An RPL is a colon-separated list of names beginning with `Root`, such as `Root:Left:Right`. RPLs naturally form a tree, where the RPL specifies the path in the tree from the root to the node that it represents. For example, `Root:Left:Right` is a child of `Root:Left`. In the execution semantics of DPJ, every region is represented as an RPL; a bare region name like `Left` is equivalent to `Root:Left`. RPLs may be *partially specified* by using `*` to stand in for any sequence of zero or more names, for example, `Root:*:Left` or `Root:Left:*`. This is useful in specifying *sets of regions* in types and effects.

[Figure 3](#) illustrates the use of RPLs to write a tree that can be traversed in parallel to update its elements. The key feature that makes this work is a *parameterized*

```
class Tree<region P> {
    region Left, Right;
    int data in P;
    Tree<P:Left> left in P:Left;
    Tree<P:Right> right in P:Right;
    int increment() writes P:*
    {
        ++data; /* writes P */
        cobegin {
            /* writes P:Left: */
            if (left != null) left.increment();
            /* writes P:Right: */
            if (right != null) right.increment();
        }
    }
}
```

Deterministic Parallel Java. [Fig. 3](#) A tree class

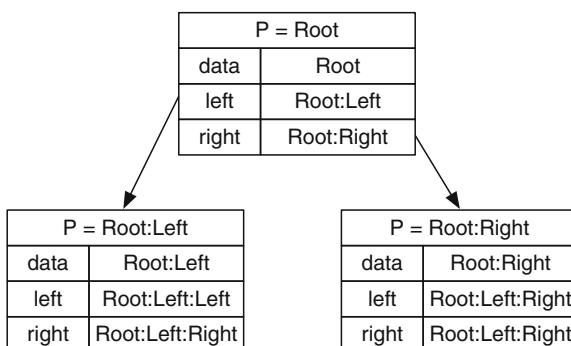

```
class SimpleTree<region P> {
    region Left, Right
    int data in P;
    SimpleTree<Left> left in Left = new SimpleTree<Left>();
    SimpleTree<Right> right in Right = new SimpleTree<Right>();
    void updateChildren(int leftData, int rightData) {
        cobegin {
            left.data = leftData; /* writes Left */
            right.data = rightData; /* writes Right */
        }
    }
}
```

Deterministic Parallel Java. [Fig. 2](#) Class region parameters

RPL: an RPL can begin with a parameter P , as shown in lines 4–5. In the execution semantics, the parameters are erased via left recursive substitution. [Figure 4](#) illustrates this procedure for the root node of a tree, and its two children. Each node of the tree has its `data` field in a distinct region, the RPL of which reflects the position of the node in the tree. Further, the DPJ type system enforces this structure: for example, it would be illegal to assign the right child to the `left` field of the root, because the types do not match.

Lines 6–14 show how to write an increment method that traverses the tree recursively in parallel and updates the data fields of the nodes. In line 6, the summary writes $P:\ast$ says that the method writes P and all regions under P . The effect of line 7 is writes P , because field `data` is declared in region P (line 3). Line 10 generates two effects: a read of $P:\text{Left}$ due to the read of field `left`, and a write to $P:\text{Left}:\ast$ obtained from the effect summary of the recursively invoked method `increment`, after substituting $P = P:\text{Left}$ from the type of `left`. Because writes subsume reads, both effects may be summarized as writes $P:\text{Left}:\ast$, as shown in line 9. Similarly, the effect of line 12 is writes $P:\text{Right}:\ast$.

As described above, the compiler has to check two things: first, that the method summary is correct; and second, that the statements inside the `cobegin` (line 8) are noninterfering. The first check passes, because all the statement effects are included in the effect writes $P:\ast$ stated in the summary in line 6. As to the second check, the effects of the two statements in the `cobegin` are writes $P:\text{Left}:\ast$ and writes $P:\text{Right}:\ast$. Because of the tree structure of

Deterministic Parallel Java. [Fig. 4](#) Runtime representation of the tree

RPLs, these two effects are on disjoint sets of regions for any common binding to P . Therefore the effects are noninterfering, so this check passes as well.

Arrays

The RPL mechanism is useful for trees, as shown above. It also supports two common patterns of parallel computation on arrays that are not well handled by previous type and effect systems: parallel updates of objects through arrays of references and divide-and-conquer updates to arrays.

Parallel updates of objects through arrays of references. DPJ supports this pattern with two features. First, an RPL may include an element $[e]$, where e is an integer expression, representing cell e of an array. This is called an *array RPL element*. Second, the region in the type of an array cell may be parameterized by the index of the cell. This is called an *index-parameterized array*. Together, these features allow the programmer to specify an array of references such that the object pointed to by each reference is instantiated with a distinct region.

[Figure 5](#) shows an example. The class `Body` has one region parameter P and a field `force` in region P . The instance method `computeForce` computes a force and writes it into `force`. The static method `computeForces` takes an array of bodies and iterates over it in parallel, calling `computeForce` on each body. The type of `bodies`, shown in line 7, is an index-parameterized array type. The `#i` declares a fresh variable i in scope over the whole array type. The element type `Body<[i]>` says that for any natural number n , the array element at index n is a reference of type `Body<Root: [n]>`.

[Figure 6](#) shows how the array might look at runtime. The assignment rules in the DPJ type system ensure that the types are correct: for instance `bodies[10]` must point to an object of type `Body<Root: [10]>`. Therefore, all the `force` fields are in distinct regions, and the parallel updates in line 10 of [Fig. 5](#) are noninterfering.

Divide-and-conquer updates to arrays. To support this pattern, DPJ allows *dynamic array partitioning*: an array may be divided into two (or more) disjoint parts that are updated in parallel. [Figure 8](#) illustrates how this works for a simple version of quicksort. The `quicksort` method (line 2) has a region parameter P and takes a `DPJArray<P>`, which points into a contiguous subset of a Java array. In lines 6–7, the array is

```

class Body<region P> {
    double force in P;
    void computeForce() reads Root writes P {
        ...
    }
    static void
    computeForces(Body<i>[]#i bodies) {
        foreach (int i in 0, bodies.length) {
            /* reads Root writes Root:[i] */
            bodies[i].computeForce();
        }
    }
}

```

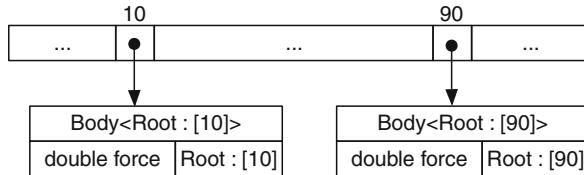

Deterministic Parallel Java. Fig. 5 Code using an index-parameterized array

```

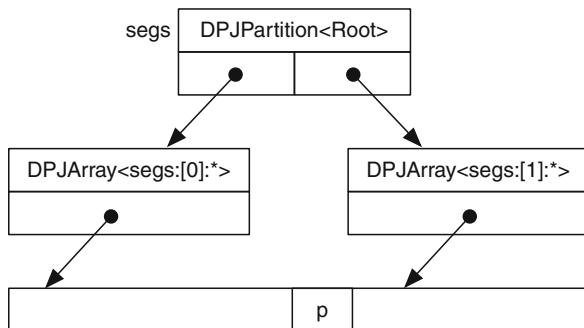

static <region P>
void quicksort(DPJArray<P> A) writes P::* {
    /* Ordinary quicksort partition */
    int p = quicksortPartition(A);
    /* Split array int two disjoint pieces */
    final DPJPartition<P> segs =
        new DPJPartition<P>(A, p);
    cobegin {
        /* writes segs:[0]:* */
        quicksort(segs.get(0));
        /* writes segs:[1]:* */
        quicksort(segs.get(1));
    }
}

```

Deterministic Parallel Java. Fig. 8 Parallel quicksort

Deterministic Parallel Java. Fig. 6 Runtime representation of the index-parameterized array

Deterministic Parallel Java. Fig. 7 Runtime representation of the dynamically partitioned array

split at index p , creating a $DPJPartition$ object holding references to two disjoint subarrays. The $cobegin$ in lines 8–13 calls $quicksort$ recursively on these two subarrays.

Figure 7 shows what this partitioning looks like at runtime, for the root of the tree and its children. A

$DPJPartition$ object referred to by the final local variable $segs$ points to two $DPJArray$ objects, each of which points to a segment of the original array. The $DPJArray$ objects are instantiated with *owner RPLs* $segs:[0]:*$ and $segs:[1]:*$ in their types. An owner RPL is like an RPL, except that it begins with a final local reference variable instead of $Root$. This allows different partitions of the same array to be represented. Again because of the tree structure of DPJ regions, $segs:[0]:*$ and $segs:[1]:*$ are disjoint region sets, and so the effects in lines 9 and 11 are noninterfering. Also, as in ownership type systems, region $segs$ is under the region P bound to the first parameter of its type, so the effect summary $writes P:*$ in line 2 covers the effects of the method body.

Commutativity Annotations

Sometimes, a parallel computation is deterministic, even if it has interfering reads and writes. For example, two inserts to a concurrent set can go in either order, and preserve determinism, even though there are interfering writes to the set object. DPJ supports this kind of computation with a *commutativity annotation* on methods (typically API methods for a concurrent data structure). For example:

```

interface Set<type T, region R> {
    commutative void add(T e) writes R;
}

```

This annotation is provided by a library or framework programmer and trusted by the compiler (it is not checked by the DPJ effect system). It means that `cobegin { add(e1); add(e2); }` is equivalent to doing the `add` operations in sequence (isolation) *and* that both sequence orders are equivalent (commutativity).

When the compiler encounters a method invocation, it generates an *invocation effect* that records both the method that was invoked, and the read-write effects of that method:

```
foreach (int i in 0, n) {
    /* invokes Set.add with writes R */
    set.add(A[i]);
}
```

The compiler uses the commutativity annotations to check interference of effect. For example, the effect `invokes Set.add with writes R` is noninterfering with itself (because `add` is declared commutative). However, the same effect interferes with `invokes Set.size with reads R`.

Expressivity and Limitations

DPJ can express a wide variety of algorithms that use a fork-join style of parallelism and access data through a combination of (1) read-only sharing; (2) disjoint updates to arrays and trees; (3) commutative operations on concurrent data structures like sets and maps; and (4) accesses to task-private heap objects. DPJ has been used to write the following parallel algorithms, among others: IDEA encryption, sorting, k-means clustering, an n-body force computation, collision detection algorithm from a game engine, and a Monte Carlo financial simulation. The main advantages of the DPJ approach are (1) a compile-time guarantee of determinism in all executions; and (2) no overhead from checking determinism at runtime, as the region information is erased before parallel code generation. Further, the effect annotations provide checkable documentation and enable modular analysis, and the defaults allow incremental transformation of sequential to parallel programs.

DPJ does have some limitations. One limitation, mentioned above, is that currently only fork-join parallelism can be expressed. A second limitation is that

to ensure soundness, the language disallows some patterns that are in fact deterministic, but cannot be proved deterministic by the type system. One example is that the type system disallows reshuffling of the elements in an index-parameterized array. This limitation poses a problem for the Barnes-Hut n-body force computation, as rearranging the array of bodies is required for good locality. A workaround for this limitation is to recopy the bodies on reinsertion into the array, but this is somewhat clumsy and could degrade performance. A third limitation is that some programmer effort is required to write the DPJ annotations, although this effort is repaid by the benefits discussed above.

D

Ongoing Work

The foregoing describes the state of the public release of DPJ as of October 2010. The following subsections describe ongoing work that is expected to be part of future releases.

Controlled Nondeterminism

DPJ is being extended to support controlled nondeterminism [6], for algorithms such as branch and bound search, where several correct answers are equally acceptable, and it would unduly constrain the schedule to require the same answer on every execution. The key new language features for controlled nondeterminism are (1) `foreach_nd` and `cobegin_nd` statements that operate like `foreach` and `cobegin`, except they allow interference among their parallel tasks; (2) `atomic` statements supported by software transactional memory (STM); and (3) *atomic regions* and *atomic effects* for reasoning about which memory regions may have interfering effects, and where effects occur inside `atomic` statements.

Together, these features provide several strong guarantees for nondeterministic programs. First, the extended language is *deterministic by default*: the program is guaranteed to be deterministic *unless* the programmer explicitly introduces nondeterminism with `foreach_nd` or `cobegin_nd`. Second, the extended language provides both strong isolation (i.e., the program behaves as if it is a sequential interleaving of `atomic` statements and unguarded memory accesses) and data race freedom. This is true even if

the underlying STM provides only weak isolation (i.e., it allows interleavings between unguarded accesses and `atomic` statements). Third, `foreach` and `cobegin` are guaranteed to behave as isolated statements (as if they are enclosed in an `atomic` statement), even inside a `foreach_nd` or `cobegin_nd`. Finally, the extended type and effect system allows the compiler to boost the STM performance by removing unnecessary synchronization for memory accesses that can never cause interference.

Object-Oriented Parallel Frameworks

DPJ is being extended to support object-oriented parallel frameworks. Current support focuses on two kinds of frameworks: (1) collection frameworks like Java’s `ParallelArray` [1] that provide parallel operations such as `map`, `reduce`, `filter`, and `scan` on their elements via user-defined methods; and (2) a framework for pipeline parallelism, similar to the pipeline framework in Intel’s Threading Building Blocks [11]. The key challenge is to prevent the user’s methods from causing interference when invoked by the parallel framework. For example, a user-defined `map` function must not do an unsynchronized write to a global variable. The OO framework support incorporates several extensions to the DPJ type and effect system for expressing generic types and effects in framework APIs, with appropriate constraints on the effects of user-defined methods.

Frameworks represent one possible solution to the problem of array reshuffling and other operations that the type system cannot express. Such operations can be encapsulated in a framework. The type and effect system can then check the *uses* of the framework, while the framework *internals* are checked by more flexible (but more complex and/or weaker) methods such as program logic or testing. This approach separates concerns between framework designer and user, and it fosters modular checking. It also enables different forms of verification with different trade-offs in complexity and power to work together. In addition, frameworks provide a natural way to extend the fork-join model of DPJ by adding other parallel control abstractions, including finer-grain synchronization (e.g., pipelined loops) or domain-specific abstractions (e.g., kd-tree querying and sparse matrix computations).

Inferring DPJ Annotations

Research is underway to develop an interactive tool that helps the user write DPJ programs by partially inferring annotations. A tool called DPJizer has been developed [14] that uses interprocedural constraint solving to infer method effect summaries for DPJ programs annotated with the other type, region, and effect information. DPJizer simplifies DPJ development by automating one of the more tedious, yet straightforward, aspects of writing DPJ annotations. The tool also reports the effect of each program statement, helping the programmer to isolate and eliminate effects that are causing unwanted interference.

The next step is to infer region information, given a program annotated with parallel constructs. This is a more challenging goal, because there are many more degrees of freedom. The current strategy is to have the programmer provide partial information (e.g., partition the heap into regions and put in the parallel constructs), and then have the tool infer types and effects that guarantee noninterference.

Runtime Checks

Research is underway to add runtime checking as a complementary mode for guaranteeing determinism, in addition to the compile-time type and effect checking. The advantage of runtime checking is that it is more precise. The disadvantages are (1) it adds overhead, so it is probably useful only for testing and debugging; and (2) it provides only a fail-stop check, instead of a compile-time guarantee of correctness. One place where runtime checking could be particularly useful is in relaxing the prohibition on inconsistent type assignments (e.g., in reshuffling an index-parameterized array). In particular, if the runtime can guarantee that a reference is unique, then a safe cast to a different type can be performed at runtime. Using both static and runtime checks, and providing good integration between the two, would offer the user a powerful set of options for managing the trade-offs among the expressivity, performance, and correctness guarantees of the different approaches.

Bibliographic Notes and Further Reading

For further information on the DPJ project and its goals, see the DPJ web site [2] and the position paper presented at HotPar 2009 [4]. The primary reference for the DPJ type and effect system is the paper presented at OOPSLA 2009 [5]. A paper on the nondeterminism work will appear at POPL 2011 [6]. The Ph.D. thesis of Robert Bocchino [3] presents the full language, together with a formal core language and effect system, soundness results for the core system, and proofs. A paper presented at ASE 2009 [14] describes the work on inferring method effect summaries.

The main influence on DPJ has been the prior work on type and effect systems, including FX [10] and the various effect systems based on ownership types [7, 8]. Other influences include work on design-by-contract for framework APIs [13], work on type and effect inference [12], and the vast body of literature on transactional memory [9].

Definition

A computer system consisting of a multiplicity of processors, each with its own local memory, connected via a network. Load or store instructions issued by a processor can only address the local memory, and different mechanisms are provided for global communication.

Discussion

Terminology

A Distributed-Memory Multiprocessor (DMM) is built by connecting *nodes*, which consist of uniprocessors or of shared memory multiprocessors (SMPs), via a *network*, also called *Interconnection Network* (IN) or *Switch*. While the terminology is fuzzy, *Cluster* generally refers to a DMM mostly built of commodity components, while *Massively Parallel Processor* (MPP) generally refers to a DMM built of more specialized components that can scale to a larger number of nodes and is used for large, compute-intensive tasks – in particular, in scientific computing. A *server farm* is a cluster

used as a server, in order to provide more performance or better cost-performance than a shared memory multiprocessor server. A *high-availability* (HA) *cluster* is a cluster with software and possibly hardware that supports fast failover so as to tolerate component failures. Finally, a *cloud* is a (generally very large) cluster that supports dynamic provisioning of computing resources, usually virtualized, to remote users, via the Internet.

Historical Background

High-performance computing was focused until the late 1970s on SMPs and vector computers built of bipolar gates. The fast evolution of VLSI technology indicated the possibility of achieving much better cost-performance by assembling a larger number of less performing, but much cheaper, microprocessors. The 64 node Cosmic Cube built at Caltech in the early 1980s was an early demonstration of this technology [9]. Several companies started manufacturing such systems in the mid-1980s; a 1,024 node nCUBE system was installed at Sandia National Lab in the late 1980s and a 400 Transputer nodes system was running at Edinburgh in 1989. The success of these systems, which was documented in the influential talk “The Attack of the Killer Micros” by Eugene D. Brooks III at the Supercomputing 1990 Conference, led to a flurry of commercial and governmental activities. Companies such as Thinking Machines (CM-5), Intel (iPSC, Paragon), and Meiko (CS-2) started offering Distributed-Memory Multiprocessor (DMM) products in the mid-1980s, followed by Fujitsu (AP100), IBM (SP1, SP2), and Cray (T3D, T3E) in the early 1990s. DMSs have dominated the TOP500 list of fastest supercomputers since the early 1990s.

The use of clusters evolved in parallel, and largely independently, in the commercial world, driven by several trends: Clusters were used in the early 1990s for *server consolidation*, replacing multiple, distinct servers with one cluster, thus reducing operating costs. The explosive growth of the Internet in the late 1990s led to a need for large clusters with a small footprint (to fit in downtown buildings) that can be quickly expanded, to serve Internet companies. Web requests can easily be served on a DMM, as each TCP/IP request is a small, independent action and request failures can be tolerated.

DMMs were also used to extend SMP architectures beyond the point where hardware could conveniently support coherent shared memory. Thus, IBM introduced in 1994 the *parallel sysplex* architecture that allowed coupling of multiple S/390 mainframes into a larger cluster. The use of such clusters became more widespread as software vendors developed distributed computing firmware and adapted applications to run on clusters.

Clusters have become increasingly used since the late 1990s for providing fault tolerance. Rather than using very specialized hardware, such as in the early Tandem computers, *High Availability (HA) Clusters* provide fault tolerance through hardware replication that eliminates single points of failure, and suitable software. Many vendors (IBM, Microsoft, HP, Sun, etc.) offer HA cluster software solutions.

Utility computing, namely the provisioning of computing resources (CPU time and storage) using a pay-per-use model, has been pursued by multiple companies over decades. Changes in technology (low-cost, high-bandwidth networking, decline in hardware cost and relative increase in operation cost, increased use of off-the-shelf software and improved support for hardware virtualization) and in market needs (very rapid and unpredictable growth of the compute needs of Internet companies) have led to the recent success of this model, under the name of *cloud computing*. Cloud computing platforms are large clusters with software that supports the dynamic provisioning of virtualized compute and storage resources (hardware as a service – HaaS) and, possibly, firmware and application software (software as a service – SaaS)

Architecture

At its simplest, a DMM can be assembled by connecting personal computers or workstations with a commercial network such as Ethernet, as shown in Fig. 1. The Beowulf system built in 1994 is an early example [2]. A more compact and more maintainable cluster can be assembled from rack-mounted servers, as shown in Fig. 2. In addition to the network that is used for communication between nodes, such a cluster will have a control network that is used for controlling and monitoring each node from a centralized console.

The network of a DMM can be (a) a commodity Local Area Network (LAN), such as Ethernet;

Distributed-Memory Multiprocessor. Fig. 1 Beowulf cluster

(b) a higher performance, third party switched network, such as Infiniband or Myrinet; or (c) a vendor-specific network, such as available on IBM and Cray systems. Communication over Ethernet will typically use the TCP/IP protocols; communication over non-Ethernet fabrics can support lower latency protocols. Adapters for networks of type (a) and (b) will connect to a standard I/O bus, such as PCIe; vendor-specific networks can connect to the (nonstandard) memory bus, thus achieving higher bandwidth and lower latency.

The basic communication protocol supported by any of these networks is *message passing*: Two nodes communicate when one node sends a message to the second node and the second node receives the message. Networks of type (b) and (c) often support *remote direct memory access* (rDMA): A node can directly access data in the memory of another node, using a *get* operation, or update the remote memory, using a *put* operation.

Distributed-Memory Multiprocessor. Fig. 2 Rack-mounted cluster

Support for such operations in user space requires an adapter that can translate virtual addresses to physical addresses. Oftentimes, such an adapter will also support read-modify-write operations on operands in remote memory, such as *increment*; this avoids the need for a round-trip for such operations and facilitates their atomic execution.

Networks of type (c) may have hardware support for collective operations, such as *barrier*, *broadcast*, and *reduce*.

The *topology* of the interconnection network impacts its performance: Networks with a low-dimension *mesh* topology (2D or 3D) can be packaged so that only short wires are needed; this enables the use of cheaper copper cables while maintaining high bandwidth. *Radix-network* topologies, such as *butterfly* or *fat-tree*, reduce the average number of hops between nodes, but require longer wires [11]. Optical cables are needed for high-speed transmission over long distances.

Commercial clusters (server farms and clouds) typically use Ethernet networking technology and communicate using TCP/IP protocols. The nodes often share storage, using Storage Area Networks (SAN) or

Network Attached Storage (NAS) technologies. Some commercial clusters, such as the IBM Parallel Sysplex, provide clustering hardware that accelerates data sharing and synchronization across nodes.

Software

DMMs reuse, on each node, software designed for node-sized uniprocessors or SMPs. This includes the operating system, programming languages, compilers, libraries, and tools. An additional layer of parallel software is built atop the node software, in order to integrate the multiple nodes into one system.

This includes, for compute clusters:

- Software for system initialization, monitoring and control. This enables the control of a large number of nodes from one console; concurrent booting of a large number of nodes; network firmware initialization; error detection; etc.
- Scheduler and resource manager for allocating resources to parallel jobs, loading them and starting them. Parallel jobs often run on dedicated partitions; the scheduler has to allocate nodes in large chunks, while ensuring high node utilization and reducing waiting time for batch jobs. The resource manager has to reduce job-loading time (e.g., by using a parallel tree broadcast algorithm) and ensure that all nodes of a job start correctly.
- Parallel file system. Such a system integrates a large number of disks into one system and provides scalable file coherence protocols. Files are striped across many nodes so as to support parallel access to different parts of the same file and ensure load balancing. Software RAID schemes may be used to enhance the reliability of such a large file system.
- Checkpoint/restart facilities. On large DMMS, the mean time between failures is often shorter than the running time of large jobs. To ensure job completion, jobs periodically checkpoint their state; if a failure occurs, then job execution is restarted from the last checkpoint. A checkpoint facility supports coordinated checkpoint or restart by many nodes.
- Message passing libraries for supporting communication across nodes. MPI is the de facto standard for message passing on large DMMs.
- Tools for debugging and performance monitoring of parallel jobs. These are often built atop node

level debugging and performance monitoring; they enable users to control many nodes in debug mode, and to aggregate information from many nodes in debug or monitoring nodes.

The use of conventional software on the nodes of DMMs is limiting; in particular, the use of a conventional operating systems on each node results in *jitter*: Background OS activities may slow down nodes at random times; applications where barriers are used frequently can slow down significantly as all threads wait at each barrier to the slowest thread. Some systems, e.g., the IBM Blue Gene system, are using on their compute node-specialized *light-weight kernels* (LWK) that provide only critical services and offload to remote server nodes heavier or more asynchronous system services.

Commercial clusters use TCP/IP for inter-node communication, and distributed file systems for file sharing. They leverage firmware and application software designed for distributed systems, such as support for remote procedure calls (or remote method invocations), distributed transaction processing monitors, messaging frameworks, and “shared-nothing” databases.

A critical component of server farms that handle Web requests is a *load balancer* that distributes TCP/IP requests coming on one port to distinct nodes.

HA clusters have software that monitor the health of the system components and its applications (heartbeat) and report failures; software to achieve consensus after failures and to initiate recovery actions; and application-specific recovery software to restart each application in a consistent state. Disk state is preserved, either through mirroring, or through the sharing of highly reliable RAID storage via multiple connections.

Clouds often use virtual machine software to virtualize processors and storage, thus facilitating their dynamic allocation. They need a resource management infrastructure that can allocate virtual machines on demand.

Research

Early DMMs had directly connected networks; the network topology was part of the programming model. Theoretical research focused on the mapping of parallel algorithms to specific topologies; in particular, hypercubes and related networks (the primary conference

on DMMs in the late 1980s was the conference on Hypercube Concurrent Computers and Applications). The abstract model used was of unit time communication on each edge, with communications either being limited to one incident edge per node at a time, or occurring concurrently on all edges incident to a node. For example, the problem of sorting on a hypercube is treated by several tens of publications.

As indirect networks became more prevalent, significant amount of research focused on the topology of routing networks and cost-performance tradeoffs, and routing protocols for different topologies that are efficient and deadlock free, and that can handle failures.

Modern DMMs largely hide the network topology from the user and may not provide mechanisms for controlling the mapping of processes and communications onto the network nodes and edges. Therefore, the topology is not part of the programming model. The abstract programming models used to represent such systems assume that communication time between two nodes is a function of the size of the message communicated. Two of the most frequently used models are the postal model [7] and the logP model [5].

System research on DMMs has focused on communication protocols, operating systems, file systems, programming environments, and applications. Some of the larger efforts in this area are the Network of Workstation (NOW) effort at Berkeley [1], and the SHRIMP project at Princeton [3].

Bibliographic Notes and Further Reading

The book of Fox et al. [9] covers the early history of MPPs, their hardware and software, and the applications enabled on them. The book of Culler and Singh [6] is a good introduction to MPP architectures and their networks, with a detailed description of the Cray T3D and IBM SP networks. The book of Pfister [11] is a general introduction to clusters, their design, and their use, while the two books of Buyya [4, 5] provide in-depth coverage of cluster hardware, software, and applications. The book of Dally and Towles [8] provides a very good coverage of IN theory and practice. Finally, the book of Leighton [10] is an excellent introduction to the theory results that are relevant to DMMs and INs.

Definition

Domain decomposition, in the context of parallel computing, refers to partitioning of computational work among multiple processors by distributing the computational domain of a problem, in other words, data associated with the problem. In the scientific computing literature, domain decomposition mainly refers to techniques for solving partial differential equations (PDE) by iteratively solving subproblems corresponding to smaller subdomains. Although the evolution of these

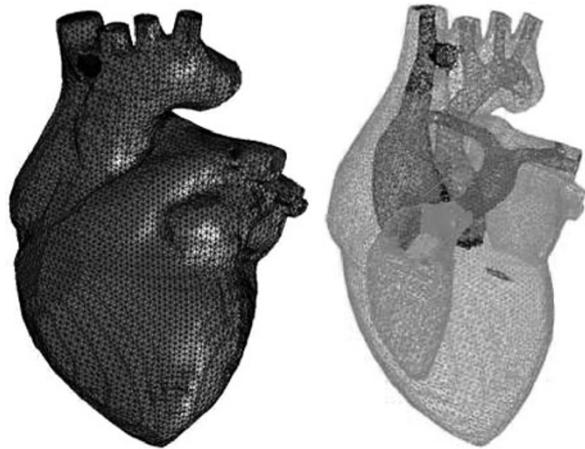

techniques is motivated by PDE-based computational simulations, the general methodology is applicable in a number of scientific domains not dominated by PDEs.

Introduction

One of the key steps in parallel computing is partitioning the problem to be solved into multiple smaller components that can be addressed simultaneously by separate processors with minimal communication. There are two main approaches for dividing the computational work. The first one is domain decomposition, which involves partitioning the data associated with the problem into smaller chunks and each parallel processor works on a portion of the data. The second approach, functional decomposition, on the other hand, focuses on the computational steps rather than the data and involves processors executing different independent portions of the same program concurrently. Most parallel program designs involve a combination of these two complementary approaches.

In this entry, we focus on domain decomposition techniques, which are based on data parallelism. [Figure 1](#) shows a 3-D finite element mesh model of the human heart [29] used for simulation of the human cardiovascular system and in particular, the flow of blood through the various chambers and valves (http://www.andrew.cmu.edu/user/jessicaZ/medical_data/Heart_Valve_new.htm). Computation is performed repeatedly for each point on the mesh using Darcy's law [19], which describes the flow of a fluid through a porous medium and is widely used in blood flow simulations. [Figure 1](#) also illustrates decomposition of this mesh model into 22 subdomains (indicated by different colors) that are relatively easier to model due to their simpler geometry.

Domain decomposition is vital for high-performance scientific computing. In addition to providing enhanced parallelism, it also offers a practical framework for solving computational problems over complex, heterogeneous and irregular domains by decomposing them into homogeneous subdomains with regular geometries. The subdomains are each modeled separately using faster, simpler computational algorithms, and the solutions are then carefully merged to ensure consistency at the boundary cases. Such decomposition is also useful when the modeling equations are different across subdomains as in the case of singularities and

Domain Decomposition. [Fig. 1](#) Tetrahedral meshing of the heart. The figure on the *right* shows the mesh partitioned into subdomains indicated with different colors

anomalous regions. Lastly, it is also useful for developing out-of-core (or external memory) solution techniques for large computational problems with billions of unknowns by facilitating the partitioning of the problem domain into smaller chunks, each of which can fit into main memory.

Domain Decomposition for PDEs

Scientific computing applications such as weather modeling, heat transfer, and fluid mechanics involve modeling complex physical systems via partial differential equations. Though there exist many different classes of PDEs, the most widely used ones are second-order elliptic equations, for example, the Poisson's equation, which manifests in many different forms in a number of applications. For example, the Fourier law for thermal conduction, Darcy's law for flows in porous media and Ohm's law for electrical networks, all arise as special cases of the Poisson's equation.

Example 1. For the sake of illustration, we consider a problem that requires solving the Poisson equation over a complex domain Ω with Γ denoting the boundary

$$\nabla^2 u = f \text{ in } \Omega,$$

$$u = u_\Gamma \text{ on } \Gamma.$$

In practice, the domain is discretized using either finite difference or finite element methods, which yields a large sparse symmetric positive definite linear system, $Au = f$ where A is determined by the discretization and u is a vector of unknowns. Domain decomposition for this problem involves partitioning the domain Ω into subdomains $\{\Omega_i\}_{i=1}^s$, which may be overlapping or nonoverlapping depending on the nature of the problem. The partitioning into subdomains is sometimes referred to as the coarse grid with the original discretization being described as the fine grid.

Given a discretized computational problem as in the example, there are four main steps that need to be addressed in order to obtain an efficient parallel solution.

- The first step is to identify the preferred characteristics of subdomains for the given problem. This includes choosing the number of subdomains, the type of partitioning (element/edge/vertex-based), and the level of overlap between the subdomains (with disjoint subdomains being the extreme case). Each of these choices depend on a variety of factors such as size, type, and geometry of the problem domain, the number of parallel processors, and the PDE/linear system being solved.
- The next step is to partition the problem domain into the desired subdomains. This can be achieved by using a variety of geometric and graph partitioning algorithms. For certain applications involving adaptive mesh refinement, one may chose to iteratively refine the partitioning based on the load imbalance.
- Given the subdomains, the next step involves solving the PDE for the entire problem domain. This consists of :
 - Solving the PDE over each subdomain, that is, $\nabla^2 u = f$ in Ω_i , for $1 \leq i \leq s$, or, equivalently the linear systems $A_i u_i = f_i$, for $1 \leq i \leq s$, where A_i , u_i , and f_i are restrictions of A , u , and f to Ω_i , respectively
 - Ensuring consistency at the interfaces (or the overlap in case of overlapping regions) of the subdomains, which is referred to as the coarse solve
- Depending on the overlap between the subdomains, there are two classes of solution approaches.

Specifically, Schur's complement techniques are suitable for subdomains with no overlap and Schwarz alternating techniques are suited for overlapping subdomains. Since these solution techniques iteratively solve the constituent subproblems, these subproblems need not be solved accurately in each step and different choices of approximation over the subproblems lead to variants of the overall algorithms.

- Given a parallel architecture, the final step is to map the subdomains and the interfaces to the individual processors and translate the domain-decomposition-based solution approach to a parallel program that can be implemented efficiently on this architecture. This mapping depends on the relative computational and communication requirements for solving the interfaces.

Each of the above steps will be discussed in the following sections.

Nature of Subdomains

The effectiveness of any domain decomposition approach critically depends on the relative suitability of the sub-domains both with respect to the computational problem (PDE/linear system) being solved and the parallel architecture being employed. Below, we discuss certain key characteristics of subdomains that influence the overall performance as well as some general guidelines proposed in literature for choosing them for a given problem.

Number of Subdomains

The choice of the number of subdomains has a significant effect on both the computational time and the quality of the final solution. In general, a large number of subdomains, or alternately a small size for the coarse grid, results in a better, but more expensive solution since a large number of subdomain problems need to be solved and there is much more communication. On the other hand, choosing a small number of subdomains has the opposite effect.

Given a fine grid, that is, a discretized problem, it has been observed empirically [12] that there exists an optimal choice for the number of subdomains that minimizes the overall computational time. However, theoretical results [3] exist only for fairly simple scenarios

where the same solver is used for all the subdomain problems as well as the original problem, and the convergence rate is independent of the coarse grid size. For example, for a uni-processor setting on a structured n^d grid with fine grid scale h and a solver with complexity $O(n^\alpha)$, the optimal choice for the coarse grid size is given by

$$H_{opt} = \left(\frac{\alpha}{\alpha - d} \right)^{\frac{1}{\alpha-d}} h^{\frac{\alpha}{2\alpha-d}}.$$

Practical scientific computing problems, however, often involve fairly complex domains as in Fig. 1 and this requires taking into account a number of other considerations. Firstly, it is preferable to partition the domain into subdomains with regular geometry on which faster solvers can be deployed. Secondly, in a parallel setting, an ideal choice is to assign each subdomain to an individual processor to minimize communication costs. Such a choice might, however, lead to load imbalance in case the number of subdomains is less than that of the available processors or there is vast difference in the relative sizes of the subdomains. For a parallel scenario, there exist limited theoretical results. For example, for a structured n^d grid where all the subdomain solves are performed in parallel followed by an integration phase performed by one of the solvers, it can be shown that the optimal number of processors is $n^{d/2}$, but this analysis only considers load distribution and ignores the communication costs. For a real-world application, one needs to empirically determine an appropriate partitioning size that optimizes both the load balance as well as the communication costs.

Type of Partitioning

There are three main types of partitioning depending on the constraints imposed on subdomain interfaces. The first type is element-based partitioning, common in case of finite-element discretizations, where each element is solely assigned to a single subdomain. The second type is edge-based partitioning, more suitable for finite-volume methods, where each edge is solely assigned to a single subdomain so as to simplify the computation of fluxes across edges. The last type is vertex-based partitioning, which is the least restrictive and only requires each vertex to be assigned to a unique subdomain. The choice of partitioning type determines how the subdomain interface values are computed and can have a significant effect on the complexity and

convergence of the algorithm, for example, Schur complement method can be implemented much more efficiently for edge-based partitionings than the other two types [22]. For most problems, the appropriate type of partitioning is determined by the nature of the computational problem (PDE) and the discretization itself, but where there is flexibility, it is important to make a judicious choice in order to optimize the computation time for the coarse solve.

Level of Overlap

Overlap between the subdomains is another important characteristic that determines the solution approach. In particular, Schur complement-based approaches are applicable only in case of nonoverlapping subdomains whereas Schwarz alternating procedures (SAP) are applicable in case of overlapping subdomains. The appropriate level of overlap is often dependent on the geometry of the problem domain and the PDE to be solved. A decomposition into subdomains with regular geometry (e.g., circles, rectangles) is often preferable irrespective of the level of overlap. In general, SAP-based techniques are easier to implement in addition to providing close to optimal convergence rate and being more robust. However, extra computational effort is required for the regions of overlap and they are not suitable for handling discontinuities.

Partitioning Algorithms

For scientific computing tasks, the problem domain is invariably discretized making it natural to use a graph (or in certain cases hypergraph) representation. Decomposing the problem domain into subdomains, therefore, becomes a graph partitioning problem. For parallel computing with homogeneous processors, it is desirable to have a partitioning such that the resulting subdomains require comparable amounts of computational effort, that is, balanced load, and there are minimal communication costs for handling the subdomain interfaces. In other words, the subdomains need to be of similar size with few edges between them. In case of structured and quasi-uniformly refined grids, such a partitioning can be obtained with relative ease. However, for unstructured grids resulting from most real-world applications, it is an NP-complete problem [11]. A number of algorithms have been proposed in literature to address this problem and [11, 14, 15] provides

a detailed survey of these algorithms. Some of the key approaches are discussed below.

Geometric Approaches

Geometric partitioning approaches rely mainly on the physical mesh coordinates to partition the problem domain into subdomains corresponding to regions of space. Such algorithms are preferable for applications such as crash and particle simulations, where geometric proximity between grid points is much more critical than the graph connectivity.

Recursive bisection methods form an important class of geometric approaches that involve computing a separator that partitions a region into two subregions in a desired ratio (usually equal). This bisection process is performed recursively on the subregions until the desired number of partitions are obtained. The simplest of these techniques is the Recursive Coordinate Bisection (RCB) [1], which uses separators orthogonal to coordinate axes. A more effective technique is Recursive Inertial Bisection (RIB) [7] that employs separators orthogonal to principal inertial axes of the geometry. Over the last 2 decades, a number of extensions [4] as well as hybrid techniques [18] that combine RIB with local search methods such as the Kernighan-Lin's method, in order to simultaneously minimize the edge cut between the subdomains have been proposed.

Space-filling curve (SFC)-based partitioning approaches [23] are another class of geometric techniques. In these methods, a space-filling curve maps an n-dimensional space to a single dimension, which provides a linear ordering of all the mesh points. The mesh is then partitioned by dividing the ordered points into contiguous sets of desired sizes, which correspond to the subdomains.

The explicit use of geometric information and the incremental nature of the above techniques makes them highly beneficial for applications where geometric locality is critical and there are frequent changes in the geometry requiring dynamic load balancing. However, these techniques have limited applicability for computational problems where one needs to consider graph connectivity and communication costs.

Coordinate-Free Approaches

Coordinate-free partitioning approaches include spectral and graph-theory-based techniques that rely only on the connectivity structure of the problem domain.

These techniques are widely used in a number of scientific computing applications since they can provide better control of communication costs and do not require an embedding of the problem in a geometric space.

There currently exist a large number of such algorithms [11], but most of them have been derived from combinations of three basic techniques: (a) Recursive Graph Bisection, (b) Recursive Spectral Bisection, and (c) Greedy approach. Of these, the recursive graph bisection method [26] begins by finding a pseudo-peripheral vertex, (i.e., one of a pair of vertices on the longest graph geodesic), computing the graph distance to all the other vertices from this vertex. This distance is then used to sort the vertices, which are then split into two groups in the desired ratio (usually equal) such that one group is closer to the peripheral vertex and the other one is away, and this process is repeated recursively till the desired number of partitions are obtained. The second technique, that is, recursive spectral bisection method [21] makes use of the Fielder vector, which is defined as the eigenvector corresponding to the second lowest eigenvalue of the Laplacian matrix of the graph. The size of this vector is the same as the number of vertices in the graph and the difference between the Fielder coordinates is closely related to the graph distance between the corresponding vertices. The Fielder vector, thus, provides a linear ordering of the vertices, which can be used to divide the vertices into two groups and recursively deployed as in the case of SFC-based partitioning algorithms. The greedy approach typically uses a breadth first search and uses graph growing heuristics to create partitions [8].

There are also a number of fast multilevel techniques that are especially suitable for large problem domains. These techniques typically consist of three phases: coarsening, partitioning, and refining. In the first phase, a sequence of increasingly coarse graphs is constructed by collapsing vertices that are tightly connected to each other. The coarsened graph is then partitioned into the desired number of subdomains in the second phase. The graph is then progressively uncoarsened and refined using local search methods such as the Kernighan-Lin method [17], which improves the edge cut via a series of vertex-pair exchanges, in the third phase.

Dynamic Approaches

When the computational structure is relatively invariant through out a simulation, it is sufficient to consider a

static partitioning of the problem domain. However, for applications where the structure changes dynamically (e.g., in crash simulations with geometric deformations or in case of adaptive mesh refinement methods), it is critical to dynamically repartition the problem domain to ensure load balance. Such a repartitioning needs to account for not only the load distribution and communication costs, but also the costs of data redistribution across the partitionings [15]. Furthermore, in case of large problems, since it is expensive to load the entire mesh onto a single processor, these partitionings themselves need to be computed in parallel. Currently, there exist a number of dynamic partitioning algorithms such as [20, 24, 27] which can viewed as extensions of existing static partitioning algorithms that incorporate an additional objective term based on the data redistribution costs. These techniques often involve a clever remapping of subdomain labels to reduce the redistribution costs. In case of multilevel methods such as Locally-Matched Scratch-Remap (LMSR) [24], the coarsening phase is similar to that in the static case, the partitioning (i.e., repartitioning) phase leads to tentative new subdomains, and the final uncoarsening/refinement phase is adapted so as to additionally optimize the data redistribution costs.

PDE Solution Techniques

There are two main classes of approaches for solving PDEs over a partitioned problem domain [22] depending on the overlap, namely, (a) Schur complement-based approaches and (b) Schwarz alternating procedures, which we discuss below.

Schur Complement-Based Approaches

This class of approaches is based on the notion of a special matrix called the Schur complement, which enables one to solve for the subdomain interface values independent of the interior unknowns. The computation of the unknowns in the interior of each of the subdomains is then performed in parallel independently.

Consider a computational problem corresponding to a second-order elliptic PDE as in Example 1. As mentioned earlier, a discretization leads to the linear system $Au = f$, $u \in \Omega$. In case of nonoverlapping subdomains, that is, $\Omega_i \cap \Omega_j = \emptyset$, and edge-based partitioning on a finite difference mesh, this linear system can be

expressed as

$$\begin{bmatrix} B_1 & & D_1 \\ & B_2 & D_2 \\ & \ddots & \vdots \\ & & B_s & D_s \\ E_1 & E_2 & \cdots & E_s & C \end{bmatrix} \begin{bmatrix} u_1^{int} \\ u_2^{int} \\ \vdots \\ u_s^{int} \\ u^{bnd} \end{bmatrix} = \begin{bmatrix} f_1^{int} \\ f_2^{int} \\ \vdots \\ f_s^{int} \\ f^{bnd} \end{bmatrix}, \quad (1)$$

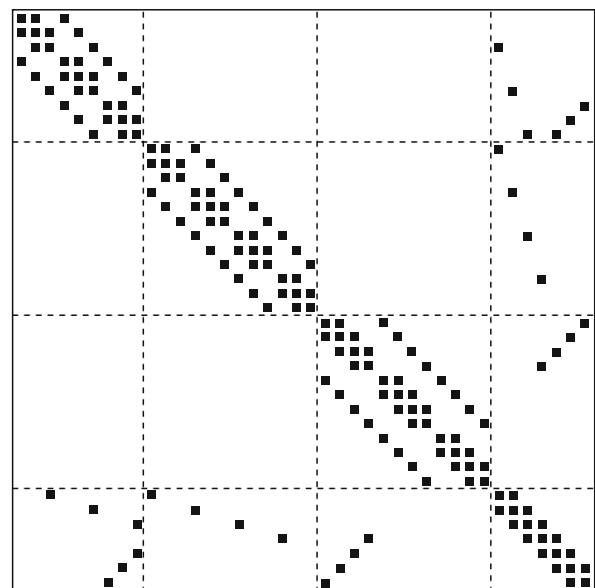

where each f_i^{int} denotes the vector of unknowns interior to subdomain Ω_i and u^{bnd} denotes the vector of interface unknowns.

Figure 2 shows the nonzero structure for such a linear system. This can be equivalently expressed in a block form as

$$\begin{pmatrix} B & D \\ E & C \end{pmatrix} \begin{pmatrix} u^{int} \\ u^{bnd} \end{pmatrix} = \begin{pmatrix} f^{int} \\ f^{bnd} \end{pmatrix}, \quad (2)$$

where B, D, E, f^{int} , and u^{int} are aggregations over the corresponding subdomain specific variables. From **Eq. 2**, by substituting for u^{int} , we obtain a reduced system

$$(C - EB^{-1}D)u^{bnd} = f^{bnd} - EB^{-1}f^{int}.$$

Domain Decomposition. Fig. 2 Nonzero structure of the resulting linear system

Algorithm 1 Schur complement method

1. Form the reduced system based on Schur complement matrix
2. Solve the reduced system for the interface unknowns
3. Solve the decoupled systems for interior unknowns by back-substituting the interface unknowns

The matrix $S = (C - EB^{-1}D)$ is called the Schur complement matrix. This matrix can be computed directly from the original coefficient matrix A given the partitioning and can be used to compute the interface values u^{bnd} . Back-substitution of u^{bnd} is then used to solve smaller decoupled linear systems $B_i u_i^{int} = f_i^{int} - D_i u^{bnd}$.

In the case of vertex-based and element-based partitionings, the coefficient matrix A exhibits a more complex block structure unlike in Eq. 1. However, even for these cases, one can construct a reduced system based on a Schur complement matrix assembled from local (subdomain specific) Schur complements and the interface coupling matrices, which can be used to solve for the interface unknowns.

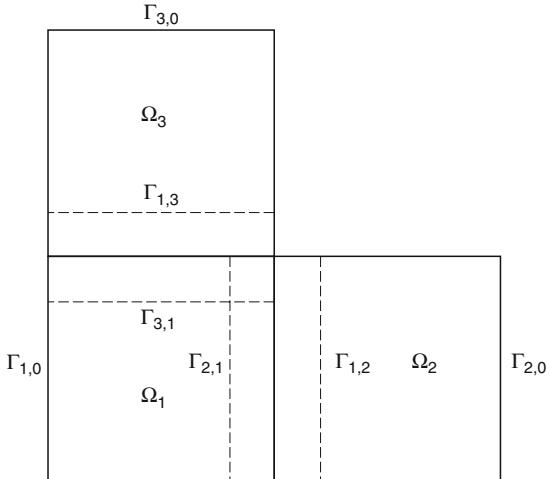

[Algorithm 1](#) describes the key steps for this class of techniques irrespective of the partitioning type. Depending on the choice of the methods (e.g., direct vs. iterative methods, exact vs. approximate solve) used for forming the Schur complement and solving the reduced systems, there are multiple possible variants.

Schwarz Alternating Procedures

Schwarz alternating procedures refer to techniques that involve alternating between overlapping subdomains and in each case, performing the corresponding subdomain solve assuming boundary conditions based on the most recent solution.

Consider the discretized elliptic PDE problem in Example 1 for the case where each subdomain Ω_i overlaps with its neighboring subdomains (as in Fig. 3). Let Γ_{ij} denote the boundary of Ω_i that is included in Ω_j . The original solution method proposed by Schwarz [25] in 1870 was a sequential method where each step consists of solving the restriction of $Au = f$ over the subdomain Ω_i assuming the boundary conditions over Γ_{ij} , $\forall j$.

Since the approach is iterative and sweeps through each subdomain multiple times, it suffices to perform

Domain Decomposition. Fig. 3 An L-shaped domain showing overlapping subdomains

an approximate subdomain solve or in the extreme case, one iteration of the subdomain solve. Thus, each step can be viewed as an additive update of u . This update step can be concretely specified using the notion of a *restriction operator*. Let $R_i \in \{0,1\}^{|\Omega_i| \times |\Omega|}$ be a binary matrix that denotes the restriction of Ω to Ω_i , that is, the j^{th} component of R_i is 1 iff the j^{th} unknown belongs to Ω_i . Given $\{R_i\}_{i=1}^s$, one can define the restriction of A to Ω_i as the matrix $A_i = R_i A R_i^T$ and the update is then given by

$$u = u + R_i^T A_i^{-1} R_i (f - Au).$$

Since the updates over each subdomain are applied sequentially, it is equivalent to a multiplicative composition and this procedure is referred to as Multiplicative Schwarz Alternation.

To make this approach amenable to parallelization, an alternate procedure Additive Schwarz Alternation [6] was proposed, which involves using the same residual ($f - Au$) to compute the incremental updates over each subdomain in a single sweep and the incremental updates are then aggregated to obtain the new solution. [Algorithm 2](#) shows the main steps for the basic additive Schwarz alternation and each of the δ_i computations in a single iteration are independent of each other and can be performed in parallel. [Algorithm 2](#) corresponds to the most basic version of additive Schwarz. Real applications, however

Algorithm 2 Additive Schwarz method

```

Choose an initial guess for  $u$ 
repeat
  for  $i = 1 \dots s$  do
    Compute  $\delta_i = R_i^T A_i^{-1} R_i (f - Au)$ 
     $u_{new} = u + \sum_{i=1}^s \delta_i$ 
  until convergence

```

employ variants of this approach with similar independent additive updates, but are based on more complex preconditioners [28].

Mapping to Parallel Processors

A natural way to map a domain decomposition algorithm to a parallel architecture is to assign each subdomain to a separate processor. In this case, the subdomain solves can be performed independently in parallel, but the coarse solve (handling of interface values) is nontrivial since the relevant interface data is scattered among all the processors. For example, in Schur complement approaches, solving the reduced system based on the Schur complement, in the general case, requires access to data from all the subdomains.

There are three common ways to address the above problem. The first is to keep the data in place and perform the solve in parallel with the necessary communication. Such an approach would require an intelligent grouping of the interface unknowns with minimal dependencies across groups, which can then be assigned to different subdomains so as to minimize the communication cost. The second option is to collect all the data on a single processor, perform the coarse solve, and broadcast the output while the third approach is to replicate the relevant data on all the processors and perform the coarse solve in parallel. There have been empirical studies [13] that evaluated the relative benefits of these approaches, but the appropriate choice typically depends heavily on the characteristics of the specific problem and the parallel architecture.

Advanced Methods

More recent work on domain decomposition has focused on efficient techniques for specific topics. These include advanced methods for graph partitioning and for solving PDEs.

In graph partitioning, researchers have developed hyper-graph algorithms [5, 16] that can be used for graphs with edges that involve more than two nodes. Such graphs arise naturally in many applications such as higher-order finite elements, and can also be constructed from regular graphs. Empirical evidence points to improvement in the efficiency of partitioning algorithms as well as in the quality of partitions. It has also been recognized for a while that large graph problems that require domain decomposition techniques often arise in a parallel setting, and as a result, work has focused on developing parallel partitioning methods. These methods are, in general, straightforward parallelization schemes, with additional care taken to ensure quality of the partitions. Another important area of work involves adaptive partitioning and refining [2, 24] for applications where the graph changes frequently during the simulation. A key component of these algorithms is the ability to repartition quickly and efficiently starting from an initial partition. The new partitioning must ensure good load balance without increasing communication requirement or introducing large overhead.

The domain decomposition step has implications on the numerical procedure used to solve the PDE. In particular, the rate of convergence of iterative solvers can be improved significantly by considering domain decomposition as a “preconditioning” step that reduces the number of iterations. In this regard, there has been some work on improving the Schur-complement approach by using Schwarz-type methods for the reduced linear system. This can be useful when the Schur complement is complex and large enough to require a parallel solver. Another approach that is motivated by solving PDEs in parallel is the Finite Element Tearing and Integration (FETI) [9, 10] method in which splitting of the domain into subdomains is accompanied by modification of the linear operator to achieve faster convergence of the iterative solver. After splitting the domain, one needs to enforce continuity across subdomain boundaries using Lagrange multipliers. The solution process determines these Lagrange multipliers via an iterative method that requires repeated subdomain solves that can be done in parallel.

Application Areas

Domain decomposition has been used in a wide variety of disciplines. These include aerospace, nuclear,

mechanics, electrical, materials, petroleum, and others. The benefits of the method are most apparent when used for applications that require large systems to be solved. In such cases, the solver phase can consume up to 90% or more of the total running time of the application. The domain decomposition concept can be applied in a fairly straightforward manner once the subdomains are identified. However, it may be important to fine-tune the parameters for each application in order to get the best performance.

Future Directions

The advent of multicore processors and the availability of large multiprocessor machines pose significant challenges to researchers and developers in the area of domain decomposition. Challenges that arise from large-scale compute capability involve the ability to use a large number of cores concurrently and efficiently. It will be much harder to achieve good partitioning and load balance on such platforms. The ability to perform asynchronous computation and to adapt to changing computational structure is equally important. In addition, it is imperative to build fault tolerance into the algorithmic structure to protect against inevitable architectural instabilities. One must also consider relaxing the numerical requirements on the computations in favor of obtaining an approximate but acceptable solution quickly. Another area of interest is the automatic tuning of parameters required by the algorithms to ensure good performance. It is also important to understand that domain decomposition is often used as a low-level computational tool in applications where the main goal is to optimize within a design space or to conduct sensitivity studies. A tighter integration of the domain decomposition step with other computational modules is necessary to realize the full benefit of this technique for an application.

Definition

Dynamic Logical Partitioning (DLPAR) is the nondisruptive reconfiguration of the real or virtual resources made available to the operating system (OS) running in a logical partition (LPAR). Nondisruptive means that no OS reboot is needed.

Discussion

Introduction

A Logical PARtition (LPAR) is a subset of hardware resources of a computer upon which an operating system instance can run. One can define one or more LPARs in a physical server, and an OS instance running in an LPAR has no access and visibility to the other OS instances running in other LPARs of the same server. In October 2002, IBM introduced the DLPAR technology on POWER4-based servers with the general availability of AIX 5.2. This DLPAR technology enables resources such as memory, processors, disks, network adaptors, and CD/DVD/tape drives to be moved nondisruptively (i.e., without requiring a reboot of the source and target operating systems) between LPARs in the same physical server. In simple terms, one can perform the following basic nondisruptive dynamic operations with DLPAR:

- Remove a unit of resource from an LPAR.
- Add a unit of resource to an LPAR.
- Move a unit of resource from one LPAR to another in the same physical server.

For POWER4 systems, the granularity/unit of resource for a DLPAR operation was 1 CPU for processors, 1 Logical Memory Block (LMB) of size 256MB for memory, and 1 IO-slot for I/O (disks, network, and media) adapters. Those units of processor, memory, and I/O-slots that are not assigned to any LPAR reside in a “free pool” of the physical server, and can be allocated to a new or existing LPARs via DLPAR operations later on. Similarly, when a unit of resource is DLPAR-removed from an LPAR, it goes into the free pool.

The fundamentals of DLPAR are described in [1].

AIX has supported DLPAR removal of memory since 10/2002; however, DLPAR removal of memory was not available for Linux on POWER until 2009, with the availability of SUSE SLES 11. On POWER5 and follow-on POWER systems, the minimum size of an LMB (unit of DLPAR removal or add) can be as small as 16MB. This minimum size is a function of the total amount of physical memory in the physical server.

Since the availability of POWER5, all POWER servers are partitioned into one or more LPARs. These LPARs are defined via the POWER HYPervisor firmware (PHYP). An LPAR can be a dedicated-processor LPAR or a Shared-Processor LPAR (SPLPAR). A dedicated-processor LPAR is an LPAR which contains

an integral number of CPUs. SPLPAR was introduced with AIX 5.3 on POWER5 systems in 6/2004. One can define a pool of CPUs to be shared by a set of LPARs, which will be called shared-processor LPARs (SPLPARs). The PHYP controls the time-slicing and allocation of CPU resources across the SPLPARs sharing the pool. An SPLPAR has the following *attributes*:

- (a) Minimum, assigned, and maximum number of *Virtual Processors (VPs)*.

The number of VPs is the degree of processor-concurrency made available to the OS instance.

- (b) Minimum, assigned, and maximum number of *processor-units of Capacity*.

Capacity is the amount of cumulative real-CPU-equivalent resources allocated to the OS instance in a reasonable interval of time (e.g., 10 ms).

- (c) *Capped or uncapped mode*. A capped SPLPAR cannot use excess CPU resources in the pool beyond its maximum capacity.
- (d) If uncapped, an SPLPAR has an *uncapped-weight value* (currently, an integer between 0 and 255), which is used for prioritizing the SPLPARs in a pool.

The DLPAR technology was then enhanced to be able to dynamically move units of a SPLPAR's CPU-resources nondisruptively from one SPLPAR to another in the same SPLPAR pool. More precisely, DLPAR technology can nondisruptively and dynamically

- Remove or add an integral number of Virtual Processors from or to an SPLPAR, or move such from one SPLPAR to another
- Remove or add Capacity (in processor-units) from or to an SPLPAR, or move capacity from one SPLPAR to another
- Change the processor Mode of an SPLPAR to Capped or Uncapped
- Change the Weight of an Uncapped SPLPAR (between a value of 0 and 255)

DLPAR Technology

DLPAR Removal of a CPU

DLPAR enables the dynamic removal of a CPU from a running OS instance in one LPAR, without requiring a reboot of the OS instance.

At a very high level, the following sequence of operations initiated from the OS is used to accomplish a DLPAR removal of a CPU:

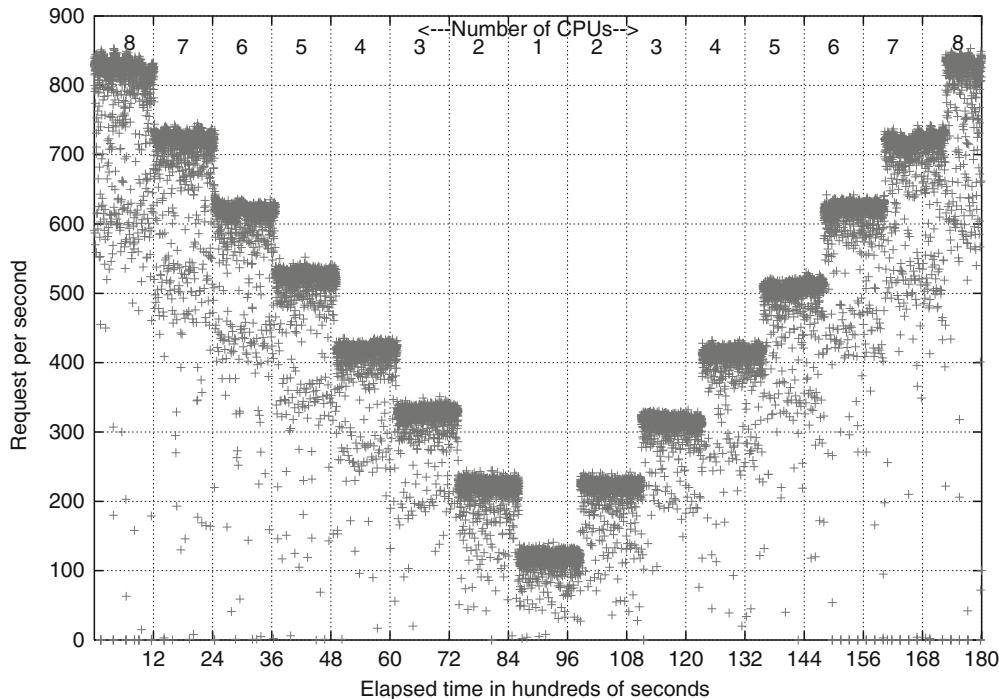

1. Notify all applications and kernel extensions that have registered to be notified of CPU DLPAR events, so that they may remove dependencies on the CPU to be removed. This typically involves unbinding their threads that are bound to the CPU being removed.
2. Migrate threads that are bound to the CPU being removed to another CPU in the same LPAR.
3. Reroute existing and future hardware-interrupts that are directed to the CPU being removed. This involves changing the interrupt controller data structures.
4. Migrate the timers and threads from the CPU being removed to another CPU in the same LPAR.
5. Notify the hypervisor/firmware to complete the removal task.

DLPAR Addition of a CPU

Dynamic addition of a CPU involves the following tasks initiated from the OS:

1. Create a process (waitproc) to run an idle loop on the incoming CPU, before it starts to do real work.
2. Set up various hardware registers (e.g., GPR1 for the kernel stack, GPR2 for the kernel Table Of Contents) of the incoming CPU.
3. Allocate and/or initialize the processor-specific kernel data structures (e.g., runqueue, per-processor data area, interrupt stack) for the incoming CPU.
4. Add support for the incoming CPU to the interrupt subsystem.
5. Notify the DLPAR-registered applications and kernel extensions that a new CPU has been added.

Dynamic addition and removal of processors to and from an LPAR allow it to adapt to varying workloads. Figure 1 shows that the throughput (in requests-per-second) of the WebSphere Trade3 benchmark scales almost linearly with the number of CPUs in a dedicated-processor-LPAR, as CPUs were removed and added to the LPAR with DLPAR operations [2].

Dynamic Logical Partitioning for POWER Systems. Fig. 1 WebSphere Trade3 benchmark: throughput (in requests-per-second) as a function of the number of CPUs (the *upper x-axis labels*), and as a function of elapsed time (the *lower x-axis labels*)

DLPAR Addition of a Memory Block (LMB)

When a DLPAR memory-add request arrives at the OS, the latter has to perform two tasks:

1. Allocate and initialize software page descriptors that will hold metadata for the incoming memory.
2. Distribute the incoming memory among the framesets of a mempool (mempools are described two paragraphs below). The challenges encountered in implementing these two tasks in AIX and how they were resolved are described as follows.

Prior to implementing DLPAR, software page descriptors could be accessed in translation-off mode (where virtual address is used as real address) while trying to reload a page mapping into the hardware page table. If page descriptors are allowed to be accessed in translation-off mode, then the memory allocated for the incoming new descriptors has to be physically contiguous to the memory for the existing descriptors; which implies that memory has to be reserved at boot-time for enough descriptors for the maximal amount

of memory that the OS instance can grow into. This reservation can incur much memory wastage and performance degradation, particularly if not utilized. We avoided this wastage by changing the AIX kernel so that software page descriptor data structures are always accessed in translation-on mode.

The challenge of distributing the incoming memory across different page replacement daemons, so that each daemon handles a roughly equal load was resolved as follows:

In AIX, memory is hierarchically represented by the data structures vmpool, mempool, and frameset. A vmpool represents an affinity domain of memory. A vmpool is divided into multiple mempools, and each mempool is managed by a single page replacement LRU (least recently used) daemon. Each mempool is further subdivided into one or more framesets that contain the free-frame lists, so as to improve the scalability of free-frame allocators. When new memory is added to AIX, the vmpool that it should belong to is defined by the physical location of the memory chip. Within that vmpool, we wanted to distribute the

memory across all the available mempools to balance the load on page replacement daemons. However, the kernel assumed that a mempool consisted of physically contiguous memory. Thus, to be able to break up the new memory (LMB) into several parts and distribute them across different mempools, the kernel was modified to allow mempools to be made up of discontiguous sections of memory.

DLPAR Removal of a Memory Block (LMB)

This is by far the hardest-to-implement of all the DLPAR operations, particularly when there are ongoing DMA operations in the OS instance. For the purpose of DLPAR memory removal, we classify the memory page-frames in AIX into five categories: unused, page-able, pinned, DMA-mapped, and translation-off memory. The approach taken to remove a page-frame (4,096 bytes) in each of these categories is as follows:

1. A page-frame containing a free/unused page is simply removed from its free-list.
2. A page-frame containing a page-able page can be made to either page out its contents to disk or to migrate its contents to a different free page-frame.
3. A page-frame containing a pinned page will have its contents migrated to a different page-frame; also the page-fault reload handler had to be made to spin during the migration.
4. A page-frame containing a DMA-mapped page cannot be removed nor have its contents migrated until all the accesses to the page are blocked. Here, the term “DMA-mapped page-frame” is used generically to mean a page-frame whose physical address is subject to read or write by an external (to kernel) entity such as a DMA engine. The contents of a DMA-mapped page-frame are migrated to a different page-frame with a new hypervisor call (*h_migrate_dma*) that will selectively suspend the bus traffic while it is modifying the TCEs (translation control entries) in system memory used by the bus unit controller for DMA accesses.

Other page-frames whose physical addresses are exposed to external entities are handled by invoking preregistered DLPAR callback routines and then waiting for completion of the removal of their dependencies on the page.

5. A page-frame containing translation-off pages will not be removed by DLPAR in AIX 5.2. Fortunately,

there is just a small amount of these page-frames, and they are usually collocated in low memory.

The design and implementation of DLPAR memory removal has manifested itself as three modular functions, such that one can mix and match these functions in several possible ways, adapting to the state of the system at the time of memory removal, thus achieving the desired end result with the most optimal path. These three modular functions perform, respectively, the following three tasks on the memory (LMB) being removed:

- (a) Remove its free and clean pages from the regular use of VMM (Virtual Memory Manager)
- (b) Page out its page-able dirty pages
- (c) Migrate the contents of each remaining page-frame in the LMB to a free page-frame outside the LMB

Memory removal can be implemented with any one of the sequences: abc, ac, bc, or just c. For example, the decision to either invoke page-out (task b) or to migrate (task c) all the pages depends on the load in the LPAR at that particular time. If the LMB being removed contains a lot of dirty pages that belong to highly active threads, then it does not make sense to invoke task b, because these pages will be paged back in almost immediately, hence negatively impacting the efficiency of the system.

As a second example, if there are not enough free frames in other LMBs to migrate the pages to, then the memory removal procedure can invoke task b before invoking task c, so that there will be far fewer pages left that need to be migrated in task c.

DLPAR of I/O Slots

The methods to dynamically configure or unconfigure a device have been introduced as early as AIX version 3. The changes required in the kernel design for the DLPAR of I/O slots were not in the same scale as those for the DLPAR of processors, and particularly as those for the DLPAR of memory. The reason is that the onus of configuring or unconfiguring a device lies with the device driver software, which operates in the kernel extension environment. The kernel just acts as a provider of serialization mechanisms for devices accessing common resources, and as an intermediary between the applications and the device drivers.

Values and Uses of DLPAR

DLPAR is the foundation of many advanced technologies for ensuring scalability, reliability, and full utilization of the resources in POWER Systems servers. It opens up a whole set of possibilities for great flexibility in dealing with dynamically changing workload demands, server consolidations of workloads from different time zones, and high availability for applications.

Some Obvious Values Enabled by DLPAR

- Ability to dynamically move processors and memory from a *test LPAR* to a *production LPAR* in periods of peak production workload demand, then move them back as demand decreases.
- Ability to programmatically and dynamically move processors and memory from less loaded LPARs to busy LPARs, whenever the need arises [14]. This is particularly useful for economically providing resources to LPARs that service *workloads in different time zones* or even different continents.
- Ability to dynamically *move an infrequently used I/O device* between LPARs, such as a CD/DVD/tape drives for installations, applying updates, and for backups. Occasionally, one may also want to move Ethernet adaptors and disk drives dynamically from 1 LPAR to another.
- Ability to dynamically release a set of processor, memory, and I/O resources into the “free pool,” so that a *new LPAR can be created* using the resources in the free pool.
- Providing high availability for the applications in an LPAR. For example, you can configure a set of minimal LPARs on a single system to act as “failover” backup LPARs to a set of primary LPARs, and also keep some set of resources free. If one of the associated primaries fails, then its backup LPAR can pick up the workload, and resources can be dynamically added to the backup LPAR as needed.

Some Non-Obvious Values Enabled by DLPAR

- *Dynamic CPU Guard*, which is the automatic and graceful de-configuration of a processor which has intermittent errors.
- *Dynamic CPU Sparing*, which is the Dynamic CPU Guard feature enhanced with automatic enablement of a spare CPU to replace a defective CPU.

- *CUoD* (Capacity Upgrade on Demand), which allows a customer to activate preinstalled but inactive and unpaid for processors as resource needs arise, as soon as IBM is notified and enables the corresponding license keys. Many enterprises with seasonally varying business activities extensively utilize this feature in their IT infrastructure.
- *Hot repair of PCI devices*, and possibly future hot repair of MCM (Multi-Chip Modules).
- *The failover of an LPAR to another LPAR in another physical server, used with the IBM HACMP LPP* (Licensed Program Product). This is detailed in the 60-page IBM Redpaper titled “HACMP v5.3, Dynamic LPAR, and Virtualization” [8]. HACMP is acronym for High Availability Cluster Multiprocessing. It is IBM’s solution for high-availability clusters on the AIX and Linux POWER platforms.

DLPAR-Safe, DLPAR-Aware, and DLPAR-Friendly Programs/Applications

A *DLPAR-safe program* is one that does not fail as a result of DLPAR operations. Its performance may suffer when resources are taken away, and performance may not scale up when new resources are added. However, by default, most applications are DLPAR-safe, and only a few applications are expected to be impacted by DLPAR.

A *DLPAR-aware program* is one that has code that is designed to adjust its use of system resources commensurate with the actual resources of the LPAR, which is expected to vary over time. This may be accomplished in two ways.

The first way is by regularly polling the system to discover changes in its LPAR resources.

The second way is by registering a set of DLPAR code that is designed to be executed in the context of a DLPAR operation. At a minimum, DLPAR-aware programs are designed to avoid introducing conditions that may cause DLPAR operations to fail. They are not necessarily concerned with the impact that DLPAR may have on their performance.

A *DLPAR-friendly program* is a DLPAR-aware application or middleware that automatically tunes itself in response to the changing LPAR resources. AIX provides a set of DLPAR scripts and APIs for applications to dynamically resize. Notable vendor applications

that are DLPAR-friendly include IBM DB2 [4], Lotus Domino [5], Oracle [6], etc.

More information about these scripts and APIs can be found in chapter 18 (Dynamic Logical Partitioning) of the online IBM manual “*AIX Version 6.1 General Programming Concepts*” [7].

To maintain expected levels of application performance when memory is removed, buffers may need to be drained and resized. Similarly when memory is added, buffers may need to be dynamically increased to gain performance.

Similar treatment needs to be applied to threads, whose numbers, at least in theory, need to be dynamically adjusted to the changes in the number of online CPUs. However, thread-based adjustments are not necessarily limited to CPU-based decisions; for example, the best way to reduce memory consumption in Java programs may be to reduce the number of threads, since this should reduce the number of active objects that need to be preserved by the Java Virtual Machine’s garbage collector.

Future Directions

Future uses of DLPAR are already being explored; among these are:

- Power/energy conservation for the server by dynamically DLPAR-remove of unused CPUs and memory
- Dynamic hot repair of server components, even MCM (Multi-Chip Modules)

Japan Agency for Marine-Earth Science and Technology
(JAMSTEC), Yokohama, Japan

Synonyms

ES

Definition

The Earth Simulator is a highly parallel vector supercomputer system consisting of 640 processor nodes and an interconnection network.

Discussion

The Earth Simulator, which was developed, as a national project, by three governmental agencies, the National Space Development Agency of Japan (NASDA), the Japan Atomic Energy Research Institute (JAERI), and Japan Marine Science and Technology Center (JAMSTEC), was led by Dr. Hajime Miyoshi. The ES is housed in the Earth Simulator Building (approximately 50 m × 65 m × 17 m). The fabrication and installation of the ES at the Earth Simulator Center of JAMSTEC by NEC was completed at the end of February in 2002. It was first on the Top500 list for two and a half years starting in June 2002 ([Fig. 1](#)).

Hardware

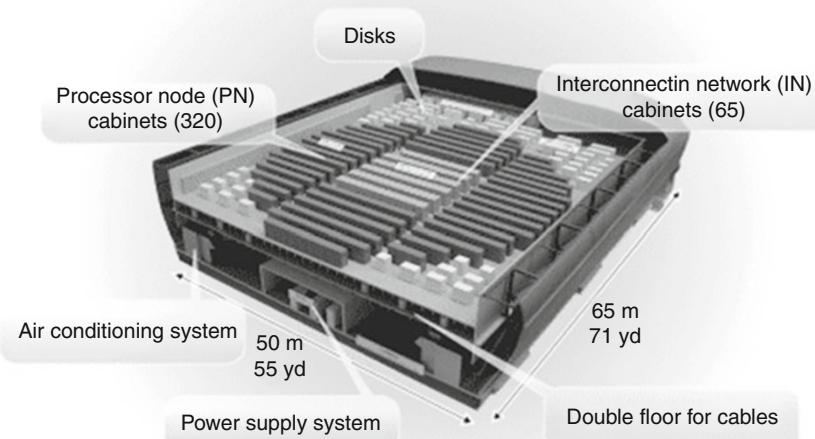

The ES is a highly parallel vector supercomputer system of the distributed-memory type, and consisted of 640 processor nodes (PNs) connected by 640×640 single-stage crossbar switches. Each PN is a system with a shared memory, consisting of eight vector-type arithmetic processors (APs), a 16-GB main memory system (MS), a remote access control unit (RCU), and an I/O processor. The peak performance of each AP is 8 Gflops.

The ES as a whole thus consists of 5,120 APs with 10 TB of main memory and the theoretical performance of 40 Tflops.

Each AP consists of a four-way super-scalar unit (SU), a vector unit (VU), and main memory access control unit on a single LSI chip. The AP operates at a clock frequency of 500 MHz with some circuits operating at 1 GHz. Each SU is a super-scalar processor with 64 KB instruction caches, 64 KB data caches, and 128 general-purpose scalar registers. Branch prediction, data prefetching, and out-of-order instruction execution are all employed. Each VU has 72 vector registers, each of which has 256 vector elements, along with eight sets of six different types of vector pipelines: addition/shifting, multiplication, division, logical operations, masking, and load/store. The same type of vector pipelines works together by a single vector instruction and pipelines of different types can operate concurrently. The VU and SU support the IEEE 754 floating-point data format. This LSI chip technology is 150 nm CMOS and eight layers copper interconnection. The die size is 20.79 mm × 20.79 mm. It has 60 million transistors and 5,185 pins. The maximum power consumption is 140 W.

The overall MS is divided into 2,048 banks and the sequence of bank numbers corresponds to increasing addresses of locations in memory. Therefore, the peak throughput is obtained by accessing contiguous data which are assigned to locations in increasing order of memory address.

The RCU is directly connected to the crossbar switches and controls internode data communications at 12.3 GB/s bidirectional transfer rate for both sending and receiving data. Thus the total bandwidth of internode network is about 8 TB/s. Several data-transfer modes, including access to three-dimensional (3D) sub-arrays and indirect access modes, are realized in hardware. In an operation that involves access to the data of a sub-array, the data is moved from one PN to

Earth Simulator. Fig. 1 Bird's-eye view of the earth simulator system

another in a single hardware operation, and relatively little time is consumed for this processing.

The Interconnection Network (IN) cabinet has two switches of 640×640 . The signal from PN changes from Serial to Parallel and is inputted into a switching circuit. The signal which came out from the switching circuit is performed Parallel/Serial conversion. Then, it is sent to PN cabinet. The number of Cables which connects PN cabinet and IN cabinet is $640 \times 130 = 83,200$, and the total extension is 2,400 km.

MDPS

In October 2003, Mass Data Processing System (MDPS) was installed as a massively data storage system which renews the tape library system. It consists of four file service processors (FSPs), 250 TB hard disk drives, and a currently used 1.5 PB cartridge tapes library (CTL).

MDPS was adopted aiming to improve data transfer throughput and accessibility.

1. The transfer speed of saving and extracting the data between the ES and the storage became two to five-times faster. This improvement can be realized by expansion of transfer cable ability and replacement of a tape archive with disks.

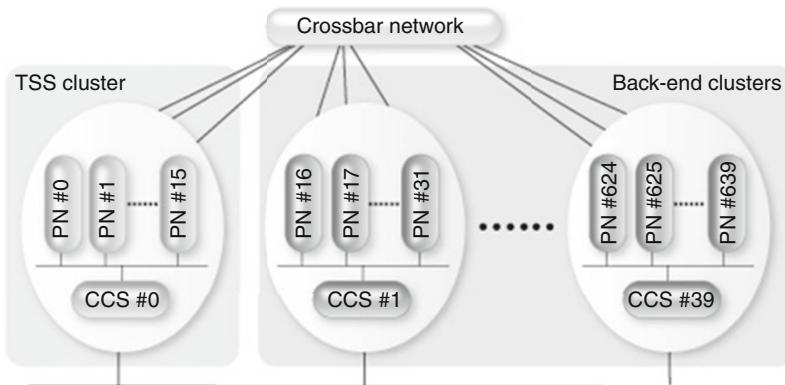

2. User view is a very large disk and usual UNIX commands and tools can access the MDPS data on the login server. Data I/O procedure becomes easy.
3. MDPS enables users to access the results computed by ES remotely, because it can transfer the data to a dedicated server out of ES LAN (ES-Network FTP Server).

Operating System

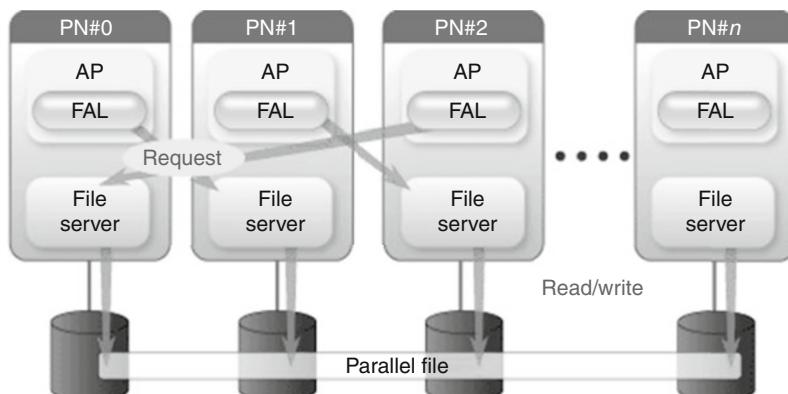

The operating system running on ES is an enhanced version of NEC's UNIX-based OS called "SUPER-UX" that is developed for NEC's SX Series supercomputers. To support ultra-scale scientific computations, SUPER-UX was enhanced mainly in the following two points:

1. Extending scalability
2. Providing special features for ES

Extending scalability up to the whole system (640 PNs) is the major requirement for the OS of ES. All functions of the OS, such as process management, memory management, file management, etc., are fully optimized to fulfill the requirement. For example, any of the OS tasks costing order n , such as scattering data in sequence over all PNs, is replaced with the equivalent one costing order $\log n$, such as binary-tree copy, if possible, where n is the number of PNs.

Earth Simulator. Fig. 2 Super cluster system of ES: a hierarchical management system is introduced to control the ES. Every 16 nodes are collected as a cluster system and therefore, there are 40 sets of cluster in total. A set of cluster is called an “S-cluster” which is dedicated for interactive processing and small-scale batch jobs. A job within one node can be processed on the S-cluster. The other sets of cluster is called “L-cluster” which are for medium-scale and large-scale batch jobs. Parallel processing jobs on several nodes are executed on some sets of cluster. Each cluster has a cluster control station (CCS) which monitors the state of the nodes and controls electricity of the nodes belonged to the cluster. A super cluster control station (SCCS) plays an important role of integration and coordination of all the CCS operations.

Earth Simulator. Fig. 3 Parallel file system (PFS): A parallel file, i.e., file on PFS is striped and stored cyclically in the specified blocking size into the disk of each PN. When a program accesses to the file, the File Access Library (FAL) sends a request for I/O via IN to the File Server on the node that owns the data to be accessed

On the other hand, the OS provides some special features which aim for efficient use or administration of such a large system. The features include internode high-speed communication via IN, global address space among PNs, super cluster system (Fig. 2), batch job environment, etc.

Parallel File System

If a large parallel job running on 640 PNs reads from/writes to one disk installed in a PN, each PN accesses to the disk in sequence, and performance degrades terribly. Although local I/O in which each PN

reads from or writes to its own disk solves the problem, it is a very hard work to manage such a large number of partial files. Therefore, parallel I/O is greatly demanded in ES from the point of view of both performance and usability. The parallel file system (PFS) provides the parallel I/O features to ES (Fig. 3). It enables handling multiple files, which are located on separate disks of multiple PNs, as logically one large file. Each process of a parallel program can read/write distributed data from/to the parallel file concurrently with one I/O statement to achieve high performance and usability of I/O.

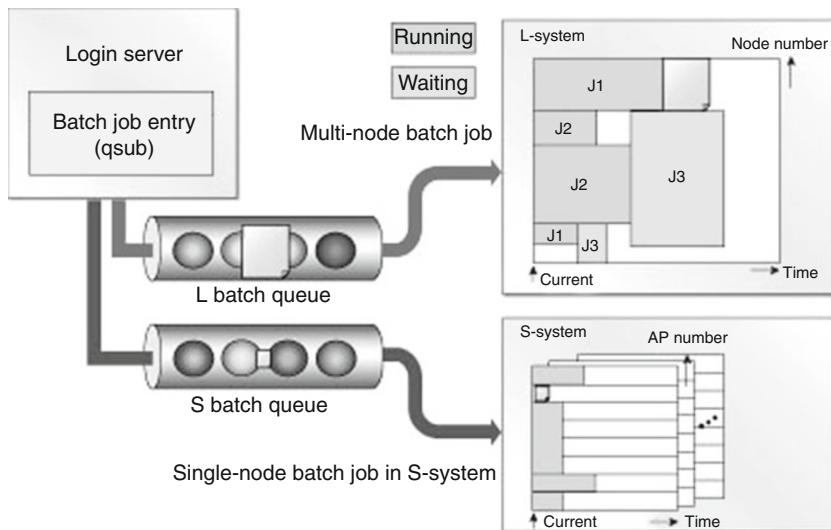

Job Scheduling

ES is basically a batch-job system. Network Queuing System II (NQSII) is introduced to manage the batch job (Fig. 4).

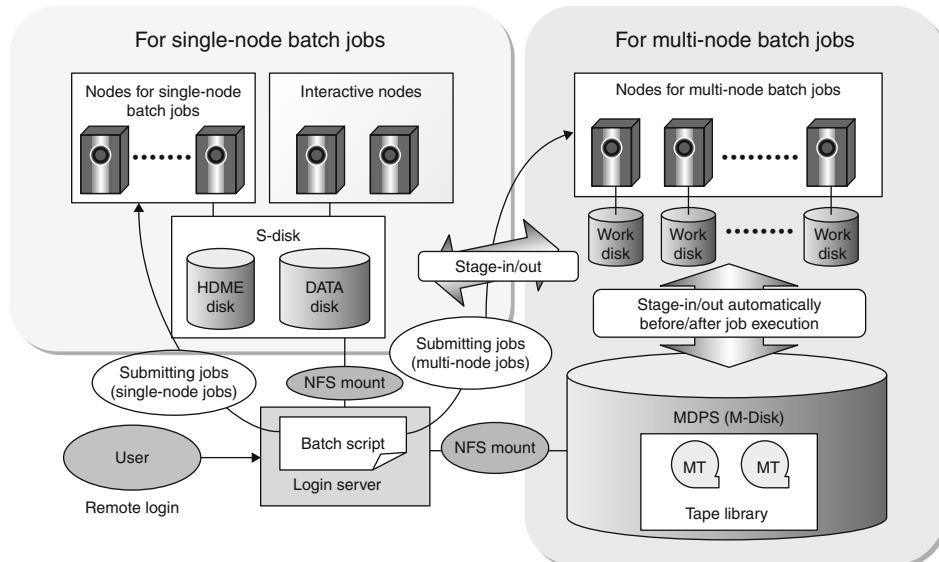

There are two type queues. One is L batch queue and the other is S batch queue. S batch queue is aimed at being used for a pre-run or a post-run for large-scale

batch jobs (making initial data, processing results of a simulation, and other processes), and L batch queue is for a production run. Users choose an appropriate queue for their jobs.

S batch queue is designed for single-node batch jobs. In S batch queue, Enhanced Resource Scheduler (ERSII) is used as a scheduler and does a job scheduling based

Earth Simulator. Fig. 4 Shows the queue configuration of ES

Earth Simulator. Fig. 5 Job execution. The user writes a batch script and submits the batch script to ES. The node scheduling, the file staging, and other processing are automatically processed by the system

on CPU time. On the other hand, L batch queue is for multi-node batch jobs. In this queue, the customized scheduler for ES is used as the scheduler. We have been developing this scheduler with following strategies:

1. The nodes allocated to a batch job are used exclusively for that batch job.
2. The batch job is scheduled based on elapsed time instead of CPU time.

Strategy (1) enables to estimate the job termination time and to make it easy to allocate nodes for the next batch jobs in advance. Strategy (2) contributes to an efficiency

job execution. The job can use the nodes exclusively and the processes in each node can be executed simultaneously. As a result, the large-scale parallel program is able to be executed efficiently.

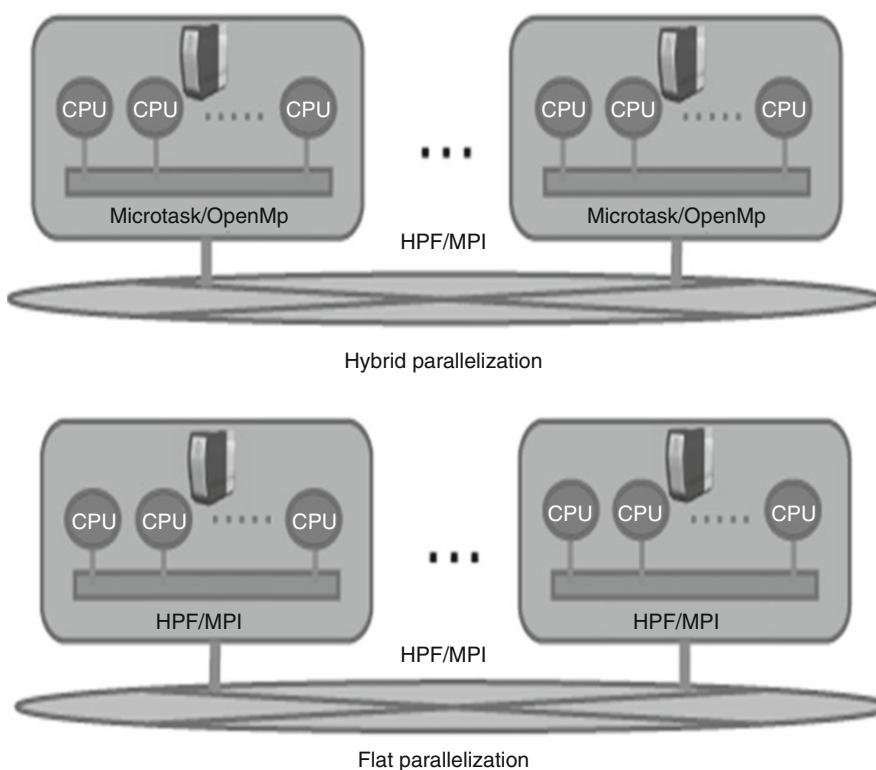

PNs of L-system are prohibited from access to the user disk to ensure enough disk I/O performance. Therefore, the files used by the batch job are copied from the user disk to the work disk before the job execution. This process is called “stage-in.” It is important to hide this staging time for the job scheduling.

Main steps of the job scheduling are summarized as follows:

1. Node allocation
2. Stage-in (copies files from the user disk to the work disk automatically)
3. Job escalation (rescheduling for the earlier estimated start time if possible)
4. Job execution
5. Stage-out (copies files from the work disk to the user disk automatically)

Earth Simulator. Table 1 Programming model on ES

	“Hybrid”	“Flat”
Inter-PN	HPF/MPI	HPF/MPI
Intra-PN	Microtasking/openMP	
AP	Automatic vectorization	

Earth Simulator. Fig. 6 Two types of parallelization of ES

When a new batch job is submitted, the scheduler searches available nodes (Step 1). After the nodes and the estimated start time are allocated to the batch job, stage-in process starts (Step 2). The job waits until the estimated start time after stage-in process is finished. If the scheduler finds the earlier start time than the estimated start time, it allocates the new start time to the batch job. This process is called “Job Escalation” (Step 3). When the estimated start time has arrived, the scheduler executes the batch job (Step 4). The scheduler terminates the batch job and starts stage-out process after the job execution is finished or the declared elapsed time is over (Step 5) ([Fig. 5](#)).

Programming Model in ES

The ES hardware has a three-level hierarchy of parallelism: vector processing in an AP, parallel processing with shared memory in a PN, and parallel processing among PNs via IN. To bring out high performance of ES fully, you must develop parallel programs that make the most use of such parallelism.

As shown in [Table 1](#), the three-level hierarchy of parallelism of ES can be used in two manners, which are called hybrid and flat parallelization, respectively ([Fig. 6](#)). In the hybrid parallelization, the internode parallelism is expressed by HPF or MPI, and the intranode by microtasking or OpenMP, and you must, therefore, consider the hierarchical parallelism in writing your programs. In the flat parallelization, the both inter- and intranode parallelism can be expressed by HPF or MPI, and it is not necessary for you to consider such complicated parallelism. Generally speaking, the hybrid parallelization is superior to the flat in performance and vice versa in ease of programming. Note that the MPI libraries and the HPF runtimes are optimized to perform as well as possible both in the hybrid and flat parallelization.

Eden

RITA LOOGEN

Philipps-Universität Marburg, Marburg, Germany

Definition

Eden is a parallel functional programming language that extends the non-strict functional language Haskell with constructs for the definition and instantiation of parallel processes. The programmer is freed from managing synchronization and data exchange between processes while keeping full control over process granularity, data distribution, and communication topology. Eden is geared toward distributed settings, that is, processes do not share any data. Common and sophisticated parallel communication patterns and topologies, that is, algorithmic skeletons, are provided as higher-order functions in a skeleton library written in Eden.

Eden is implemented on the basis of the Glasgow Haskell Compiler GHC [[31](#)], a mature and efficient Haskell implementation. While the compiler frontend is almost unchanged, the backend is extended with a *parallel* runtime system (PRTS) [[7](#)]. This PRTS uses suitable middleware (currently PVM or MPI) to manage parallel execution.

Discussion

Introduction

Functional languages are promising candidates for parallel programming, because of their high level of abstraction and, in particular, because of their referential transparency. In principle, any sub-expression could be evaluated in parallel. As this implicit parallelism would lead to too much overhead, modern parallel functional languages allow the programmers to specify parallelism explicitly. The underlying idea of Eden is to enable programmers to specify process networks in a declarative way. Processes map input to output values. Inputs and outputs are transferred via unidirectional one-to-one channels. A comprehensive definition of Eden including a discussion of its formal semantics and its implementation can be found in the journal paper [[27](#)]. We describe only the essentials here.

Basic Eden Constructs

The basic Eden coordination constructs are *process abstraction* and *instantiation*:

```
process :: (Trans a, Trans b) =>
  (a -> b) -> Process a b
(#)    :: (Trans a, Trans b) =>
  Process a b -> a -> b
```

The function `process` embeds functions of type `a -> b` into *process abstractions* of type `Process a b`, while the instantiation operator (`#`) takes such a process abstraction and input of type `a` to create a new process which consumes the input and produces output of type `b`. Thus, the instantiation operator leads to a function application, with the side effect that the function is evaluated by a remote child process. Its argument is concurrently, that is, by a new thread, evaluated in the parent process and sent to the child process which, in turn, fully evaluates and sends back the result of the function application. Both processes are using *implicit 1:1 communication channels* established between child and parent process on process instantiation.

The type context `(Trans a, Trans b)` states that both `a` and `b` must be types belonging to the type class `Trans` of transmissible values. In general, Haskell type classes provide a structured way to define overloaded functions. `Trans` defines *implicitly* used communication functions which by default transmit normal form values in a single piece. The overloading is used twofold. Lists are communicated element-wise as streams and tuple components are evaluated concurrently. An independent thread will be created for each component of an output tuple and the result of its evaluation will be sent on a separate channel. The connection points of channels to processes are called *imports* on the receiver side and *outports* on the sender side. There is a one-to-one correspondence between the threads and the outports of a process while data that is received via the imports is shared by all threads of a process. Analogously, several threads will be created in a parent process for tuple inputs of a child process. During its lifetime, an Eden process can thus contain a variable number of threads.

The demand-driven (lazy) evaluation of Haskell is an obstacle for parallelism. A completely demand-

driven evaluation creates a parallel process only when its result is already needed to continue the main evaluation. This suppresses any real parallel evaluation. Although Eden overrules the lazy evaluation, for example, by evaluating inputs and outputs of processes eagerly and by sending those values immediately to the corresponding recipient processes, it is often necessary to use explicit demand control in order to start processes speculatively before their result values are needed by the main computation. Evaluation strategies [32] are used for that purpose. We will not go into further details. In the following, we will use the (pre-defined) Eden function `spawn` to eagerly and immediately instantiate a finite list of process abstractions with their corresponding inputs. Appropriate demand control is incorporated in this function. Neglecting demand control, `spawn` would be defined as follows:

```
spawn :: (Trans a, Trans b) =>
  [Process a b] -> [a] -> [b]
-- definition without demand control
spawn = zipWith (#)
```

The variant `spawnAt` additionally locates the created processes on given processor elements (identified by their number).

```
spawnAt :: (Trans a, Trans b) =>
  [Int] -> [Process a b] -> [a] -> [b]
```

Example: A parallel variant of the function `map :: (a -> b) -> [a] -> [b]` which creates a process for each application of the parameter function to an element of the input list can be defined as follows:

```
parMap :: (Trans a, Trans b) =>
  (a -> b) -> [a] -> [b]
parMap f
= spawn (repeat (process f))
```

The Haskell prelude function `repeat :: a -> [a]` yields a list infinitely repeating the parameter element. □

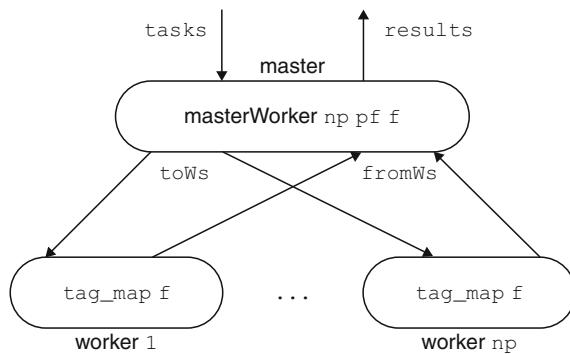

To model many-to-one communication, Eden provides a nondeterministic function `merge` that merges a list of streams into a single stream.

```
merge :: Trans a => [[a]] -> [a]
```

This function can, for example, be used by the master in a master-worker system to receive the results of the workers as a single stream in the time-dependent order in which they are provided.

Although `merge` is of great worth, because it is the key to specify many reactive systems, one has to be aware that functional purity and its benefits are lost when `merge` is being used in a program. Fortunately, functional purity can be preserved in most portions of an Eden program. In particular, it is, for example, possible to use sorting in order to force a particular order of the results returned by a `merge` application and thus to encapsulate `merge` in a deterministic context.

Example: A simple master-worker system with the following functionality can easily be defined in Eden as shown in Fig. 1. The master process distributes tasks to worker processes, which solve the tasks and return the results to the master:

The Eden function `masterWorker` (evaluated by the “master” process) takes four parameters: `np` specifies the number of worker processes that will be spawned, `prefetch` determines how many tasks will initially be sent by the master to each worker process, the function `f` describes how tasks have to be solved by the workers, and the final parameter `tasks` is the list of tasks that have to be solved by the whole system. The auxiliary pure Haskell function `distribute :: Int -> [a] -> [Int] -> [[a]]` (code not shown) is used to distribute the tasks to the workers. Its first parameter determines the number of output lists, which become the input streams for the worker processes. The third parameter is the request list `reqs` which guides the task distribution. The same list is used to sort

the results according to the original task order (function `orderBy :: [[b]] -> [Int] -> [b]`, code not shown).

Initially, the master sends as many tasks as specified by the parameter `prefetch` in a round-robin manner to the workers (see definition of `initReqs`). Further tasks are sent to workers which have delivered a result. The list `newReqs` is extracted from the worker results tagged with the corresponding worker id which are merged according to the arrival of the worker results. This simple master-worker definition has the advantage that the tasks need not be numbered to reestablish the original task order on the results. Moreover, worker processes need not send explicit requests for new work together with the result values.

Defining Non-hierarchical Process Networks in Eden

With the Eden constructs introduced up to now, communication channels are only established between parent and child processes during process creation. This results in purely hierarchical process topologies. Eden further provides functions to create and use explicit channel connections between arbitrary processes. These functions are rather low level and it is not easy to use them appropriately. Therefore, we will not show them here, but explain two more abstract approaches to define non-hierarchical process networks in Eden: remote data and graph specifications.

Remote data of type `a` is represented by a handle of type `RD a` with the following interface functions [13]:

```
release :: a -> RD a
fetch   :: RD a -> a.
```

The function `release` yields a remote data handle that can be passed to other processes, which will in turn use the function `fetch` to access the remote data. The data transmission occurs automatically from the process that releases the data to the process which uses the handle to fetch the remote data.

Example: We show a small example where the remote data concept is used to establish a direct channel connection between sibling processes. Given functions `f` and `g`, one can calculate $(g \circ f) a$ in parallel creating a process for each function.

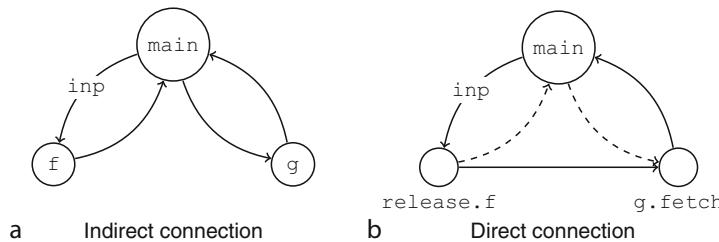

```

masterWorker :: (Trans a, Trans b) =>
               Int → Int → (a → b) → [a] → [b]
masterWorker np prefetch f tasks
= orderBy fromWs reqs
where
  fromWs = spawn workers toWs
  workers = process (tag_map f) | n ← [1..np]
  toWs = distribute np tasks reqs
  newReqs = merge [[i | r ← rs] | (i, rs) ← zip [1..np] fromWs]
  reqs = initReqs ++ newReqs
  initReqs = concat (replicate prefetch [1..np])

```

E

Eden. Fig. 1 Eden definition of a simple master-worker system

Eden. Fig. 2 A simple process graph

Simply replacing the function calls by process instantiations

```
(process g # (process f # inp))
```

leads to the process network in Fig. 2a where the process evaluating the above expression is called `main`. Process `main` instantiates a first child process calculating `g`, thereby creating a concurrent thread to evaluate the input for the new child process. This thread instantiates the second child process for calculating `f`. It receives the remotely calculated result of the `f` process and passes it to the `g` process. The drawback of this approach is that the result of the `f` process will not be sent directly to the `g` process. This causes unnecessary communication costs.

In the second implementation, we use remote data to establish a direct channel connection between the child processes:

```
process (g o fetch) #
  (process (release of) # inp)
```

It uses function `release` to produce a handle of type `RD a` for data of type `a`. Calling `fetch` with remote data returns the value released before. The use of remote

data leads to a direct communication of the actual data between the processes evaluating `f` and `g` (see Fig. 2b). The remote data handle is treated like the original data in the first version, that is, it is passed via the main process from the process computing `f` to the one computing `g`. \triangleleft

The remote data concept enables the programmer to easily build complex topologies by combining simpler ones [13].

Grace

(Graph-based Communication in Eden) is a library that allows a programmer to specify a network of processes as a graph, where the graph nodes represent processes and the edges of communication channels [22]. The graph is described as a Haskell data structure `ProcessNetwork a`, where `a` is the type of the result computed by the process network. A function `build` is used to define a process network, while a function `start` instantiates such a network and automatically sets up the corresponding process topology, that is, the processes are created and the necessary communication channels are installed.

```

build :: forall f a g r p n e.
    -- type context
    (Placeable f a g r p,
     Ord e, Eq n) =>
    (n, f)      -> -- main node
    [Node n]    -> -- node list
    [Edge n e]  -> -- edge list
    ProcessNetwork r
start :: (Trans a) =>
    ProcessNetwork a -> a
  
```

The function `build` transforms a graph specification into a value of type `ProcessNetwork r`. The graph is defined by a list of nodes of type `[Node n]` and a list of edges of type `[Edge n e]`. Type variables `n` and `e` represent the types of node and edge labels, respectively. To allow functions with different types to be associated with graph nodes, the type `f` of node functions is existentially quantified and only explicitly given for the main node, because the function placed on the main node determines the result type `r` of the process network. This is also the reason why the main node is not a member of the node list but provided as a separate parameter. The function `build` uses multiparameter classes with functional dependencies and explicit quantification to achieve flexibility in the specification of graphs, for example, by placing arbitrary functions on nodes and nevertheless using standard Haskell lists to represent node lists. The type context `Ord e` and `Eq n` ensures that edges can be ordered by their label and that nodes can be identified by their label. `Placeable` is a multiparameter type class with dependent types, which is used by the Grace implementation to partition user supplied function types into their parts, for example,

```

example = start network
where
  -- fct. spec. of process behaviour
  f, g, root :: (Trans a) -> [a] -> [a]
  ...
  -- process graph specification
  network = build ("root", root) nodes edges
  nodes   = [N "nd_f" f, N "nd_g" g]
  edges   = [E "nd_f" "nd_g" 0 nothing,
            E "nd_g" "root" 0 nothing,
            E "root" "nd_f" 0 nothing]
  
```

parameter and result types. This is needed to create individual channels for these parts. Suitable instances will be derived automatically for every possible function. In the type context `Placeable f a g r p` the function's type `f` determines the other types: `a` is the type of the function's first argument, `g` is the remaining part of the function's type without the first argument. The final result type of the function after applying all parameters is `r`. Finally, `p` is a type level list of all the parameters.

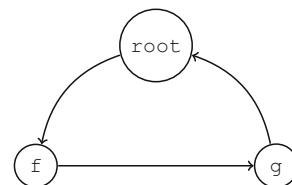

The main benefit of Grace is a clean separation between coordination and computation. The network specification encapsulates the coordination aspects. The graph nodes are annotated with functions describing the computations of the corresponding processes.

Example: We consider again a simple process network which is similar to the one in Fig. 2b and show its specification in Grace. The behavior of the three processes is specified by functions `f`, `g`, and `root`. The communication topology is defined by a graph consisting of three nodes (a root node and two additional nodes) and three edges. The specification is shown in Fig. 3. \triangleleft

Algorithmic Skeletons

Algorithmic skeletons [11] capture common patterns of parallel evaluations like task farms, pipelines, divide-and-conquer schemes, etc. The application programmer only needs to instantiate a skeleton appropriately, thereby concentrating on the problem-specific matters and trusting on the skeleton with respect to all parallel details.

The small introductory example functions `parMap` and `masterWorker` shown above are examples for skeleton definitions in Eden. In Eden and other parallel functional languages, skeletons are no more than polymorphic higher-order functions which can be applied

Eden. Fig. 3 Grace specification of a simple process graph

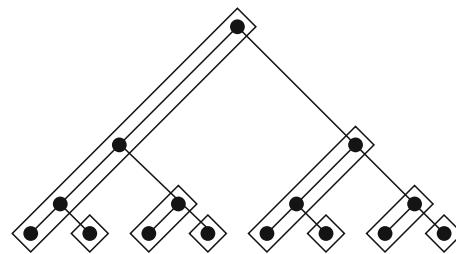

with different types and parameters. Thus, programming with skeletons follows the same principle as programming with higher-order functions. An important issue is that skeletons can be both *used* and *implemented* in Eden. In other skeletal approaches, the creation of new skeletons is considered as a system programming task, or even as a compiler construction task. Skeletons are implemented by using imperative languages and/or parallel libraries. Therefore, these systems offer a closed collection of skeletons which the application programmer can use, but without the possibility of creating new ones, so that adding a new skeleton usually implies a considerable effort.

The Eden skeleton library contains a big collection of different skeletons. Various kinds of skeleton definitions in Eden together with cost models to predict the execution time of skeleton instantiations have been presented in a book chapter [26]. Parallel map implementations have been analyzed in [23]. An Eden implementation of the large-scale *map-and-reduce* programming model proposed by Google [12] has been investigated in [3]. Hierarchical master-worker schemes with several layers of masters and submasters can elegantly be created by nesting a simple single-layer master-worker scheme. More elaborate hierarchical master-worker systems have been discussed in [4].

Example: (A regular fixed-branching divide and conquer skeleton) As a nontrivial example of a skeleton definition we present a dynamically unfolding divide-and-conquer skeleton [2]. The essence of a divide-and-conquer algorithm is to decide whether the input is trivial and, in this case, to solve it, or else to decompose nontrivial input into a number of subproblems, which are solved recursively, and to combine the output. A general skeleton takes parameter functions for this functionality, as shown here:

```
type DivideConquer a b
= (a → Bool) → -- trivial?
  (a → b) → -- solve
  (a → [a]) → -- split
  ([b] → b) → -- combine
  a → b → -- input / result
```

The resulting structure is a tree of task nodes where successor nodes are the sub-problems, the leaves representing trivial tasks. A fundamental Eden skeleton which specifies a general divide and conquer algorithm structure can be found in [26]. Here, we show a version where every nontrivial task is split into a *fixed* number of sub-tasks. Moreover, the process tree is created in a *distributed* fashion: One of the tree branches is processed locally, the others are instantiated as new processes, as long as PEs are available. These branches will recursively produce new parallel subtasks, resulting in a *distributed expansion* of the computation. In the following binary tree of task nodes, the boxes indicate which task nodes will be evaluated by the eight processes:

In this setting, explicit placement of processes is essential to ensure that processes are not placed on the same processor element while leaving others unused. In [2], this kind of skeleton is compared with a *flat expansion* version, where the main process unfolds the tree up to a given depth, usually with more branches than available processor elements (PEs). The resulting subtrees can then be evaluated by a farm of parallel worker processes, the main process combines the results of the subprocesses. A master-worker system (as shown above) can be used to implement this version.

Figure 4 shows the distributed expansion divide-and-conquer skeleton for k -ary task trees. Besides the standard parameter functions, the skeleton takes the branching degree, and a ticket list with PE numbers to place newly created processes. The left-most branch of the task tree is solved locally, other branches are instantiated using the Eden function `spawnAt`, which instantiates a collection of processes (given as a list) with respective input, on explicitly specified PEs. Results are combined by the `combine` function.

Explicit Placement via Tickets: The ticket list is used to control the placement of newly created processes. First, the PE numbers for placing the immediate child

```

dcN :: ('Trans a, Trans b) =>
    Int → [Int] → -- branch degree/tickets
    DivideConquer a b
dcN k tickets trivial solve split combine x
| null tickets = seqDC x
| trivial x     = solve x
| otherwise      = ... -- code for demand control omitted
                    combine (myRes:childRes ++ localRes)
where
    -- sequential computation
    seqDC x = if trivial x then solve x
               else combine (map seqDC (split x))
    -- child process generation
    childRes = spawnAt childTickets childProcs procIns
    childProcs = map (process o rec_dcN) theirTs
    rec_dcN ts = dcN k ts trivial solve split combine
    -- ticket distribution
    (childTickets, restTickets) = splitAt (k-1) tickets
    (myTs: theirTs)             = unshuffle k restTickets
    -- input splitting
    (myIn:theirIn)              = split x
    (procIns, localIns)          = splitAt (length childTickets) theirIn
    -- local computations
    myRes = ticketF myTs myIn
    localRes = map seqDC localIns

```

Eden. Fig. 4 Distributed expansion divide and conquer skeleton for k -ary task trees

processes are taken from the ticket list. Then, the remaining tickets are distributed to the children in a round-robin manner using the function `unshuffle :: Int -> [a] -> [[a]]` which unshuffles a given list into as many lists as the first parameter tells. Child computations will be performed locally when no more tickets are available. The explicit process placement via ticket lists is a simple and flexible way to control the distribution of processes as well as the recursive unfolding of the task tree. If too few tickets are available, computations are performed locally. Duplicate tickets can be used to allocate several child processes on the same PE. \triangleleft

Implementation

Eden's implementation follows a microkernel approach. The kernel implements a few, general control mechanisms and provides them as primitive operations (see Fig. 5). The more complex high-level language constructs are implemented in libraries using the primitive base constructs. Apart from simplifying the implementation, this approach has important advantages with respect to productivity and maintainability of the system.

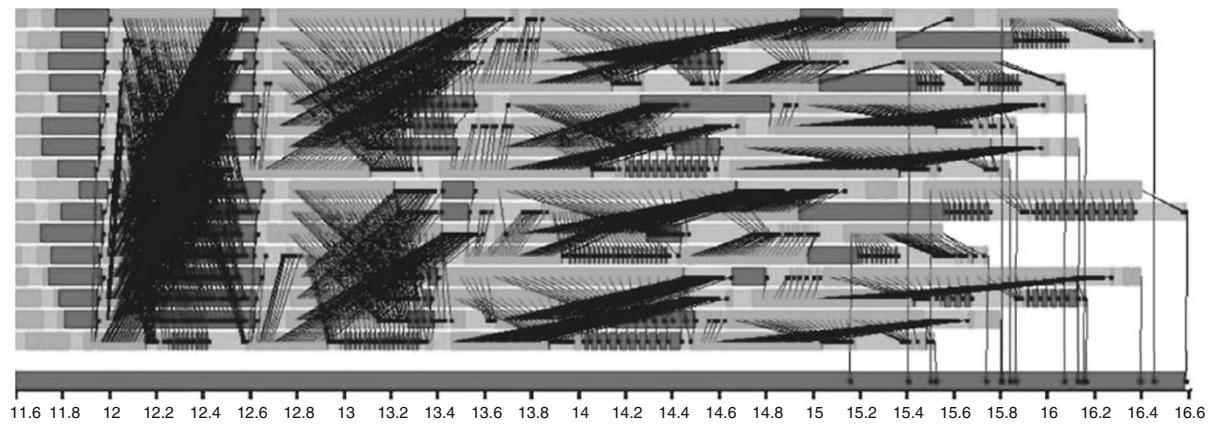

Details on Eden's implementation, especially on primitives provided by the interface of the parallel runtime system (PRTS) and the implementation of the Eden module can be found in [5, 7].

EdenTV – The Eden Trace Viewer Tool

The Eden trace viewer tool (EdenTV) [8] provides a *postmortem analysis* of program executions on the level of the computational units of the PRTS. The latter is instrumented with special trace generation commands activated by a runtime option. In the space-time diagrams generated by EdenTV, machines (i.e., processor elements), processes, and threads are represented by horizontal bars, with time on the x -axis. The diagram bars have segments in different colors, which indicate the activities of the respective logical unit in a period during the execution. Bars are grey, when the logical unit is running, light grey, when it is runnable, but currently not running, and dark grey, when the unit is blocked. Messages between processes or machines are optionally shown by gray arrows which start from the sending unit bar and point at the receiving unit bar. The representation of messages is very important for programmers, since they can observe

hot spots and inefficiencies in the communication during the execution as well as control communication topologies.

Figure 6 shows in grayscale (light grey = yellow, grey = green, dark grey = red) the trace of a recursive parallel quicksort in a hypercube of dimension 4 with message traffic, exposing the well-known butterfly communication pattern imposed by the hypercube structure.

Future Directions

Lines of future studies are

- It is planned for the future to maintain a *common parallel runtime environment* for Eden, Glasgow parallel Haskell (GpH), and other parallel Haskells. Such a common environment is highly desirable and

would improve the availability and acceptance of parallel Haskells.

- Recent results [9] show that the Eden system, although tailored for distributed memory machines, behaves equally well on workstation clusters and on *multi-core machines*. It needs to be investigated whether the Eden system can be optimized for multi-core machines by exploiting the shared memory and thereby avoiding unnecessary communications.
- We plan to design and investigate further skeletons. The flexibility of defining individual skeletons for several algorithm classes has not been completely exploited yet. Much more experience in the design and use of skeletons is necessary.
- Recent studies on remote data and the Grace system have shown that high-level parallel programming notations simplify parallel programming a lot. More

research is necessary to find even more abstract parallel programming constructs.

- Supporting tools like profiling, analysis, visualization, and debugging tools are essential for real-world parallel program development. Much more work is needed to further develop existing, and to design new powerful tools which help the programmers to analyze and tune parallel programs.

Glasgow parallel Haskell (GpH) is another parallel Haskell extension that is less explicit about parallelism than Eden. It provides a simple parallel combinator `par` to annotate sub-expressions that should be evaluated in parallel if free processing elements were available. In contrast to Eden, GpH assumes a global shared memory (at least virtually), and the parallel runtime system decides whether an annotated sub-expression will be evaluated in parallel or not.

NESL is a strict data-parallel functional language that supports nested parallel array comprehensions. Parallelism is hidden and concentrated in data-parallel operations.

SISAL (Streams and Iteration in a Single Assignment Language) and *MultiLisp* are early strict parallel functional languages. SISAL is a first-order functional language with implicit parallelism, a rich set of array operations and stream support. It has been designed for numerical applications. MultiLisp extends the LISP dialect Scheme with explicit parallel constructs, in particular so-called futures. Futures initiate parallel evaluations without forcing the main computation to wait for the result. In this respect, futures lead to a special form of laziness within a strict computation language.

Concurrent ML extends the strict functional language SML (Standard ML) with concurrency primitives like thread creation and synchronous message passing over explicit channels. Blocking send and

receive functions are provided for channel communication. First-class synchronous operations, called events, however, allow to hide channels and complex communication and synchronization protocols behind appropriate abstractions. In contrast to Eden and other parallel functional languages, Concurrent ML has been designed for concurrent programming, that is, with a focus on structuring software and not with the goal of speeding up computations. Recently, however, a shared-memory parallel implementation has been developed [30].

Manticore is a strict parallel functional language that supports different kinds of parallelism. In particular, it combines explicit concurrency in the style of Concurrent ML with various implicitly parallel constructs which provide fine-grain data parallelism.

Bibliographic Notes and Further Reading

The seminal book on research directions in parallel functional programming [17] edited by Hammond and Michaelson covers not only fundamental issues but also provides summaries about selected research areas. Various parallel and distributed variants of the functional programming language Haskell are discussed in a journal paper by Trinder et al. [33]. A comprehensive overview on patterns and skeletons for parallel and distributed programming can be found in a book edited by Gorlatch and Rabhi [29]. The three parallel functional languages, Glasgow parallel Haskell, PMLS (a parallel version of ML), and Eden, have been compared with respect to programming methodology and performance in [25].

Comprehensive and up-to-date information on Eden is provided on its web site

<http://www.mathematik.uni-marburg.de/~eden>

Basic information on its design, semantics, and implementation as well as the underlying programming methodology can be found in [27]. Details on the parallel runtime system and Eden's concept of implementation can best be found in [5, 7]. The technique of layered parallel runtime environments has been further developed and generalized by Berthold et al. [1, 10]. The Eden trace viewer tool EdenTV is available on Eden's web site. A short introductory description is given in [8]. Another tool for analyzing the behavior of Eden programs has been developed by de la Encina et al. [14, 15]

by extending the tool Hood (Haskell Object Observation Debugger) for Eden. Extensive work has been done on skeletal programming in Eden. An overview on various skeleton types have been presented as a chapter in the mentioned book by Gorlatch and Rabhi [26]. Definitions and applications of specific skeletons can, for example, be found in the following papers: parallel map [23], topology skeletons [6], adaptive skeletons [16], Google map-reduce [3], hierarchical master-worker systems [4], divide-and-conquer schemes [2]. Special skeletons for computer algebra algorithms are developed with the goal to define the kernel of a computer algebra system in Eden [24]. An operational and a denotational semantics for Eden have been defined by Ortega-Mallén and Hidalgo-Herrero [18, 19]. These semantics have been used to analyze Eden skeletons [20, 21]. A non-determinism analysis has been presented by Segura and Peña [28].

Eden is intensively being used in teaching parallel programming and algorithms and as a platform for investigating high-level parallel programming concepts, techniques, methodology, and parallel runtime systems. Up to now, its main use in practice has been the implementation of parallel computer algebra components [24, 34].

Acknowledgments

The author is grateful to Yolanda Ortega-Mallén, Jost Berthold, Mischa Dieterle, Thomas Horstmeyer, and Oleg Lobachev for their helpful comments on previous versions of this essay.

Eigenvalue and Singular-Value Problems

BERNARD PHILIPPE¹, AHMED SAMEH²

¹Campus de Beaulieu, Rennes, France

²Purdue University, West Lafayette, IN, USA

Definition

Given a matrix $A \in \mathbb{R}^{n \times n}$ or $A \in \mathbb{C}^{n \times n}$, an **eigenvalue problem** consists of computing eigen-elements of A which are:

either eigenvalues: these are the roots λ of the n -degree characteristic polynomial:

$$\det(A - \lambda I) = 0. \quad (1)$$

The set of all eigenvalues is called the spectrum of A : $\Lambda(A) = \{\lambda_1, \dots, \lambda_n\}$. Eigenvalues can be real or complex, whether the matrix is real or complex.

or eigenpairs: in addition to an eigenvalue λ , one seeks for the corresponding eigenvector $x \in \mathbb{C}^n - \{0\}$ which is the solution of the singular system

$$(A - \lambda I)x = 0. \quad (2)$$

When the matrix A is real symmetric or complex hermitian, the eigenvalues are real.

Given a matrix $A \in \mathbb{R}^{m \times n}$ (or $A \in \mathbb{C}^{m \times n}$), the **singular-value decomposition (SVD) of A** consists of computing orthogonal matrices $U \in \mathbb{R}^{m \times m}$ and $V \in \mathbb{R}^{n \times n}$ (or unitary matrices $U \in \mathbb{C}^{m \times m}$ and $V \in \mathbb{C}^{n \times n}$) such that the $m \times n$ matrix

$$\tilde{\Sigma} = U^T A V \quad (3)$$

(or $\tilde{\Sigma} = U^H A V$) has zero entries except for its diagonal leading $p \times p$ real submatrix $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_p)$ with $\sigma_1 \geq \dots \geq \sigma_p \geq 0$. The first p columns of $U = [u_1, \dots, u_m]$, and of $V = [v_1, \dots, v_n]$, are called the *left* and *right singular vectors*, respectively. The *singular triplets* are (σ_i, u_i, v_i) for $i = 1, \dots, p$.

Discussion

Mathematical Fundamentals

Eigenproblems. Equation 1 has n complex roots, some of them possibly multiple. For every eigenvalue $\lambda \in \mathbb{C}$, the dimension of the eigenspace $\mathcal{X}_\lambda = \ker(A - \lambda I)$ is at least 1. The algebraic multiplicity of λ (its multiplicity as root of (1)) is larger or equal to its geometric multiplicities (the dimension of \mathcal{X}_λ). When all the geometric multiplicities are equal to the algebraic ones, a basis $X = [x_1, \dots, x_n] \in \mathbb{C}^{n \times n}$ of eigenvectors (say *right eigenvectors*) can be built by concatenating bases of the invariant subspaces \mathcal{X}_λ where $\lambda \in \Lambda(A)$. In such a situation, the matrix A is said to be *diagonalizable* since by expressing the same operator in the basis X ,

$$D = X^{-1} A X = \text{diag}(\lambda_1, \dots, \lambda_n). \quad (4)$$

By denoting $X^{-H} = Y = [y_1, \dots, y_n]$, Eq. 4 becomes $D = Y^H A X$ with $Y^H Y = I$. For $i = 1, \dots, n$, the vector y_i is the left eigenvector corresponding to the eigenvalue λ_i .

The well-known *Jordan normal form* generalizes the diagonalization when Eq. 4 does not hold. However, the problem of determining such a decomposition is ill-posed. Transforming it into a well-posed problem can be done by proving the existence of matrices with an assigned block structure in a neighborhood of the matrix. For more details see Kagström and Ruhe's contribution in [25].

A decomposition which is numerically computable is called the *Schur decomposition*, in which a unitary matrix U exists such that the complex matrix

$$T = U^H A U = \begin{pmatrix} \lambda_1 & \tau_{12} & \cdots & \tau_{1n} \\ \ddots & \ddots & & \vdots \\ & \ddots & \tau_{n-1,n} \\ & & & \lambda_n \end{pmatrix}, \quad (5)$$

is upper triangular. Eigenvectors can then be computed from T . When the matrix A is Hermitian – or real symmetric – so is the matrix T which becomes diagonal and real. The *symmetric eigenvalue problem* deserves a lot of attention since it arises frequently in practice.

When the matrix A is real unsymmetric, pairs of complex conjugate eigenvalues may exist. In order to avoid complex arithmetic in that case, the *real Schur decomposition* extends the Schur decomposition by allowing 2×2 diagonal blocks with pairs of conjugate eigenvalues.

SVD problems. Since the complex case is similar to the real one and since the SVD of A^T is obviously obtained from the SVD of A , the study is restricted to the situation $A \in \mathbb{R}^{m \times n}$ with $m \leq n$.

Let A have the singular-value decomposition (3), then, the symmetric matrix

$$B = A^T A \in \mathbb{R}^{n \times n}, \quad (6)$$

has eigenvalues $\sigma_1^2 \geq \dots \geq \sigma_n^2 \geq 0$, with corresponding eigenvectors (v_i), ($i = 1, \dots, n$). B is called the *normal*

matrix, while the augmented symmetric matrix

$$A_{\text{aug}} = \begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix} \quad (7)$$

has eigenvalues $\pm \sigma_1, \dots, \pm \sigma_n$, corresponding to the eigenvectors

$$\frac{1}{\sqrt{2}} \begin{pmatrix} u_i \\ \pm v_i \end{pmatrix}, \quad i = 1, \dots, n.$$

Every method for computing singular values of A is based on computing the eigenpairs of B or A_{aug} .

E

The Symmetric Eigenvalue Problem

Three class of methods are available for solving problems (1) and (2) when A is symmetric:

Jacobi iterations: The oldest method, introduced by Jacobi in 1846 [23], consists of annihilating successively off-diagonal entries of the matrix via orthogonal similarity transformations: $A_0 = A$ and $A_{k+1} = R_k^T A_k R_k$ where R_k is a plane rotation. The scheme is organized into sweeps of $n(n-1)/2$ rotations to annihilate every off-diagonal pairs of symmetric entries once. One sweep involves $6n^3 + O(n^2)$ operations when symmetry is exploited in the computation. The method was abandoned due to high computational cost but has been revived with the advent of parallelism. However, depending on the parallel architecture, it remains more expensive than other solvers.

QR iterations: The aim of the QR algorithm relies on the following iteration:

$$A_0 = A \text{ and } Q_0 = I$$

$$\begin{cases} \text{For } k \geq 0, \\ (Q_{k+1}, R_{k+1}) = qr(A_k) \text{ (QR Factorization)} \\ A_{k+1} = R_{k+1} Q_{k+1}, \end{cases} \quad (8)$$

where the QR factorization is defined in [linear least squares and orthogonalization 12]. Under weak assumptions, matrix A_k approaches a diagonal matrix for sufficiently large k . A direct implementation of (8) would involve $O(n^3)$ arithmetic operations at each iteration. If,

however, one obtains the tridiagonal matrix $T = Q^T A Q$ via orthogonal similarity transformations at a cost of $O(n^3)$ arithmetic operations, the number of arithmetic operations of a QR iteration is reduced to $O(n^2)$ or even $O(n)$ if only the eigenvalues are needed. To accelerate convergence, a shifted version of the QR algorithm is given by

$$\left\{ \begin{array}{l} T_0 = T \text{ and } Q_0 = I \\ \text{For } k \geq 0, \\ (Q_{k+1}, R_{k+1}) = qr(T_k - \mu_k I) \text{ (QR Factorization)} \\ T_{k+1} = R_{k+1} Q_{k+1} + \mu_k I, \end{array} \right. \quad (9)$$

where μ_k is an approximation of the smallest eigenvalue of T_k .

Sturm sequence evaluation: The Sturm sequence in $\lambda \in \mathbb{R}$ is defined by $p_0(\lambda) = 1$ and for $k = 1, \dots, n$ by $p_k(\lambda) = \det(A_k - \lambda I_k)$ where A_k and I_k are the principal matrices of order k of A and of the identity matrix. The number $N(\lambda)$ of sign changes in the sequence is equal to the number of eigenvalues of A which are smaller than λ . $N(\lambda)$ can also be computed as the number of negative diagonal entries of the matrix U in the LU factorization of the matrix $A - \lambda I = LU$. As for the QR iteration, the algorithm is applied to the tridiagonal matrix T , so that each Sturm sequence computation has complexity $O(n)$. Sturm sequence allows one to partition a given interval $[a, b]$ as desired to obtain each of the eigenvalues in $[a, b]$ to a desired accuracy. When needed, the eigenvectors are then obtained by inverse iterations.

Many references exist which describe the theory underlying the three methods outlined above, e.g., see [20].

Parallel Jacobi algorithms. A parallel version of the cyclic Jacobi algorithm was given by Sameh [30]. It is obtained by the simultaneous annihilation of several off-diagonal elements by a given orthogonal matrix U_k , rather than only one rotation as is done in the serial version. For example, let A be of order 8 (see Table 1) and consider the orthogonal matrix U_k as the direct sum of four independent plane rotations simultaneously determined. An example of such a matrix is

$$U_k = R_k(1, 3) \oplus R_k(2, 8) \oplus R_k(4, 7) \oplus R_k(5, 6),$$

Eigenvalue and Singular-Value Problems. Table 1

				x	6	2	3
					x	5	2
						x	1
							x

where $R_k(i, j)$ is that rotation which annihilates the (i, j) off-diagonal element (\oplus indicates that the rotations are assembled in a single matrix and extended to order n by the identity). Let one sweep be the collection of such orthogonal similarity transformations that annihilate the element in each of the $\frac{1}{2}n(n-1)$ off-diagonal positions (above the main diagonal) only once, then for a matrix of order 8, the first sweep will consist of seven successive orthogonal transformations with each one annihilating distinct groups of maximum four elements simultaneously as described in the Table 1. For the remaining sweeps, the structure of each subsequent transformation U_k , $k > 8$, is chosen to be the same as that of R_j where $j = 1 + (k-1) \bmod 8$. In general, the most efficient annihilation scheme consists of $(2r-1)$ similarity transformations per sweep, where $r = \lfloor \frac{1}{2}(n+1) \rfloor$, in which each transformation annihilates different $\lfloor \frac{1}{2}n \rfloor$ off-diagonal elements (see [30]). Several other annihilation schemes are possible which are based on round-robin techniques. Luk and Park [27] have demonstrated that various parallel Jacobi rotation ordering schemes are equivalent to the sequential row-ordering scheme, and hence share the same convergence properties.

The above algorithms are well-suited for shared memory computers. While they can also be implemented on distributed memory systems, their efficiency on such systems may suffer due to communication costs. In order to increase the granularity of the computation (i.e., to increase the number of floating point operations between two communications), block algorithms are considered. A parallel Block-Jacobi algorithm is given by Gimenez et al. in [19]. This algorithm takes advantage of the symmetry of the matrix.

Tridiagonalization of a symmetric matrix by Householder reductions. The goal is to compute a symmetric tridiagonal matrix T , orthogonally similar to A : $T = Q^T A Q$ where $Q = H_1 \dots H_{n-2}$ combines Householder reductions. These transformations are defined in [linear least square and orthogonalization 12]. The transformation H_1 is chosen such that $n - 2$ zeros are introduced in the first column of $H_1 A$, the first row being unchanged:

$$H_1 A = \begin{pmatrix} * & * & * & * & * & * \\ * & * & * & * & * & * \\ 0 & * & * & * & * & * \\ 0 & * & * & * & * & * \\ 0 & * & * & * & * & * \\ 0 & * & * & * & * & * \end{pmatrix}.$$

Therefore, by symmetry, applying H_1 on the right results in the following pattern:

$$A_1 = H_1 A H_1 = \begin{pmatrix} * & * & 0 & 0 & 0 & 0 \\ * & * & * & * & * & * \\ 0 & * & * & * & * & * \\ 0 & * & * & * & * & * \\ 0 & * & * & * & * & * \\ 0 & * & * & * & * & * \end{pmatrix} \quad (10)$$

In order to take advantage of the symmetry, the reduction $A_1 = H_1 A H_1$ can be implemented by a symmetric rank-two update which is a routine of the Level 2 BLAS [6]. The tridiagonal matrix T is obtained by repeating successively similar reductions on columns 2 to $n - 2$. The total procedure involves $4n^3/3 + O(n^2)$ arithmetic operations. Assembling the matrix $Q = H_1 \dots H_{n-2}$ requires $4n^3/3 + O(n^2)$ additional operations.

As indicated in [linear least square and orthogonalization 12], successive applications of Householder reductions can be compacted into blocks which allow use of routines of Level 3 BLAS [6]. Such reduction is implemented in routine DSYTRD of LAPACK [2] which takes advantage of the symmetry of the process.

A parallel version of the algorithm is implemented in routine PDSYTRD of ScaLAPACK [5].

Parallel QR for the symmetric tridiagonal eigenvalue problem. The QR scheme is the method of choice when all the eigenvalues and the eigenvectors are sought. A Divide-and-Conquer algorithm was introduced by Dongarra and Sorensen in [16]. It consists of partitioning the triadiagonal matrix by rank-one tearings.

A tridiagonal matrix T of order n can be partitioned

$$\text{as follows: } T = \begin{pmatrix} T_1 & 0 \\ 0 & T_2 \end{pmatrix} + \rho f f^T \text{ where } T_1 \text{ and } T_2$$

are two tridiagonal matrices of order n_1 and n_2 such that $n = n_1 + n_2$ and where f is a vector with zero entries except in position n_1 and $n_1 + 1$. If the Schur decompositions $T_1 = Q_1 D_1 Q_1^T$ and $T_2 = Q_2 D_2 Q_2^T$ are already known, the problem is reduced to computing the eigenvalues of $\tilde{D} = Q^T T Q = D + \rho z z^T$ where

$$Q = \begin{pmatrix} Q_1 & 0 \\ 0 & Q_2 \end{pmatrix}, D = \begin{pmatrix} D_1 & 0 \\ 0 & D_2 \end{pmatrix}, \text{ and } z = Q f.$$

The eigenvalues of T are interleaved with the diagonal entries of D and satisfy a simple secular equation obtained from the characteristic polynomial of \tilde{D} . The eigenvectors are then explicitly known but they must be expressed back in the original basis by pre-multiplying them by Q . The back transformation may even include the initial orthogonal transformation which reduces the original symmetric matrix to the tridiagonal form.

By p recursive tearings, the problem is reduced to 2^p independent eigenvalue problems of order $m = n/2^p$. Then, the technique described above is recursively applied in parallel to update the eigendecompositions. The total number of arithmetic operations is $O(n^3)$.

Parallel Sturm sequences. Sturm sequences are often used when only the part of the spectrum, in an interval $[a, b]$, is sought. Several authors discussed the parallel computation of Sturm sequences for a tridiagonal matrix T , and among them are Lo et al. in [26]. It is hard to parallelize the LU factorization of $(T - \lambda I)$ which provides the number of sign changes in the Sturm sequences, because the diagonal entries of U are obtained by a nonlinear recurrence. One

possible approach is to consider the linear three-term recursion which computes the Sturm sequence terms $p_k(\lambda) = \det(T_k - \lambda I_k)$, for $k = 0, \dots, n$. Since this computation corresponds to solving a triangular banded system of three diagonals, it can be parallelized, as for instance, by the algorithm described by Chen et al. in [10]. An analysis of the situation is given in [26]. Because the sequence $(p_k(\lambda))_{0,n}$ could suffer from overflow or underflow, Zhang proposed the computation of a scaled sequence in [33] and provided the backward error of the sequence.

To parallelize the computation, a more beneficial approach is to consider simultaneous computation of Sturm sequences by replacing bisection of intervals by multisection. However, multisections are efficient only when most of the created subintervals contain eigenvalues. Therefore, in [26] a strategy in two steps is proposed: (1) isolating all the eigenvalues with disjoint intervals, (2) extracting each eigenvalue from its interval. Multisections are used for step (1) and bisections or other root finders are used for step (2). This approach proved to be very efficient. When the eigenvectors are needed, they are computed independently by Inverse Iterations. A difficulty could arise if one wishes to compute all the eigenvectors corresponding to a cluster of very poorly separated eigenvalues.

Demmel et al. discussed in [11] the reliability of the Sturm sequence computation in floating point arithmetic where the sequence is no longer monotonic. Therefore, in very rare situations, it is possible to obtain a wrong answer with regular bisection. A robust algorithm, called MRRR developed by Dhillon et al. [13], is implemented via LAPACK with routine DSTEMR for the computation of high-quality eigenvectors. Several approaches are discussed in [13] for possible parallel implementations of the scheme in DSTEMR.

The Unsymmetric Eigenvalue Problem

Reduction to the Hessenberg form. Similar to the symmetric case, the reduced form is obtained by Householder reductions. But here, lack of symmetry implies that, unlike the picture in (10), zeros are not introduced in the upper part of the matrix. Therefore, the process results in an upper Hessenberg matrix. The total procedure involves $10n^3/3 + O(n^2)$ arithmetic operations. Assembling the matrix $Q = H_1 \dots H_{n-2}$ requires $4n^3/3 + O(n^2)$ additional operations.

Also, successive applications of Householder reductions can be compacted into blocks which allow use of Level 3 BLAS [6]. The algorithm is implemented via routine DGEHRD of LAPACK [2]. A parallel version of the algorithm is implemented via routine PDGEHRD of ScaLAPACK [5].

Parallel solution of the Hessenberg eigenproblem. Several attempts for generalizing the Divide-and-Conquer approach used in the symmetric case have been considered, including Dongarra and Sidani in [15], Adams and Arbenz in [1]. In these algorithms, the Hessenberg matrix is partitioned into a sum of a two-block upper-triangular matrix and a rank-one update. Compared to the symmetric case, there are two major drawbacks that limit the benefit of the tearing procedure: (1) the condition number of the eigenproblems defined by the two diagonal blocks of the first matrix can be much higher than that of the original eigenproblem as shown by Jessup in [24]. (2) the Newton iterations involved in the updating process include solving triangular or Hessenberg linear systems rendering the procedure rather more expensive than without tearing.

Henry et al. discussed in [21] existing approaches for realizing a parallel QR procedure and ended up considering an improved implicit multishifted strategy which allows the use of Level 3 BLAS [6]. The algorithm is implemented in subroutine PDLAHQR of ScaLAPACK [5].

The Singular-Value Problem

As mentioned above, methods for solving the symmetric eigenvalue problems can be reconsidered as methods for solving SVD problems. In this section, the study is restricted to the case where $A \in \mathbb{R}^{m \times n}$ with $m \geq n$.

Parallel Jacobi algorithms for SVD. In the special case where $m \gg n$, one should first perform an initial “skinny” QR factorization of $A = QR$ where $Q \in \mathbb{R}^{m \times n}$ is orthogonal and $R \in \mathbb{R}^{n \times n}$ is triangular. Next, the SVD of $R = \tilde{U}\Sigma V^T$ provides the SVD of $A = U\Sigma V^T$ with $U = Q\tilde{U}$. Computing the QR factorization in parallel has been outlined in [linear least squares and orthogonalization 12]. The complete process is obtained at the cost of $4mn^2 + O(mn + n^3)$ arithmetic operations.

One-sided and two-sided Jacobi algorithms. The first one-sided algorithm was introduced by Hestenes in [22]. Applying a rotation R to both sides of $B = A^T A$ for annihilating the entry β_{ij} is equivalent to post-multiply A by R for making the columns i and j of AR orthogonal. Therefore, any parallel Jacobi algorithm for solving a symmetric eigenvalue problem can be considered as a parallel one-sided Jacobi algorithm for solving a SVD problem. Each sweep is a sequence of orthogonal transformations V_k made of a set of independent rotations that are successively applied on the right side by $A_{k+1} = A_k \tilde{V}_k^T$ ($A_0 = A$). When the right singular vectors are needed, they are accumulated by $V_{k+1} = V_k \tilde{V}_k = (V_0 = I)$. At convergence, the singular values are given by the norms of the columns of A_k and the normalized columns are the corresponding left singular vectors. Each sweep performs $3mn^2 + O(mn)$ arithmetic operations. Brent and Luk [8] and Sameh [31] described possible implementations of this algorithm on multiprocessors.

Charlier et al. [9] demonstrate that an implementation of Kogbetliantz's algorithm for computing the SVD of upper-triangular matrices is quite effective on a systolic array of processors. Therefore, the first step in a Jacobi SVD scheme is the QR factorization of A , followed by computing the SVD of $\in \mathbb{R}^{n \times n}$. The Kogbetliantz's method for computing the SVD of a real square matrix A mirrors the method for computing the eigenpairs of symmetric matrices, in that the matrix A is reduced to the diagonal form by an infinite sequence of plane rotations

$$A_{k+1} = U_k A_k V_k^T, \quad k = 1, 2, \dots, \quad (11)$$

where $A_1 \equiv A$, and $V_k = V_k(i, j, \phi_{ij}^k)$, $U_k = U_k(i, j, \theta_{ij}^k)$ are plane rotations. It follows that A_k approaches the diagonal matrix $\Sigma = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_n)$, where σ_i is the i th singular value of A , and the products $(U_k \dots U_2 U_1)$, $(V_k \dots V_2 V_1)$ approach matrices whose i th column is the respective left and right singular vector corresponding to σ_i .

Block Jacobi algorithms. The above algorithms are well-suited for shared memory architectures. While they can also be implemented on distributed memory systems, their efficiency on such systems will suffer due to communication costs. In order to increase the granularity of the computation (i.e., to increase the number of floating

point operations between two communications), block algorithms are considered. For one-sided algorithms, each processor is allocated a block of columns instead of a single column. The computation remains the same as discussed above with the ordering of the rotations within a sweep is as given in [27].

For the two-sided version, the allocation manipulates 2-D blocks instead of single entries of the matrix. Bećka and Vajtešić propose in [4] a modification of the basic algorithm in which one annihilates, in each step, two off-diagonal blocks by performing a full SVD on a small-sized matrix. While reasonable efficiencies are realized on distributed memory systems, this block strategy increases the number of sweeps needed to achieve convergence.

We note that parallel Jacobi algorithms can only surpass the speed of the bidiagonalization schemes of ScaLAPACK when the number of processors available are much larger than the size of the matrix under consideration.

Bidiagonalization of a matrix by Householder reductions. The classical algorithm which reduces A into an upper-bidiagonal matrix B , via the orthogonal transformation $B = U^T A V$, was introduced by Golub and Kahan (see for instance [20]). The algorithm requires $4(mn^2 - n^3/3) + O(mn)$ arithmetic operations. U and V can be assembled in $4(mn^2 - n^3/3) + O(mn)$ and $4n^3/3 + O(n^2)$ additional operations, respectively. A parallel version of this algorithm is implemented in routine PDGEQR of ScaLAPACK.

The one-sided reduction for bidiagonalizing a matrix was proposed by Raha [29]. It appears to be better suited for parallel implementation. It consists of determining in a first step the orthogonal matrix V which would appear in the tridiagonalization of $A^T A$: $T = V^T A^T A V = B^T B$. The matrix V can be obtained by using Householder or Givens reductions, without first forming $A^T A$ explicitly. The second step performs a QR factorization of $F = AV$: $F = QR$. Since $F^T F = R^T R = T$ is tridiagonal, its Cholesky factor R is upper-bidiagonal which means that any two nonadjacent columns of F are orthogonal. This allows a simplified QR factorization. Bosner and Barlow introduced in [7] two adaptations of Raha's approach: a block version which allows use of Level 3 BLAS routines and a parallel version.

Once the bidiagonalization is performed, all that remains is to compute the SVD of B . When only

the singular values are sought, it can be done by the iterative Golub and Kahan algorithm where the number of arithmetic operations is $O(n)$ per iteration (see for instance [20]) which is performed only on uniprocessor. The whole Singular-Value Decomposition is implemented in routine PDGESVD of **ScalAPACK**.

EPIC Processors

DAVID I. AUGUST, ARUN RAMAN
Princeton University, Princeton, NJ, USA

Definition

Explicitly Parallel Instruction Computing (EPIC) refers to architectures in which features are provided to facilitate compiler enhancements of instruction-level parallelism (ILP) in all programs, while keeping hardware complexity relatively low. Using ILP-enhancement techniques such as speculation and predication, the compiler identifies the operations that can execute in parallel in each cycle and communicates a plan of execution to the hardware.

Discussion

Introduction

The performance of modern processors is dependent on their ability to execute multiple instructions per cycle. In the early 1990s, instruction-level parallelism (ILP) was the only viable approach to achieve higher performance without rewriting software. Programs for ILP processors are written in a sequential programming model, with the compiler and hardware being responsible for automatically extracting the parallelism in the program. *Explicitly Parallel Instruction Computing* (EPIC) refers to architectures in which features are provided to facilitate compiler enhancements of ILP in all programs. These architectures allow the compiler to generate an effective *plan of execution* (POE) of a given program, and provide mechanisms to communicate the compiler's POE to the hardware.

EPIC processors combine the relative hardware simplicity of *Very Long Instruction Word* (VLIW) processors and the runtime adaptability of *superscalar* processors. VLIW processors require the compiler to specify a POE consisting of a cycle-by-cycle description of independent operations in each functional unit, and the hardware follows the POE to execute the operations. While VLIW considerably simplifies the hardware, it also results in machine-code incompatibility between implementations of a VLIW architecture. Due to the strict adherence to the compiler's POE, code compiled for one implementation will not execute correctly on other implementations with different hardware resources or latencies. Superscalar processors discover ILP and construct a POE entirely in hardware. This means that code compiled for a particular superscalar architecture will execute correctly on all implementations of that architecture. However, ILP extraction in hardware entails significant complexity, resulting in diminishing performance returns and an adverse impact on clock rate. EPIC processors retain VLIW's philosophy of statically exposing ILP and constructing the POE, thereby keeping the hardware complexity relatively low, but incorporate the ability of superscalar processors to cope with dynamic factors such as variable memory latency. Combined with techniques to provide binary compatibility for correctness, EPIC processors provide a means to achieve high levels of ILP across diverse applications while reducing the hardware complexity needed for the same.

Design Principles

In EPIC architectures, the compiler is responsible for designing a POE. This means that the compiler must identify the inherent parallelism of a sequential program and map it efficiently to the parallel hardware resources in order to minimize the program's execution time. The main challenge faced by the compiler in determining a good POE is on account of dynamic events that determine the program's runtime behavior. Will a load-store pair access the same memory location? If yes, then the operations must be executed sequentially; otherwise, they may be scheduled in any order. Will a conditional branch be taken? If yes, then operations along the taken path may be scheduled in parallel with operations before the branch; otherwise, they must not be executed. In such situations, the compiler can

speculate that a load-store pair will not alias, or that a branch will be taken, with the compiler's confidence in the speculation typically being determined by the outcomes of profiling runs on representative inputs. EPIC architectures support compiler speculation by providing mechanisms in hardware to ensure correctness if speculation fails. Finally, the architecture must be rich enough for the compiler to express its POE; specifically, which operations are to be issued in parallel and which hardware resources they must use.

Section "ILP Enhancement" presents the major techniques used to enhance ILP of programs. Section "Enabling Architectural Features" describes the micro-architectural features that enable these and other ILP enhancement techniques.

ILP Enhancement

The code example in Fig. 1 is used to illustrate the main compiler transformations for ILP enhancement that are made possible by EPIC architectures. In the example, a condition is evaluated to alternatively update a memory location `p4` with the contents of location `p2` or `p3`. Outside the if-construct, the variable `val` is updated with the value at location `p5`, with the latter potentially aliasing with `p4`. The processor model assumed for illustration purposes, shown in Table 1, is a six-issue processor capable of executing one branch per cycle, with no further restrictions on the combination of operations that may be concurrently issued. Conditional branches require separate comparison and

EPIC Processors. Table 1 Assumed processor model to illustrate ILP enhancement techniques

Issue width	Six instructions
Latency of conditional branches	Two cycles
Latency of memory loads	Two cycles
Latency of other instructions	One cycle

```

if (*p1 == 0)
    *p4 = *p2;
else
    *p4 = *p3;
val += *p5;

```

EPIC Processors. Fig. 1 Example C code to illustrate ILP enhancement techniques

control transfer operations. All operations are assumed to have a latency of one cycle, with the exception of memory loads that have a latency of two cycles.

Figure 2a shows the scheduled, assembly code. The compiler conservatively respects all dependences, resulting in a rather sparse schedule with several slots going to waste. The execution time along either branch is ten cycles.

Speculation

Compiler-controlled speculation refers to breaking inherent programmatic dependences by guessing the outcome of a runtime event at compile time. As a result, the available ILP in the program is increased by reducing the height of long dependence chains and by increasing the scheduling freedom among the operations.

Control Speculation

Many general-purpose applications are branch-intensive. The latency to resolve a branch directly affects ILP since potentially multiple issue slots may go to waste. It is crucial to overlap other instructions with branches. Control speculation breaks control dependences which occur between branches and other operations. An operation is control dependent on a branch if the branch determines whether the operation will be executed at runtime. By guessing the direction of a branch, the control dependence may be broken effectively making the operation's execution independent of the branch. Control speculation allows operations to move across branches, thus reducing dependence height and resulting in a more compact schedule.

Data Speculation

Many general-purpose applications exhibit irregular memory access patterns. Often, a compiler is conservative because it respects a memory dependence that occurs infrequently or because it cannot determine that the dependence does not actually exist. In either case, data speculation breaks data flow dependences between memory operations. Two memory operations are flow dependent on one another if the first operation writes a value to a memory location and the second operation *potentially* reads from the same location. By guessing that the two memory operations will access different locations, the load operation may be hoisted above the

EPIC Processors. Fig. 2 Predication and speculation have a synergistic relationship: applying speculation after predication results in the best improvement in ILP. (a) Sequential schedule. (b) Schedule using control and data speculation alone. (c) Schedule using predication alone. (d) Schedule using predication and speculation combined

store. EPIC provides for more aggressive code motion: operations dependent on the load may also be hoisted above potentially aliasing stores.

Applying speculation to the code in Fig. 1 results in the tighter schedule shown in Fig. 2b. $\langle CS \rangle$ and $\langle DS \rangle$, respectively, denote operations which have been speculated with respect to control or data. The resultant increase in ILP is achieved primarily by applying speculation to the loads (operations 4, 7, and 9). Note that loads from either side of a branch may be speculatively executed. If the branch is highly biased, then the compiler may choose to speculatively execute just the loads from the biased path. Operations 4 and 7 are control dependent on operation 3. Control speculation enables the compiler to break the dependences and move 4 and 7 to the top of the block. Operation 9 is memory dependent on operations 5 and 8: these ambiguous memory dependences arise because the compiler is unable to prove that pointer p_5 does not point to the same location as pointer p_4 . The net result of applying speculation is that the dependence height of the code segment is reduced to seven cycles.

While speculation enhances ILP, it requires hardware support to handle exceptions. Exceptions generated by speculated operations can either be genuine, reflecting exception conditions present in the original code, or spurious, resulting from unnecessary execution of speculative operations. Since speculative operations, like ordinary operations, may cause long-latency exceptions such as page faults and TLB misses, time is wasted if spurious exceptions are repaired. Spurious exceptions are eliminated by taking exceptions only when the results of speculative operations are used nonspeculatively, since it is guaranteed at that point that the speculated code would have executed in the original program. A symbolic operation, called a *check*, is responsible for detecting any problems that occurred in a previous speculative execution. When an error is detected by a check instruction, either an exception is reported or repair is initiated. By positioning the check at the point of the original operation, the error detection and repair is guaranteed to occur only when the original operation would have been executed by a nonspeculated version of the program.

For data speculation, repair is necessary when an actual data dependence existed between the speculated load and one or more stores predicted to be independent at compile time. The check queries the hardware

to detect if a dependence actually existed for this execution and initiates repair if required. In general, all data-speculative and all potentially excepting control-speculative operations require checks. In Fig. 2b, operations 4', 7', and 9' are the previously discussed symbolic check operations.

Predication

Predicated execution is a mechanism that supports conditional execution of individual operations based on Boolean guards, which are implemented as predicate register values. A compiler converts control flow into predicates by applying *if-conversion* [1]. If-conversion translates conditional branches into predicate defining operations and guards operations along alternative paths of control under the computed predicates. A predicated operation is fetched regardless of its predicate value. An operation whose predicate is TRUE is executed normally. Conversely, an operation whose predicate is FALSE is prevented from modifying the processor state. With if-conversion, complex nests of branching code can be replaced by a straight-line sequence of predicated code. Predication increases ILP by allowing separate control flow paths to be overlapped and simultaneously executed in a single thread of control.

Figure 2c illustrates an if-conversion of the code segment from Fig. 1. The predicate for each operation is shown within angle brackets. For example, operation 4 is predicated on pT . The absence of a predicate indicates that the operation is always executed.

Predicates are computed using predicate define operations, such as operation 11. The predicate pT is set to 1 if the condition evaluates to true, and to 0 if the condition evaluates to false. The predicate pF is the complement of pT . Operations 4 and 7, and operations 5 and 8 are executed concurrently with the appropriate ones taking effect based on the predicate values. The net result of applying predication is that the dependence height of the code segment is reduced to nine cycles.

Combining Speculation and Predication

Both speculation and predication provide effective means to increase ILP. However, the example shows that their means of improving performance are fundamentally different. Speculation allows the compiler to break control and memory dependences, while predication allows the compiler to restructure program control flow

and to overlap separate execution paths. The problems attacked by both techniques often occur in conjunction; therefore, the techniques can be mutually beneficial.

Figure 2d illustrates the use of predication and speculation in combination. If-conversion removes the branch resulting in a stream of predicated operations. As before, data speculation breaks the dependences between operations 5 and 9, and operations 8 and 9, allowing the compiler to move operation 9 to the top of the block. Even though no branches remain in the code, control speculation is still useful to break dependences between predicate definitions and guarded instructions. In this example, the control dependences between operations 11 and 4, and operations 11 and 7 are eliminated by removing the predicates on operations 4 and 7. This form of speculation in predicated code is called *promotion*. As a result of this speculation, the compiler can hoist operations 4 and 7 to the top of the block to achieve a more compact schedule of height six cycles.

In summary, predication is only 11% faster and speculation is only 43% faster than the original code segment. As the example shows, speculation in the form of promotion can have a greater positive effect on performance after if-conversion than before. This synergistic relationship between predication and speculation yields a combined speedup of 67% over the original code segment.

Enabling Architectural Features

Since EPIC delegates the responsibilities of enhancing ILP and planning an execution schedule to the compiler, the architecture must provide features:

1. To overcome the worst impediments to a compiler's ability to enhance ILP, namely, frequent control transfers and ambiguous memory dependences
2. To specify an execution schedule

Speculation Support

As discussed in Section "ILP Enhancement", an architecture that supports speculation must provide mechanisms to detect potential exceptions on control-speculative operations as they occur, to record information about data-speculative memory accesses as they occur, and then to check at an appropriate time whether an exception should be taken or data-speculative repair should be initiated.

First, speculative operations must be distinguished from nonspeculative operations, since the latter should report exceptions immediately. Also, loads that have not been speculated with regard to data dependence need not interact with memory conflict detection hardware. For this, each operation that can be speculated has an extra bit, called the *S-bit*, associated with it. This bit is set on operations that are either control speculated or are data dependent on a data-speculative load. Each load has an additional bit, called the DS-bit. This bit is set only on data-speculative loads.

Second, to defer the reporting of exceptions arising from speculative operations until it is clear that the operation would have been executed in the original program, a 1-bit tag called the *NaT* (Not a Thing) bit is added to each register. When a speculative load causes an exception, the NaT bit is set instead of immediately raising the exception. Speculative instructions that use a register with its NaT bit set propagate the bit through their destination registers until a check operation determines whether speculation failed in which case the deferred exception is suppressed.

Third, a mechanism must be provided to store the source addresses of data-speculative loads until their independence with respect to intervening stores can be established. This functionality can be provided by the Memory Conflict Buffer (MCB) [2] or the Advanced Load Address Table (ALAT) [3]. The MCB temporarily associates the destination register number of a speculative load with the address from which the value in the register was speculatively loaded. Destination addresses of subsequent stores are checked against the addresses in the buffer to detect memory conflicts. The MCB is queried by explicit data speculation check instructions, which initiate recovery if a conflict was detected.

Predication Support

A set of predicate registers are used to store the results of compare operations. For example, the Intel Itanium processor family has a set of 64 (1-bit) predicate registers. An EPIC processor must also implement some form of predicate squash logic, which prevents instructions with false predicates from committing their results. The IMPACT EPIC architecture [4] also provides predication-aware bypass/interlock logic, which forwards results based on the predicate values associated with the generating instructions.

Static Scheduling Support

EPIC provides many features for enabling the compiler to specify a high-quality Plan Of Execution (POE). These features include the ability to specify multiple operations per instruction, the notion of architecturally visible latencies, and an architecturally visible register structure.

Multiple Operations per Instruction (MultiOp)

EPIC architectures allow the compiler to specify explicit information about independent operations in a program. A MultiOp is a specification of a set of operations that are issued simultaneously to be executed by the functional units. Exactly one MultiOp is issued per cycle of the *virtual time*. The virtual time is the schedule built by the compiler, and may differ from the actual time if the hardware inserts stalls due to dynamic events.

For example, the Itanium architecture [3] consists of *instruction groups* that have no read-after-write (RAW) or write-after-read (WAR) register dependences, delimited by *stops*. The Itanium implementation consists of 128-bit instruction bundles comprising three 41-bit opcodes and a 5-bit template that includes intra-bundle stop bits. The use of template bits greatly simplifies instruction decoding. The use of stops enables explicit specification of parallelism.

Architecturally Visible Latencies

A lot of the hardware complexity of a superscalar processor arises from the need to maintain an illusion of sequential execution (i.e., each operation completes before another begins) in the face of non-atomicity of the operations. To avoid the complexity, EPIC processors expose operations as being nonatomic; instead, read-and-write events of an operation are viewed as the atomic events. There is a contractual specification of *assumed latencies* of operations that must be honored by both the hardware and the compiler. A MultiOp that takes more than one cycle to generate all the results is said to have *non-unit assumed latency* (NUAL). The guarantee of NUAL affords multiple benefits to EPIC processors. Since the hardware is certain that the read event of an operation will not occur before the write event of the operation that produces the value to be read, there is no need for stall/interlock capability. Since the compiler is certain that an operation will not write its result before its assumed latency has elapsed, it

can schedule other operations that are anti- or output-dependent on the operation in question, resulting in tighter schedules.

As mentioned earlier, EPIC processors may still have interlocking to account for the deviation of actual latencies of operations from their assumed latencies. However, MultiOp and NUAL permit an in-order implementation of the architecture while still extracting substantial ILP.

Register Structure

ILP processors require a large number of registers. Specifically in EPIC processors, techniques such as control and data speculation cause increased register pressure. Fundamentally, since multiple operations are executing in parallel, there is a demand for a larger store for temporary values. Superscalar processors architecturally expose only a small fraction of the physical registers, and rely on register renaming to generate parallel schedules. However, this requires complex hardware for dynamic scheduling. Since EPIC demands a schedule from the compiler in order to simplify the hardware, it becomes necessary to expose a larger set of architectural registers to generate the same parallel schedule as achieved through hardware register renaming.

EPIC architectures also provide a mechanism to rotate the register file to speed up inner-loop execution. Speeding up loops involves executing instructions from multiple loop iterations in parallel. One way to do this is by using *Modulo Scheduling* [5]. Modulo scheduling schedules one iteration of the loop such that when this schedule is repeated at regular intervals, no intra- or inter- iteration dependence is violated, and no resource conflict arises between the dynamic operations within and across loop iterations. While generating code, it is important that false dependences do not arise owing to dynamic instances on different iterations of the same operation writing to the same registers. While the loop could be unrolled, followed by static register renaming, this typically results in substantial code growth. EPIC architectures implement a *rotating register file* that provides register renaming such that successive writes to the same virtual register actually go to different physical registers. This is accomplished through the use of a *rotating register base* (RRB) register. The physical register number accessed by each operation is the sum of the virtual register number specified in the instruction

and the number in the RRB register, modulo the number of registers in the rotating register file. The RRB is updated at the end of each iteration using special operations. In this manner, EPIC architectures provide compiler-controlled dynamic register renaming.

Another interesting feature is the *register stack* that is used to simplify and speed up function calls. Instead of spilling and filling all the registers at a procedure call and return sites, EPIC processors enable the compiler to rename the virtual register identifiers. The physical register accessed is determined by renaming the virtual register identifier in the instruction through a base register. The callee gets a physical register frame that may overlap with the caller's frame; the overlap constitutes the registers that are passed as parameters.

Cache Management

EPIC architectures allow the compiler to explicitly control data movement through the cache hierarchy by exposing the hierarchy architecturally. Generating a high-quality schedule often requires the compiler to be able to accurately predict the level in the cache hierarchy where a load operation will find its data. This is normally achieved by profiling or analytical means, and the source-cache specifier is encoded as part of the load instruction. This informs the hardware of the expected location of the datum as well as the assumed latency of the load.

EPIC architectures also provide a target cache specifier for load/store operations that allow a compiler to instruct the hardware of where the datum should be put in the cache hierarchy for subsequent references to that datum. This allows the compiler to explicitly control the content of the caches. The compiler could, for example, prevent pollution of the caches by excluding data with poor temporal locality from the higher-level caches, and remove data from the last level cache after the last use.

Many streaming programs operate on data without accessing them again. To improve the latency of such accesses, EPIC architectures provide a *data prefetch cache*. Prefetch load instructions can be used to prefetch data with poor temporal locality into the data prefetch cache. This prevents the displacement of first-level data cache contents that may potentially have much better temporal locality.

Bibliographic Notes and Further Reading

The EPIC philosophy was primarily developed by HP researchers in the early 1990s [6, 7]. As mentioned in the introduction, the EPIC philosophy was fundamentally influenced by the VLIW philosophy developed in the 1980s in the Multiflow and Cydrome processors [8, 9]. EPIC inherited various features from Cydrome, most significantly:

- Predicated execution
- Support for software pipelining of loops in the form of rotating register files
- A rudimentary MultiOp instruction format
- Hardware support for speculation including speculative opcodes, a speculative tag bit in each register, and deferred exception handling

Many of the ideas on speculation and its hardware support were developed independently by researchers in the IMPACT group at the University of Illinois [10] and IBM Research [11]. The most famous commercial EPIC processor is the Itanium processor family jointly developed by HP and Intel. The first processor in the family was released in 2001, with successors having improved memory subsystems, multiple cores on the same die, and improved power efficiency.

More information on the EPIC philosophy and implementation can be found in the technical reports and manuals on the topic [3, 6].

developed, mainly by W. Händler. Such a system is a collection of nodes where each node consists of one processor and one shared memory unit at least. The nodes are organized in several hierarchically ordered planes (layers) and one top-node. Each plane is a collection of m^2 identical nodes arranged in an $m \times m$ grid, where each node is connected to its four nearest neighbors via shared memory. At the border of the plane, the nodes are interconnected in such a way that the layer forms a torus. Each upper plane is smaller than the layer immediately below. It has a quarter of the nodes of the lower plane. Each node, which is not part of the lowest plane, has access to the shared memory of four child nodes of the layer immediately below. The base layer, called working plane, is that part of the system where most of the real work is to be done. The upper layers and the top-node feed the working plane with data and offer support functions. In larger systems, only some of the lower planes are realized. In this case, the top-node is connected to the highest realized plane via bus.

A special EGPA system is MEMSY. In such a system, only the two lower planes and the top-node are realized. Furthermore, by adding a bus system, long distance communication via messages is possible. Consequently, several programming models, not only shared memory, are supported.

From 1978 to 1994, three such systems of the EGPA class have been realized: the Pilot Pyramid (4+1 nodes), the DIRMU Pyramid, and the MEMSY Prototype (16 + 4 + 1 nodes both).

Discussion

Introduction

In 1974, W. Händler published first ideas [A] and proposed one year later together with F. Hofmann and H.J. Schneider a new subclass of multiprocessors [16]: the Erlangen General Purpose Array (EGPA, Erlangen is an university city near Nürnberg in Bavaria). (Many of the following text is taken from [14, 15, 18].) The essential features and design objectives of these MIMD-computers are:

1. Homogeneity: There is only one identical type of element – the node often called PMM (processor-memory-module).
2. Memory-coupling: Connection between nodes is via memory.

MEMSY

Definition

During the 1970s, the concept of the multiprocessor class Erlangen General Purpose Array (EGPA) was

3. Restricted neighborhood: No node has access to the whole memory, and no memory block can be accessed by all nodes.
4. Hierarchy: The PMMs are arranged in several layers and these layers form a total order.
5. Regularity: The nodes of one layer are ordered like a grid.

W. Händler explained these features as follows: The reasons for these demands are speed (memory coupling), programmability (regularity, homogeneity), control (hierarchy), technical limits (restricted neighborhood), and expandability (all).

In the following years, several EGPA systems were built. The first one, the pilot pyramid, was assembled in 1978 and was used until 1984. It consisted of four PMMs at the working plane level 0 (A-processors) and one PMM at level 1 (B-processor).

From 1985 to 1988, DIRMU (Distributed Reconfigurable Multiprocessor Kit [4]) was used for testing applications written for EGPA systems. DIRMU was a kit consisting of PMMs, 8086 based, where processor-ports of one PMM could be interconnected with memory-ports of other PMMs by cables. Using several of these PMMs, different topologies could be realized: rings, trees, and so on. Especially an EGPA pyramid with three layers (16 + 4 + 1 PMMs) could be built.

From 1989 to 1994, a new EGPA system started running in Erlangen. It was called MEMSY (Modular Expandable Multiprocessor System). In this multiprocessor, three layers were realized. It consisted of 16 nodes in the working plane and 4 nodes in the next layer.

These machines were used to demonstrate the feasibility and usefulness of EGPA systems.

In the following, the principles of EGPA systems are discussed, and the pilot pyramid and MEMSY serve as examples.

Motivation

EGPA systems are general purpose machines, but they were especially designed for numerical simulations. With the emergence of powerful computer systems, the interest in computational science was awakened. This computational approach in natural science and engineering sciences was and is very successful in context with fluid dynamics, condensed matter physics, plasma

physics, applied geophysics, and others. The corresponding models of physical phenomena are either continuum models or many-body models.

Essential is that there is an inherent “locality” in these approaches. The designer of EGPA kept this fact in mind when they developed their machines according to the possibilities the computer technology offered at that time, the 1980s.

E

Design Goals

The EGPA architecture was defined with the following design goals in mind:

Scalability

The architecture should be scalable with no theoretical limit. The communication network should grow with the number of processing elements in order to accommodate the increased communication demands in larger systems.

Portability

Algorithms should run on EGPA systems of any size.

Cost effectiveness

As far as possible, off-the-shelf components should be used.

Flexibility

The architecture should be usable for a great variety of user problems.

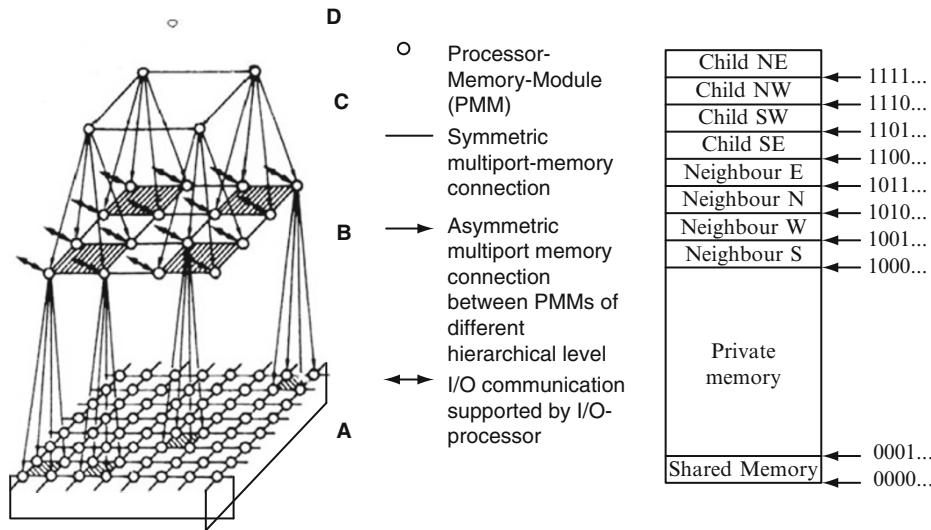

Efficiency

The computing power of the system should be big enough to handle real problems which occur in scientific research.

System Topology

An EGPA system consists of identical PMMs (nodes): one processing unit and one attached communication (multiport) memory form one PMM (Processor Memory Module). The processing element consists of one or more processors. Optionally, there can exist a coprocessor and/or a private memory only accessible by the processing unit itself.

The PMMs are hierarchically arranged in several layers (planes). An example with four layers (A, B, C, D) is given in Fig. 1a. At the topmost layer, there is only a single PMM which serves as a front-end to the system. At each lower layer, each PMM is connected to exactly four neighbors at the same layer, e.g., each processor has access to the communication memories of its neighboring PMMs. Thus, at each plane, the hardware has a

Erlangen General Purpose Array (EGPA). Fig. 1 (a) EGPA with 64 PMMs in the working plane (b) address space of a node

grid-like structure. As in each row, the most left node is connected to the most right PMM, and in each column, the corresponding nodes are connected too, each layer forms a torus. (In Fig. 1a, for clarity, only two of these turn-around connections are drawn.) In addition to the horizontal accesses, each node, except the very lowest, has access to four PMMs at the next lower layer. Consequently, the address space of a processor looks like in Fig. 1b. Each access with an address lying in the address space part of a child or neighbor will be translated by hardware to a shared memory address of that child or neighbor and that location of the child or neighbor will be accessed (e.g., the address 1010 01... causes an access to the cell 0000 01... of the neighbor in the north).

The vertical connections are equipped to broadcast data downward to all four of the lower PMMs simultaneously, say, to transmit code segments. On the other hand, though the lower nodes do not have memory access to those at higher layers, they are able to interrupt their supervising PMM. These substructures, consisting of four nodes and their supervisor, are called elementary pyramid. Several of them are highlighted in Fig. 1a. Each elementary pyramid has an I/O processor with corresponding I/O devices, mainly disks. The I/O processor which has access to all of its elementary pyramid memories is controlled by the supervising PMM. The topmost PMM is connected to a network containing a software development system.

The overall arrangement of an EGPA system is pyramidal. Each pyramid can be extended downward to any size by adding new levels. Such an extension significantly increases the computing power of the system. An EGPA system is a distributed memory multiprocessor. Remote communication between nodes is done via chains of copies and not via messages as usual.

System Software

Each node has its own local operating system that exactly renders those services the resources of which are available. Now, in case a process needs a system service, this service either will be rendered at once or the addressed operating system cannot perform it and now informs his superior processor, i.e., its operating system, of the order.

In the pilot pyramid, this technique was realized as follows. For each A-processor, a shadow process existed in the B-processor. At the four A-processors, only a user interface to the operating system of the B-processor was implemented. If there was an order to the operating system of the B-processor, this interface communicated with its shadow process. Then this shadow process sent the request to the proper operating system which executed the desired function afterward.

This approach can be extended to larger EGPA computer; since each such system is composed of elementary pyramids (see Fig. 1a). Each B-processor is

part of an elementary pyramid one level higher and so on. Consequently, the technique of shadow processes could be used in upper elementary pyramid as well.

The proposed user interface for programming such a multiprocessor was in addition to several tools for testing parallel programs the EGPA monitor. This monitor consists of an EGPA frame program and a pool of subroutines. If a parallel program is executed, the frame program runs first installing the necessary system processes and then starting the user routines. The subroutines of the monitor are tools for controlling user programs. They allow to distribute programs and data to the system, to control the processes and to execute coordinating tasks (see [25]). Two very important tools are EXECUTE (PROGNAME, PROC) (starts routine PROGNAME at the indicated processor – child or neighbor) and WAIT (PROGNAME, PROC) (wait until the routine has finished at the processor).

The EGPA monitor was realized for the Pilot Pyramid. But the concept can be carried to larger systems. It supports only one parallel program at a time in contrast to MEMSOS (see later) used in the MEMSY pilot.

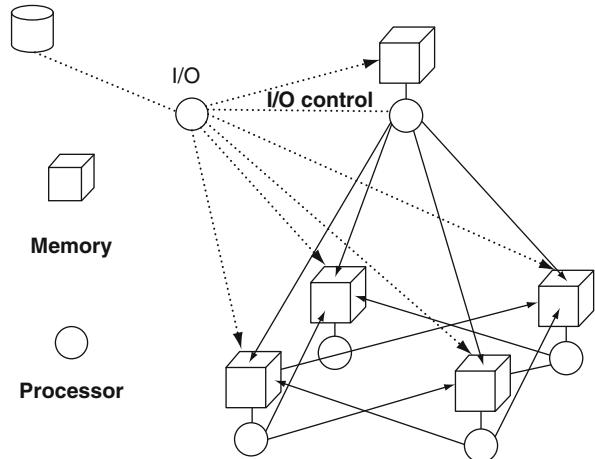

The Pilot Pyramid

The pilot pyramid, equivalent to an elementary pyramid, was assembled in 1978 and was used until 1984 (see Fig. 2). It consisted of four PMMs at the working plane level 0 (A-processors) and 1 PMM at level 1 (B-processor). All nodes were commercially available computers AEG 80/60 which offered a multiport memory. The characteristics of these processors were internal processor cycles of 80, 120, and 240 ns and a word length of 32 bits. The access time to a word was 1–2 μ s. Each A-processor had a memory of 128 KB and the B-processor 512 KB. For more details, see [20].

The operating system was an expansion of the original available operating system MARTOS. The EGPA monitor could be called from user programs written in FORTRAN or SL3 (a subset of ALGOL68).

Application Programming with the EGPA Monitor

EGPA was designed for mainly solving problems using data partitioning. The corresponding programming model is known as SPMD (Single Program Multi Data).

Erlangen General Purpose Array (EGPA). Fig. 2 Pilot Pyramid

Before implementing a parallel program, the user has to partition his problem domain in such a way that parallel work can be done as much as possible. Furthermore, he has to assign himself the data to the processing elements and, in contrast to a global shared memory systems, in EGPA, the user had to take into account that needed data should not only exist within the system but also in the right memory at the right time. The synchronization and the control of data were done by using the EGPA monitor. The allocation of data was effected by segments, and most of data transports happened under user control. There were two possibilities for synchronization: under system control using messages or under user control by special routines of the monitor. The latter was a factor thousand faster, but deadlocks were possible if the user made a mistake. Nevertheless, it was preferred by nearly all users and the gained speedups were much better.

One very important area for using EGPA systems are partial differential equations. Under the assumption that the region of interest is a square (or a cube) represented by a grid, for numerical purposes, and a grid-point-wise relaxation method is performed in red black order, the partitioning is very simple. To each processor one part is assigned. Each processor handles its portion of the grid and needs only values produced by neighboring processors. In Fig. 3a, the access area of one processor is hatched.

On an EGPA system, one iteration step performed at a processor p is as follows:

1. Relax red points which do not depend on points of any neighbor.
2. Wait until all neighbors have signaled that their values can be used, e.g., the western neighbor has set the variable “ready” to iteration number (p accesses this variable using the name “ready&western”).
3. Relax red points which depend on black points of neighbors. These are points at the border of p.
4. Relax black points.
5. Ready := Iteration number +1; /* signal to neighbors own borders are ready for next iteration.

For this simple case, speedups near the number of processors in the working layer were achieved. If it was possible to map a rectangle onto a non-square physical space (see, e.g., Fig. 3b), the results were equivalent. If the domain under investigation is not so optimal, the programmer had to search for other solutions. If, e.g., the domain is a circle, it is not possible to give all nodes the same load and consequently, the efficiency of the system is smaller. Sometimes it helps to divide the region into several blocks. Then the grid is so folded onto the multiprocessor that each processor operates on a part of several blocks and each block is calculated by several processors simultaneously (Fig. 3c). Thereby, the torus structure of the layer is necessary. In Fig. 3d, this is illustrated for a circle. Each square is distributed to all nodes of the working plane.

In many cases, the application designer has to search for new algorithm to use the power of the system. Thereby, he has to take into account the interconnection structure of an EGPA system. Matrix multiplication ($H = F \cdot G$) with $m \times m$ nodes in the working

plane shall serve as an example. At the first glance, the interconnection topology of an EGPA seems to be a serious restriction for calculation of any new element, since data stored in remote memories (in the sense of restricted neighborhoods) are needed and have to be transported using the communication memories. The following algorithm is based on an idea of Cannon [2].

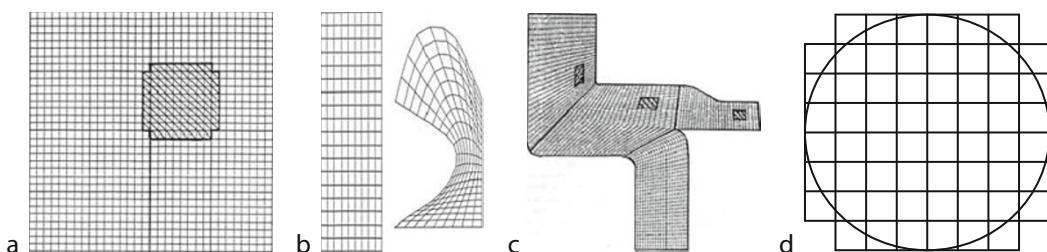

At the beginning, all matrices are equally distributed over the lowest plan as well as possible and H is set to 0. H_{ij} , F_{ij} , and G_{ij} are stored in node p_{ij} (see Fig. 4 Start position for $m = 4$). The start position is transformed by more or less rotation of the partial matrices F_{ij} and G_{ij} in rows respectively columns of the working plane until the data are distributed as depicted in Fig. 4 step 1 for $m = 4$. For example, p_{34} reads G_{44} and copies it into the communications memory of processor p_{24} , this data is read and written into its own shared memory by p_{14} . These data transports can be done in parallel by the hardware. Thereby, the toroidal connections are used.

Step 1: Each processor p_{ij} multiplies the partial matrices F_{ik} and G_{kj} stored at its memory at the beginning of step i and adds the resulting matrix to H_{ij} . Subsequently, the processor writes the matrix F_{ik} into the memory of the processor “west” of it and the matrix G_{ij} into the memory of the processor “north” of it.

After m steps, the result H is distributed on the working plane as shown in Fig. 4. Result:

Parts of the program for demonstration purposes written in SL3 (subset of ALGOL68).

It is one SPMD program per layer: The same code runs at each processor of one layer. For that reason, relative names with the following syntax were used.

        DO WAIT (T) OD;
    COPY (GMATRIX, GMATRIX&NORTH);
    GSEM&NORTH := STEP + 1
```

OD

The codes for gaining the data distribution at the beginning of Step 1 (see Fig. 4) as well as for COPY and for MULT are not represented. These routines need the size of the matrices which depend on the position of

Erlangen General Purpose Array (EGPA). Fig. 5 MEMSY prototype

the processor. Therefore, the EGPA monitor provides each processor with its position (column, row) in the working plane together with the value of m .

MEMSY

One essential result of all investigations concerning EGPA was the following. For many kinds of computations, the main computing load was carried by the lowest layer. The higher levels were mainly used for distributing partial tasks and data and for the realization of communication mechanisms. The consequence was that the higher layers were left underutilized. For removing this problem, the first idea was to taper the pyramid so that each lower level in an elementary pyramid has 9 or even 16, rather than merely four PMMs. Experiences with a test system showed that excessive tapering (more than nine nodes in the elementary pyramid) can lead to bottlenecks at the higher layers. During these investigations, the best solution was found: The plane B must be mighty enough (elementary pyramid with five nodes) that the upper levels can be removed if the topmost node is connected to the B-plane by a bus. Such a special EGPA system is called MEMSY.

A prototype with 16 nodes in the A-plane and 4 nodes in the B-plane had been realized. The theoretical peak performance was 2 GMIPS or 960 MFLOPS (double precision), the measured performance was up to 500 MFLOPS [3, 4]. (Most of the following information presented in this chapter is taken from [21].)

The node structure of MEMSY differed from that one of the pilot pyramid. Each node consisted of a Motorola multiprocessor board MVEME188 (4 MC88100, 25 MHz clock rate) and additional hardware. It contained a local memory, an attached shared memory, and an I/O-bus with access to different devices.

The programming model of MEMSY was defined as a set of library calls which could be called from C and C++. In contrast to the EGPA model, it was not only based on the shared memory paradigm of EGPA. Instead, the model defined a variety of different mechanisms for communication and coordination. From these mechanisms, the application programmer could pick those calls which were best suited for his particular problem.

The use of the shared memory was based on the concept of “segments,” very much like the original shared memory mechanism provided by UNIX System V. A process which wants to share data with another process (possibly on another node) first has to create a shared memory segment of the needed size. To have the operating system, select the correct location for this memory segment; the process has to specify with which neighboring nodes this segment needs to be shared. After the segment has been created, other processes may map the same segment into their address space by the means of an “attach” operation. The segments may also be unmapped and destroyed dynamically.

For coordination purposes, three mechanisms had been provided: short (two word) messages, semaphores, and spinlocks. There was a second message type for transports of high-volume and fast data transfer between any two processors of the system.

To express parallelism within a node, the programmer had to create multiple processes on each processing element by a special variant of the system call “fork.” Parallelism between nodes was handled by a configuration description, which forced the application environment to start one initial process on each node that the application should run on. In this starting phase, the application was consistent with the SPMD

model. Through the execution of fork-calls, a configuration could be established which is beyond this model.

The operating system of the MEMSY prototype was MEMSOS, it was based on UNIX V/88 Release 3 of Motorola, which was adapted to the multiprocessor architecture of the processor board [20].

In MEMSOS, most of the users' needs were supported by the implementation of the “*application concept*.” An application was defined as the set of all processes belonging to one single user program. A process, belonging to an application, could be identified by (a) a globally unique application id, (b) a task id which was assigned to each process (called *task*) of an application and which was locally unique for this application and processor node and (c) a globally unique node id which identified any node in the system. This concept allowed a very simple steering and controlling of applications. MEMSOS could distinguish different applications and was able to run several of them concurrently in “space sharing” as well as in “time sharing” style.

Additionally, a very important new concept, called “*gang scheduling*,” had been implemented. The purpose of this was to assure the concurrent execution of tasks of one application on all nodes at the same time. This was achieved by creating a runqueue for each application on each allocated node. A global component, called *applserv*, retrieved information about the nodes and the applications started and running there. It established a ranking of applications which were to be scheduled.

Exemplary Applications

In order to validate the concepts of EGPA, certain applications from different scientific areas were adapted to the programming models of the EGPA monitor and of MEMSOS. In some cases, it was necessary to develop new parallel algorithms.

The corresponding programs were written a lot of years ago. The listings of them are no more available. Therefore, it is not possible to give an impression of the amount for writing such a program, e.g., in lines of code. Only the matrix multiplication (see page 7) gives an idea: 50 lines (an estimation of the not shown part is included).

The authors of such parallel programs wrote in their papers mainly about the principles of the underlying parallel algorithms and the runtimes. In many cases, they only published the maximal speedups received by

examples which were well-dimensioned for the used system. This means the problem size is maximal and, e.g., in case of the relaxation, the region under investigation is a square and not a circle or something else (see Fig. 3d). In a few cases, the dependency of the speedup on the problem size is depicted (see Gauss-Seidel and Table 1).

Using the Pilot pyramid, the maximum speedup was 4. Here are some of the measured speedups. The example “text formatting” demonstrates that not all types of tasks will run well on an EGPA system.

Linear algebra [9, 17]:

Matrix inversion: Gauss-Jordan (3.8), Column Substitution (3.95)

Matrix multiplication (3.7)

Gauss-Seidel iteration (4).

Speedup/dimension of the dense matrix: 1/10,
3.4/50, 3.8/200, 3.9/300, 3.99/500

Differential equations [21]:

Relaxation (3.5)

Image processing and graphics [10]:

Topographical representation (3.6)

Illumination of topographical model (2.9),

Vectorizing a grey level matrix (2.9),

distance transformation

- Each processor is working on a fixed part of data (3.0),
- Dynamic assignment of varying parts of data (3.3).

Nonlinear programming [8]:

Search for a minima of a multi-dimensional objective function (3.2)

Graph theory

Network flow with neighborhood aid (3.5)

Text formatting [19] (2.6)

Erlangen General Purpose Array (EGPA). Table 1 Results with 16 processors in the working plane [4]

Poisson equation with Dirichlet conditions: (speedup/number of cells in finest grid)	(11/1024), (14.4/16641), (15.3/65025)
Steady state Stokes equation with staggered grid: (speedup/number of cells in finest grid)	(10.3/1024), (13.7/4096), (15.3/16384)

In order to have a larger system, the DIRMU (Distributed Reconfigurable Multiprocessor based on 8086 with coprocessor 8087) was used for building an EGPA with three layers. Among other things, that multiprocessor was used to investigate multigrid methods which were established in the industry at that time. Though in coarser grids the work per processor is very small, the results were very good (see Table 1). In this context, it is worth mentioning that on a system, which only realized a working plane consisting of 25 DIRMU-PMMs, adaptive multigrid approaches were implemented with high efficiency [5].

On the MEMSY Prototype, several algorithms were realized with great success. The measured efficiency was mostly greater than 80%. This is true for all the above-mentioned algorithms which were ported from pilot or DIRMU to MEMSY [7], but also for the following real world applications [23]:

- Calculation of the electronic structure of polymers
- Parallel molecular dynamic simulation
- Parallel processing of seismic data by wave analogy of the common depth point
- Mapping parallel program graphs into MEMSY by the use of a hierarchical parallel. Algorithm
- Parallel application for calculating one-/two- and ecp-electron integrals for polymers

Only for sparse matrix algorithms, efficiencies near 60% were measured.

Outlook

At the same time when the mentioned EGPA systems were realized in Japan, a very similar systems, named PAX [22], has been built. Also in Japan, the System HAP represented a lot of the principles of EGPA systems [24].

In the 1990s, large commercial multiprocessors came into the market. Distributed memory MIMDs were now available which consisted of much more processors than, e.g., the MEMSY prototype. Even global shared memory systems with cache coherence were larger with respect to the number of processors. Especially the latter multiprocessors were easier to program than EGPA systems with their restricted neighborhoods. Consequently, the research on EGPA machines was stopped even in Erlangen.

Definition

Ethernet is the name of the first commercially successful Local Area Network technology invented by Robert Metcalfe and David Boggs while working at Xerox's Palo Alto Research Center (PARC) in 1973. While the prototype developed worked at 2.96 Mbps, the commercial successor was called Ethernet and worked at 10 Mbps. Several faster versions have been developed and marketed since then.

Ethernet networks are based on the idea of a shared serial bus and the use of Carrier Sense Multiple Access with Collision Detection (CSMA/CD) technique for network peers to communicate. Ethernet media access is fully distributed. Ethernet evolution brings the use of switching instead of CSMA/CD and full-duplex links. At the same time, coaxial cable is first replaced by twisted pair and then by fiber optics.

Discussion

Introduction

The world of Computing has always been a scenario of fast changes where state of the practice is challenged on a daily basis. Most of the advances in our field have come from this attitude of challenging the existing wisdom.

Thanks to that, we moved from the mainframe to the mini, and from it to the Personal Computer and now to embedded systems.

When we lived in a world of a few computers, networking seemed not to be in big demand, but as the number of computers in enterprise grew, a new need started to develop to make efficient use of companies' computing resources. It was the dawn of the Local Area Network (LAN).

In the early days of computing, most of the interconnection focused on adding dumb terminals to the existing mainframe computers. For that purpose, different variations of serial connections sufficed. However, as first minicomputers and then personal computers started to spread on the enterprise there was a need of another type of interconnection. In this new environment, the computing power started to move from a central location to be distributed to each desk. Together with that, the need of keeping systems interconnected became apparent, especially at those locations that have a significant number of mini or personal computers.

Xerox Corporation played an important role in the development of both the personal computer and LANs. More specifically, Xerox founded Palo Alto Research Center (PARC) in 1970 to conduct independent research. Many current technologies can be traced back to PARC, from the personal computer to the Graphical User Interface to Ethernet LANs. Xerox Alto was the first personal computer. It was developed in 1973 ([Fig. 1](#)).

The advent of Ethernet as a successful wired networking technology is based on a wireless precursor

developed at the University of Hawaii and first deployed in 1970 by Normal Abramson and others. They used amateur radios to create a computer network so teletypes at different locations could access a time-sharing system. It was called the ALOHA network. All terminals use a shared frequency to transmit to the host. Simultaneous transmissions destroy each other but if a transmission was successful then it was acknowledged from the host.

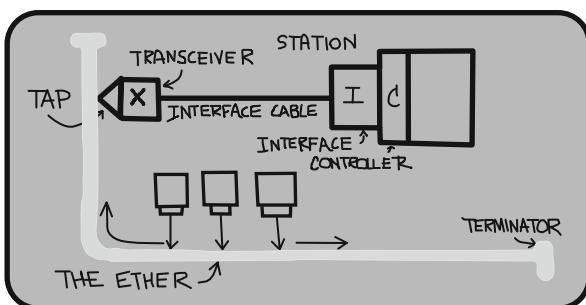

A network technology was needed to link together Alto computers with printers and other devices. No existing technology was found suitable so a team at PARC was set to develop a new technology. That was the embryo of Ethernet.

Collision Sense Multiple Access with Collision Detection

The basic principle of the ALOHA network that allowed a node to transmit at any time was simple but not very efficient. Harvard University student Robert Metcalfe sought to improve the basic idea, and so he did his PhD on a better system and joined PARC. The main improvement was that network nodes should check for an ongoing transmission before starting their own. The way to do this was to check whether a carrier signal was present or not. This technique is also called Listen Before Talk (LBT). This gave way to a technique called Carrier Sense Multiple Access (CSMA).

CSMA could be improved further by adding another mechanism called Collision Detection (CD). It consisted of stopping an ongoing transmission as soon as a collision was detected. A collision happens when two or more network nodes transmit at the same time. The purpose of this second improvement was to reduce the duration of collisions. This newer version of the access method was called Carrier Sense Multiple Access with Collision Detection or CSMA/CD and it was the base for the Ethernet network [1].

A third improvement over ALOHA was what to do after an unsuccessful transmission (collision). While ALOHA called for a random (but short) timer, Metcalfe's proposal was to set the retransmit timer as a random slot number chosen from a special set. Ethernet's Binary Exponential Backoff algorithm calls for random numbers to be selected from a range that starts as {0, 1} and doubles after each collision. The maximum range is {0 ... 1023}. This algorithm ensures that the

Ethernet. Fig. 1 Original Ethernet drawing by Robert Metcalfe

probability of a new collision after a collision is halved. While CSMA/CD works on continuous time, Binary Exponential Backoff works on slotted time, each slot being the time required to transmit 512 bits.

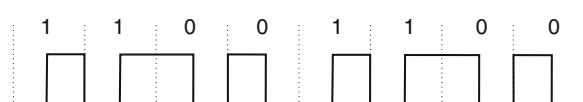

Robert Metcalfe was helped by Stanford student Dave Boggs and they created a working system by 1973 networking together several Alto computers.

Ethernet Topologies

Original Ethernet design used a bus topology with a coaxial cable as the shared media for all the transmissions. Data transmission used a baseband signal using Manchester encoding. A bus was found as a suitable way to broadcast information to all the network nodes and no switching was needed. The network bus was terminated with a resistive load on each end to reduce signal reflection. Maximum segment length was up to 500 m. Repeaters could be used to connect two or more segments together. No more than four consecutive repeaters were allowed. Maximum network diameter was 2,500 m (Fig. 2).

Coaxial cable, specially the thick cable, was difficult to use in an office setup due to its size and it was expensive. This topology had the main drawback of a bus being a single point of failure.

In order to reduce the cost of the network some revisions of Ethernet called for a thinner cable. This so-called Thin Ethernet was still based on a bus topology but using a thinner cable would make it not only cheaper but also easier to install cable runs. Unfortunately, the new setup with thinner cable was not without its own troubles as the attachment of each station was made using so-called T-connectors that required the coaxial cable to be cut at each joint and required two connectors to be added. Both the number of connectors and the physical characteristic of the cable (RG-58) limited the length of Thin Ethernet segments to 185 m.

Ethernet. Fig. 2 Manchester encoding as used on Ethernet

The availability of broadband coaxial cable on some premises for cable TV distribution enabled another variation for Ethernet, but now using broadband signals and these call for a change as transmission is here unidirectional. This broadband version of Ethernet was never very successful but it allowed a maximum distance of 3,600 m.

In a quest for cheaper alternatives, coaxial cable was replaced by twisted pair and the bus topology gave way to a star topology. While the first attempt at this only worked at a fraction of the coaxial data rate, the same speed was achieved with a later version. The main advantage of using twisted pair was its wide availability in office setups as it was used for voice communications. Twisted pair was also cheaper and easier to install and to handle. But the use of star topology called for a central multi-port repeater or hub. Hub device was, in essence, a bus-in-a-box. However, the star topology meant that if a cable was severed only one network node was affected. In a bus topology, if the coaxial cable is severed the whole network stops working. The star topology proved to be much more robust than the bus counterpart but each cable run was limited to 100 m giving a maximum distance of 200 m for each segment.

Support for fiber optic media came from the need for both longer distance links and electrically isolated links. The first use of fiber optic media in Ethernet networks was for the interconnection of repeaters. It later developed as an alternative media to coaxial or twisted pair. While more expensive than copper, fiber optic media allowed longer distances of up to 1,000 m. Ethernet fiber optic links were point to point and that meant a star topology. A passive-star over fiber was proposed but it was never implemented.

The First Ethernet, and the First Commercial Ethernet Success

The first version of Ethernet was deployed in PARC in 1973 and it ran at 2.94 Mbps and used 8-bit values for source and destination addresses. The first 16 bits of the data field were reserved for a type identifier, so different protocols could be used over the same network each one using a different value for the type identifier. Data frames were protected against errors by means of a Cyclic Redundancy Check of 16 bits placed at the end of the frame.

The original name for this network was the Aloha Alto Network, as it was developed for interconnecting Alto computers together and with laser printers. One of the original prototype boards can be found now at the Smithsonian.

However, it was soon recognized that such a name suggested it would only work with Alto computers. The *Ethernet* name was a vendor-neutral name that was based on an old concept of wireless transmissions. During nineteenth century, it was believed that wireless signals propagate using an invisible media called *ether*, although physicists Michelson and Morley rejected that misconception in 1887.

DEC, Intel and Xerox

In 1979, Xerox, DEC and Intel joined to develop a common specification for Ethernet products: The first commercially successful Ethernet network was born. The specification was published as the “blue book” [2].

The new Ethernet specification, also known as DIX (acronym based on the three companies names), called for 10 Mbps data rate, 48-bit addresses, 16-bit type field, and 32-bit Cyclic Redundancy Check (CRC) field (Fig. 3). The data field was of variable size of up to 1,500 bytes. It was a new and improved version of the first Ethernet and now it was set to become a viable commercial product. At this same time, the market for personal computers blossomed with many different models. While this first commercially available version of Ethernet sold well, there were some concerns about the potential lock-in by the three companies. The Institute of Electrical and Electronic Engineers (IEEE) came into play. Ethernet would be standardized within the networking group 802, who met for the first time on February 1980. Ethernet became the IEEE 802.3 standard in 1983 [3]. The availability of the 802.3 standard eased the doubts about the maturity level of Ethernet networks. At the same time, many different companies started selling compatible products many of them intended for the — by then — new IBM PC computer.

IEEE 802.3 also developed several choices for physical media and used a naming convention that prepended the data rate to a word describing the modulation scheme (baseband or broadband) and next the physical media used. 10BASE5 described a 10 Mbps version of Ethernet using Manchester encoding over RG-8X coaxial cable. 10BASE-T described a similar network but over twisted-pair cable.

Eventually twisted pair became the cabling of choice, mostly using two of the four pairs of Category 3 and Category 5 cable. While twisted-pair setups required the use of expensive active hubs, the savings for using cheaper cable and the improved reliability of the network compensated for the additional costs.

CSMA/CD Ethernet Modeling and Problems

One of the early criticisms of Ethernet was the fact that media access is probabilistic (nondeterministic). That means transmission latency cannot be known beforehand. The deterministic behavior of other media access algorithms, like IEEE 802.5 (Token Ring) was considered superior, but average transmission latency is much lower on Ethernet than on a token-passing network (except under very heavy network loads).

Ethernet (and CSMA/CD by extension) was found to exhibit what was called “capture effect,” that happens when two stations contending for the medium have a collision and both have more frames to transmit. The winner will transmit successfully and it will keep an edge on future transmissions against the station that lost the transmission slot after the collision. This effect causes a transient channel-access unfairness that in turn can interfere with higher layer protocols, like TCP, that can amplify the effect.

A second cause of concern was the behavior of heavy loaded Ethernet networks [4, 5]. As traffic grows beyond a certain limit, the chances of a transmission attempt to end up in a collision grow too. Having an increased chance of a collision when traffic load is high introduces a positive feedback that can bring the network to a congestion state. But as Ethernet data rate goes up, so

Ethernet. Fig. 3 Ethernet frame format

does the overload limit. Again, the use of full-duplex Ethernet avoids this problem.

Next Stop: 100 Mbps Ethernet

Once the 10 Mbps Ethernet IEEE standard was approved, the 802 group was tasked to develop a 100 Mbps version. This faster version was known as *Fast Ethernet*. Different standards allowed this faster speed over different types of physical media using both copper and fiber optic media. Twisted-pair cable is not very well suited for high speed communication so different modulation schemes were used over different types of twisted-pair cables to give way to several physical layer specifications: 100BASE-TX use 4B5B MLT-3 coded signals over Category 5 twisted-pair cable while 100BASE-T4 uses 8B6T OAM-3 coded signals over four twisted pairs of Category 3. Similarly, 100BASE-FX is Fast Ethernet media access for multimode fiber. Depending on whether half-duplex or full-duplex links are used, 400 m or 2 km is the maximum link distance respectively for fiber media.

Switched Ethernet

Ethernet evolved not only becoming faster but also adding new components to the original architecture. A shared bus proved to be not enough for large networks. The maximum distance constraints together with traffic considerations opened the way to bridges. One way to increase the capacity of a network segment was to split it into two smaller segments, each one now having fewer computers competing for the available capacity. But these two segments need now to be interconnected so distributed applications can still work as before.

The original bus topology gave way to a star topology using twisted-pair cable. Hubs provided the interconnection between multiple stations but there was a problem: All the stations had to work at the same data rate on the same collision domain. Bridges could be used to split one collision domain into several interconnected network segments where only intersegment traffic was shared.

Therefore, both hubs and repeaters enabled the interconnection of two or more network segments. The term “hub” is used only for the interconnection of point-to-point links while repeaters could be used for interconnecting two coaxial-cable Ethernet segments.

From the logical point of view, both exhibit the same behavior working at the physical layer. A repeater retransmits a digital signal so it can reach a longer distance. A repeater does not create a separation of the collision domain.

A bridge is an interconnection device that works at the Link Layer. Bridges connect two or more cable runs called network segments. Bridges understand MAC addresses and create several independent collision domains. Only traffic intended for other network segment is actually forwarded by a bridge. The aggregate bandwidth of a network interconnected by a bridge is higher than if the interconnection uses a repeater, but so is latency.

The term “bridge” was usually associated with the interconnection of large and usually coax-based segments while the term “switch” referred mostly to interconnection devices using point-to-point links, where each port would have a workstation or server. From the logical point of view, bridges and switches are similar.

Little by little, bridges were replaced by new devices called switches that offered similar functionality but many ports per unit. Switches started to replace network hubs. There was a performance increase but the cost was high too.

The different topologies of Ethernet had to be loop-free. But given that bridges or switches were used to interconnect network segments there was a risk of creating network loops. On the other hand, having network loops is a way to introduce redundancy to the topology of a network, a feature that could be very useful if it did not interfere with Ethernet media access. The problem was that a new component was needed for Ethernet not to have problems in the presence of loops in the network topology or frames would be forwarded forever within the loops.

The brilliant solution to the problem was the Spanning-Tree protocol [6], invented by Radia Perlman while working at Digital Equipment Corporation and ratified as the IEEE 802.1d standard. This protocol running on switches and bridges creates a spanning tree out of the existing network topology. Frames are only forwarded on network segments that belong to the spanning tree and, being a tree a loop-free topology, the problem of forwarding loops is solved. Whenever one of the links in use stops working, a new spanning

tree is calculated making use of the available redundant links. Bridges and switches exchange control frames periodically to maintain the spanning tree.

A switch, like a bridge, works on Link Layer and creates an independent collision domain on each port. Switches are store-and-forward devices that can easily handle different data rates on different ports. Switches can handle simultaneous frame forwarding on different ports, an event that would have caused a collision should a hub were used. Different proprietary flow-control mechanisms were developed for half-duplex switches based on back pressure *congestion management*: A switch may transmit a carrier signal on those ports it wants to alleviate congestion.

Ethernet switches may use different approaches to switching. The simpler way was to use the store-and-forward approach where a frame is stored in a buffer to be retransmitted once it is received entirely by the switch. Cut-through switches only store the very first bytes of the frame and once the destination address is known the forwarding of the frame can start. This second approach leads to a significant reduction of the switching latency experienced by frames.

An Ethernet network that uses switches instead of hubs enables a new improvement: full-duplex links. Provided that the physical media has two different circuits for simultaneous transmission and reception (e.g., two different copper pairs on 100BASE-TX), it is possible for a station to transmit and receive at the same time. While full-duplex Ethernet does work at the same data rate as half-duplex, higher throughput can be achieved with full-duplex. Besides, collisions do not occur in a full-duplex point-to-point link. A collision-free link is going to be more effective as the time devoted to collisions can now be put to use to transmit more data. However, network adapters still need to keep the CSMA/CD functionality for backward compatibility.

Together with full-duplex operation came the 802.3x flow-control mechanism. Sometimes, a receiver on a full-duplex link may not be able to handle frames fast enough. Ethernet flow-control is based on the receiver transmitting a special *pause* frame to a multicast MAC address. Such a frame reports the amount of time (using 512 bit-time units) the sender on that full-duplex link must wait before the next transmission. If a receiver is

able to accept data sooner than expected, a new pause frame with zero wait-time can be transmitted.

Ethernet Gets Faster

In May 1996, the Gigabit Ethernet Alliance was founded by eleven companies interested in the development of Gigabit Ethernet (i.e., 1,000 Mbps Ethernet). The original aim of this new Ethernet version, faster than Fast Ethernet, was to make server and backbone connections even faster. Gigabit Ethernet was covered in IEEE 802.3z and 802.ab standards and it was approved in 1999. Gigabit Ethernet can use either multi-mode fiber, single-mode fiber, or twisted-pair copper cable.

Gigabit Ethernet over copper (known as 1000BASE-T) poses a special challenge for twisted-pair connections that could use Category 5 cable only if it meets some restrictions. This is the reason for Category 5E or Category 6 copper cable. Different techniques were used for making possible to get gigabit speed over copper (e.g., QAM-modulation to more efficiently utilize the channel bandwidth).

Many changes were needed beyond speed. Half-duplex operation was still allowed and so a technique called *carrier extension* was added to allow Ethernet to keep CSMA/CD and the ordinary 200 m maximum network distance. An extension field is appended as needed to ensure a minimum frame length of 512 bytes. Alternatively, another optional improvement was *frame bursting*: It allows the transmission of consecutive data frames after one MAC arbitration on half-duplex channels.

In June 2002, 10 Gigabit Ethernet was ratified. With this new version of Ethernet the performance level is reaching or surpassing other Metropolitan Area Network (MAN) and Wide Area Network (WAN) technologies such as OC-12 and OC-48, SONET or SDH technologies. This is the first version of Ethernet only supporting fiber optic media (10GBASE-CX4 barely supports 15 m of copper cable, just for attaching a switch to a router). A 10 Gbps link range is between 65 m and 40 km. Both multi-mode and single-mode fibers are supported.

Ethernet and Beyond

New versions of Ethernet are coming as 40 Gbps Ethernet and 100 Gbps Ethernet. The IEEE 802.3ba standard

has been ratified in June 2010. A bit unusual was the fact that an interim 40Gbps version was developed largely as a step towards 100Gbps Ethernet. The 802.3ba calls for full-duplex fiber optic links.

Data Center Ethernet (DCE) extends Ethernet architecture to improve networking and management in data centers. Several features like Priority-Based Flow-Control, Enhanced Transmission Selection (standardized as 802.1Qaz), Multipathing or Congestion Management (802.1Qau) focus on improving network features and manageability. The vision of DEC is a unified fabric where LAN, storage area network (SAN), and inter-process communication traffic (IPC) converge.

Technologies like Fiber Channel over Ethernet (FCoE) enable data centers to consolidate interconnection and internetworking technologies into a single network, which may simplify connectivity and reduce data center power consumption.

Whether this is the last stop of Ethernet's network technology or not, it is unclear. However, if past is an indication of what may be ahead, an even faster version of Ethernet should be expected in a few years time.

Bibliographic Notes and Further Reading

Access to many standards has been fee-based. IEEE 802 standards started a move a few years ago by opening their documents to the public, for free. The documents of published standards are available for free download 12 months after they are published. That means all details about any approved Ethernet standard version is easily available visiting <http://standards.ieee.org/getieee802/802.3.html>

Unfortunately, standards are usually written so all details are covered but many times they are not reader-friendly. For getting a good understanding of Ethernet technology, the Charles Spurgeon's [7] guide is a very appropriate text.

Definition

Exascale computing refers to computing with systems that deliver performance in the range of 10^{18} (exa) operations per second.

Discussion

Introduction

In computing literature, it is customary to measure progress in factors of 1000. The term exa, standing for 10^{18} or 1000^6 , is derived from the Greek word ἕξ, meaning six. Thus exascale computing refers to systems that execute between 1000^6 and 1000^7 operations per second. This performance level represents a 1000-fold increase in capability over petascale computing, which itself represents a 1000-fold increase over terascale computing.

There is often confusion over how to denote the performance of a system. The most common measure is the number of double-precision floating-point operations that are completed every second (flops) when the system is running the Linpack dense linear algebra benchmark. By this measure, an exascale system is one which can execute Linpack at the rate of 1 exaflops or higher. For a given system, this is usually less than the peak double-precision floating-point execution rate, typically by 10–30%, because of practical limitations in exploiting the full floating-point capability in a system. In many systems that implement only single-precision floating point in hardware, the peak single-precision floating-point capability may be more than double the flops as measured for Linpack. Petascale computing was ushered in with the introduction of the IBM Roadrunner system in May 2008, when it ran Linpack at 1.1 petaflops. If trends continue as in the past, it is reasonable to expect an exascale system to be operational around 2018.

A list of the Top 500 supercomputers in the world has been maintained since June 1993 and is a useful indicator of trends in the capabilities of the largest scientific machines. The list shows that there has indeed been a trend of doubling of Linpack performance every year, but that the manufacturer of the highest-performing system and the architecture of the system have been changing over time. While shared-memory computers and even uniprocessors made the list in earlier days, today the list is dominated by cluster supercomputers and massively parallel processors, the latter being distinguished from the former by their highly customized interconnection between nodes.

With growing interest in the use of large-scale machines for applications that are considered commercial (or, more appropriately, nonscientific), the term exascale is also being used to refer to systems which can carry out 1000^6 operations per second (1 exaops). There continues to be ambiguity in what constitutes an operation in this terminology. An operation is variously defined as an instruction, an arithmetic or logical operation, an operation intrinsic to the execution of an algorithm, and so on. This has led to one abstract definition of an exascale system to be one that has a performance capability roughly 1000 times more than a system solving the same problem in 2008.

In any case, the needs of the two worlds, scientific and commercial, appear to be converging especially from the points of view of compute capability, system footprint, energy requirements, and cost. It remains to be seen whether, in comparison to systems of 2008, the first exascale system will execute only Linpack 1000 times faster, or whether it will solve a variety of problems, both scientific and commercial, faster by a factor of 1000.

The Importance of Exascale

Large supercomputers are already being used to solve important problems in a variety of areas. The International Exascale Software Project (IESP) has categorized the present areas of application of supercomputers as follows:

- Material Science
- Energy Science
- Chemistry
- Earth Systems

- Astrophysics and Astronomy
- Biology/Life Systems
- Health Sciences
- Nuclear and High Energy Physics
- Fluid Dynamics

Each of these areas has specific problems and a set of algorithms customized to solve those problems. However, there is an overlap in the use of algorithms across these domains, because of similarity in the basic nature of some of the problems across domains. Many of these problems could benefit from even larger supercomputers, but the expectation is that exascale systems will also bring a qualitative change to problem solving, allowing them to be used in new types of problems and in new areas.

There are two ways in which larger supercomputers can help in the solution of existing problems. The first is called strong scaling, where the problem remains the same, but the solution takes less time. Thus, a weather calculation that forecasts the weather a week ahead is more useful if it takes 5 h to solve rather than 5 days. The other form of scaling is called weak scaling, where the size of the problem that can be solved is vastly increased with the help of exascale computers with its significantly larger resources. Thus the quality of a weather forecast can be improved if it is based on global data rather than local data, or if the forecast is made based on data from a larger number of more closely located sensors, or if the model is increased in complexity, for example, through the use of more types of meteorological information.

Beyond just scaling of existing applications, large-scale computing enables new types of computation. It becomes possible to model in a single application a physical phenomenon at different scales in time, space, or complexity simultaneously, for example, at the atomic, molecular, granular, component, or structural scale, or at the molecular, cellular, tissue, organ, or organism scale. This capability is already becoming evident at the petascale level and will be further exploited at the exascale level. Another new and interesting class of applications that will be further exploited in exascale computing is the quantification of uncertainty in mathematical models. These applications involve the use of massive parallel computing to understand the behavior

of physical systems in the presence of both systematic and random variations.

The list of areas that could benefit from the use of supercomputers has been increasing steadily. Applications for supercomputing are also emerging in areas that were not traditionally considered scientific areas. Examples of these are visualization, finance, and optimization. Supercomputers have been used in the past by large movie production companies to render animated movies frame-by-frame over long periods of time. However, for typical scientific applications, the results produced by supercomputers were often packaged and shipped to a significantly smaller computer which the scientist used to analyze and visualize the results. The point where it will be too expensive to ship the vast amount of data produced by supercomputers is fast approaching. Increasingly, supercomputers will be used to process the results of their computation and produce visualization data to be shipped over to the scientist.

The area of business analytics, traditionally considered a commercial application, is fast embracing the use of massive computers. The potential use of massive computation in such areas suggests that exascale computers are likely to represent the point at which supercomputers shift from being the largely simulation-oriented scientific machines that they have traditionally been to more versatile machines solving fundamentally different types of problems for a larger section of humanity.

The Challenges of Exascale

The principal engine for the advances made by supercomputers over the past decades has been Dennard scaling through which the electronics industry has enjoyed the perfect combination of increased density, better performance, and reduced energy per operation with successive improvements in silicon technology. When all dimensions of an electronic circuit on a chip, for example, the transistor gate width, the diffusion depth, and the oxide thickness, are reduced by a factor α , and when the voltage at the circuit is also reduced by a factor α , it is possible to increase the density of packing of devices on the chip by a factor of α^2 and increase the frequency of operation of the device by a factor of α , with a reduction in energy per operation by a factor of α^3 . With process technologists providing lithography improvements that

allowed a doubling of transistor density roughly every 2 years, with microarchitects discovering new ways to expose parallelism at the instruction level, and with system architects engineering sophisticated techniques to combine multiple processors into ever large parallel systems, it was not difficult to maintain a steady doubling of supercomputer system performance every year at almost constant cost.

Going forward from the current 32 nm technology node, it will become increasingly difficult to keep up with Dennard scaling. With oxide thickness down to a few atoms, voltages cannot be scaled proportionally without serious compromise to the reliability and predictability of the operation of devices. It is no longer reasonable to expect the same frequency improvement for constant power density that was enjoyed in the past. At the same time, the nature of typical application programs makes the detection and exploitation of additional parallelism within a single thread of execution difficult. Thus, scaling the total number of threads in a system remains the main option to increase the performance of future large-scale systems. With current petascale systems already sporting hundreds of thousands of cores, the expected number of cores in an exascale system is likely to be in hundreds of millions. Due to various restrictions that will be enumerated below, most of this increase will have to come from using whatever lithography advances are possible to increase the density of cores on a chip.

The task of achieving the goal of building an exascale system by 2018 is daunting. There are challenges in implementing the hardware, in designing the software environment, in programming the system, and in keeping the machine running reliably for long periods at a stretch. Listed below are brief descriptions of some of these challenges.

Power

A quick glance at the Top 500 list shows that the power ratings for the top two petascale systems are, respectively, 4 MW/Petaflops for the Cray system and 2.25 MW/Petaflops for the IBM Roadrunner system. At this rate, an exascale system could consume as much as 2000–4000 MW of power, a quantity that is larger than the amount of power consumed by a medium-sized

US city. The cost of acquiring the largest supercomputer has remained largely constant over the years at around \$100–200 million. This is the cost of about 100–200 MW-years of energy. Thus it is unlikely that exascale installations will be willing to provide more than about 30–50 MW of power, a third of which can be expected to be lost in cooling and power distribution. There is thus a gap of 70x–100x between the power efficiency of today's machines and the desired efficiency of exascale machines. Traditional CMOS scaling would have bridged that gap in about four technology generations, but with the slowing down of CMOS scaling and with longer intervals between introductions of technology generations, it is imperative to look for other avenues to achieve the desired power efficiency.

This gap must be bridged for all components of the system – the processor, the memory system, and the interconnection network. At the processor level, it is likely that exascale systems will include domain-specific accelerators because it is easier to build hardware that is power efficient in a specific domain rather than across a general range of applications. Vector units, which perform the same computation on multiple data simultaneously, could play an even bigger role in exascale systems precisely for this reason. Unlike what is seen in desktop and server processors today, processor designers will be forced to take a minimalist view in every part of the processor, paring overhead down to a minimum without significant impact on performance. Power-efficient optics technology will need to be deployed in interconnection networks if the total system bandwidth has to be scaled proportionally from what exists today. Memory system designs, both at the main memory level and at the cache level, will have to be reinvented with the above stringent power-efficiency requirements in mind.

Memory

One of the trends seen in the top supercomputers is that the fraction of the total cost of the system and the fraction of the total system power going into memory has been steadily rising, even though the ratio of memory capacity to the computational performance (bytes/flop) has been decreasing. In the Top 500 machines, this ratio has decreased from 1 byte/flop to as low as 0.1 byte/flop in some cases. The result of this is that there is a greater pressure on applications

to adapt to the reduced amount of memory by carefully managing the locality of applications, and a pressure on processor designers to provide ever-growing cache capacities and deeper cache hierarchies, both of which add to the challenge of streamlining the processor design to achieve a low power-performance ratio for exascale systems.

Another problem is the bandwidth at the memory interface. DRAM designs have been catering mainly to the commodity market and hence, while their capacities have been keeping up with Moore's Law, their bandwidths have not kept up with increases in processor performance. Cost considerations have prevented supercomputer vendors from designing custom DRAM solutions. However, the rampant data explosion in all types of information processing is forcing even commodity memory vendors to rethink the designs of memory interfaces and modules. It is conceivable that such new designs along with new storage-class memory technologies and new packaging technologies will do a better job in meeting the needs of exascale systems.

Communication

An important aspect of all large-scale scientific applications is the amount of time spent communicating between computation nodes. Applications impose a certain communication pattern which often reflects the locality of interactions of objects in the physical world. Thus the topologies of interconnection networks in large systems tend to be optimized for such communication patterns. Increasingly, however, the nature of algorithms and the types of problems being solved are imposing greater randomness in the pattern of communications and hence greater pressure on the available bandwidth.

One measure used to characterize the behavior of systems for nonlocal communication patterns is the bisection bandwidth. This is the least bandwidth available between any two partitions of the system each having half the total number of computing nodes. Petascale systems for the High Productivity Computing Systems (HPCS) program are required to have a bisection bandwidth of at least 0.5 PB/s. But few organizations will either need or will be able to afford such a high bandwidth per flops ratio.

At the exascale level, costs will force the bandwidth per flops ratio to be even lower. The ExaScale Computing Study sponsored by DARPA estimated the bisection bandwidth requirements at the exascale level to be in a range between 10 PB/s and 1 EB/s. Such a high bandwidth will force a predominant use of optics technology across the system, not just between racks, but also at the board level and perhaps even at the chip level. Exascale computing would benefit from lower costs through commoditization of optics components and from further advances in optics technology, like silicon photonics.

Packaging

As mentioned earlier, the power goal of 30–50 MW for an exascale system will impose challenging requirements in all aspects of the system. One such aspect is packaging. The number of racks in an exascale system cannot be allowed to increase dramatically from today because of limitations in the size and cost of installations. Thus each rack will have to accommodate more boards and each board will have to accommodate more chips than at present. Increased packaging density will increase power density at various levels of the system and will make testing, debugging, and servicing of the system more challenging.

Two technologies that are maturing and that could help in this respect are 3D stacking of silicon dies and the use of silicon carriers. 3D stacking not only helps in providing a compact footprint but also reduces the latency of communication between circuits on different layers. With judicious use of through-silicon vias (TSVs), 3D technology could also provide greater bandwidth between sections of the processor design without having to resort to large, expensive dies.

In comparison to the 1 mm pitch of printed-circuit board technology, silicon carrier technology allows mounting of dies closer than 100 um, wiring pitch of 1–10 um, and an I/O pitch of 10–100 um. The higher signaling rates, the bandwidth, and the higher I/O density promised by silicon carrier technology at lower power and in a compact footprint will go a long way toward meeting exascale goals.

Supercomputers have always been at the forefront in packaging; exascale promises to be no different.

Reliability

The number of components in a system has a direct bearing on the reliability of the system. Today's petascale systems, even with their redundancy and error-correcting techniques at the cache and memory levels, have a mean time between failures (MTBF) of less than a month. A direct extrapolation for a 1000-fold increase in the number of components brings this number down to a few minutes. The conventional method of handling failures is to take a checkpoint of the relevant state of an application at an interval well under the MTBF of the system. When a failure occurs, the system is interrupted, the state reverted back to a previously checkpointed state, and execution resumed. The maintenance of checkpoints requires the system to be periodically interrupted and typically involves copying of processor and memory state to some other part of memory or to storage. The overhead of this checkpointing process could impede forward progress of the application if it has to be performed too often. New techniques for detection of faults and for recovery from faults are needed for future exascale systems.

While coding and redundancy techniques could be used to improve the MTBF of the system, they come at a cost – in area, in power, and often in performance. With the exascale goal already a significant challenge on all these fronts, there is a growing belief that reliability techniques can no longer be application agnostic, and that applications will need to guide when and how checkpointing needs to be done in future large systems.

Usability

The eventual success of exascale computing will be measured not by whether it can execute the Linpack benchmark at an exaflops rate but by how successfully it is embraced by the community and how fundamentally it transforms both science and commerce. The preceding discussion about the challenges of implementing an exascale system suggests that the role of software will be important in the effective exploitation of such a system. On the one hand, life for application developers will be made easier if the system supports today's programming models without change, but on the other hand, software will have to work around the necessary restrictions in hardware due to reasons mentioned above.

Perhaps the most effective way in which this can be accomplished is through widespread adoption of a

new exascale programming model. Neither MPI, the standard message-passing paradigm, nor OpenMP, the standard shared-memory paradigm, alone can exploit a system almost certainly likely to include a cluster of shared-memory SIMD processors. There is growing interest in a hybrid model, for example, one that uses OpenMP at the local chip level and MPI at higher levels. New programming languages classified as Partitioned Global Address Space (PGAS) languages like X10, UPC, Co-Array Fortran, and Titanium provide the programmer the view of one large shared address space for the entire system, but still allow the programmer to specify partitions of the address space local to each thread.

Various parts of the software stack will also be expected to incorporate features to tolerate the expected high rate of failures as discussed in the previous section. While this could be handled directly through the programming language, ease-of-use considerations are likely to force reliability to be taken care of either at the compiler level or in the runtime system, as in the Map-Reduce programming model.

The role of compilers and runtime systems also becomes important if the system is heterogeneous like some of today's petascale systems or if domain-specific accelerators and field-programmable gate-arrays (FPGAs) become part of the system hardware. While a small number of proficient users, the so-called top-gun programmers, would enjoy programming with such a diverse array of components, the vast majority of users would prefer a compiler or the system to decide when and how to employ these components to deliver optimal performance for their programs.

A new organization, the International Exascale Software Project (IESP) has been formed with the recognition that unless a coordinated global effort is begun now, the programming community will not be ready to utilize exascale systems effectively when they are deployed. The IESP has taken upon itself the task of outlining a roadmap for the development of systems software (including operating systems, runtime systems, I/O systems, systems management software), of development environments (including programming models, frameworks, compilers, libraries, and debugging tools), of algorithm support (including data management, analysis, and visualization), and also of algorithms for common applications.

Conclusion

Exascale systems promise to usher in a new era of computing where massive supercomputers will be used not only for traditional simulations of large scientific problems but also to process the vast amount of data that is being produced especially from new types of ubiquitous devices. The success of such large systems, however, will be determined by how effectively they are utilized. Exascale systems can be expected to blaze new trails in power-efficient hardware design, in a system-wide approach to ensuring availability despite expected failures, and in new software approaches to maximize the utilization of the available computation power.

Bibliographic Notes and Further Reading

The most comprehensive description of the challenges of exascale systems can be found in the report of a study [7] under the sponsorship of the DARPA Information Processing Techniques Office. The software challenges are detailed in a similar study described in [9]. The International Exascale Software Project [5] is also actively pursuing an agenda to ensure adequate software exploitation of future exascale systems. DARPA also sponsored a study on reliability aspects of exascale systems and the resulting whitepaper is available at [2].

The Top500 Web site [10] gives a historical trend of the performance and capabilities of the highest-performing scientific computers. The limits of CMOS scaling and its effect on power consumption in future technologies are described well in [3]. An excellent overview of the architecture, power consumption, and economics of large datacenters may be found in [1].

There are several new technologies that promise to supplant or complement nonvolatile storage. A good description of storage-class memories may be found in [4]. There is recent interest also in the use of such memories as extensions to traditional DRAM main memory [8].

A comprehensive description of challenges in packaging and potential solutions can be found in [6]. The promise of 3D technology is discussed in [11]. An introduction to recent advances in silicon photonics appears in [12].

Fault Tolerance

HANS P. ZIMA, ALLEN NIKORA
California Institute of Technology, Pasadena, CA, USA

Definition

Fault tolerance denotes the capability of a system to adhere to its specification and deliver correct service in the presence of faults.

Discussion

Introduction

Modern society relies increasingly on highly complex computing systems across a wide spectrum of applications, ranging from commercial transactions to the control of transportation and communication systems,

the electrical power grid, nuclear reactors, and space missions. In many cases, human lives and huge material values depend on the well-functioning of these systems even under adverse conditions. Despite the successes in verification and validation technology over past decades, theoretical as well as practical studies convincingly demonstrate that large systems typically *do* contain design faults, even when subject to the strictest development disciplines. Moreover, even a perfectly designed system may be subject to external faults, such as radiation effects and operator errors. As a consequence, it is essential to provide methods that avoid system failure and maintain the functionality of a system, possibly with degraded performance, even in the case of faults. This is called *fault tolerance*.

A *fault* is defined as a defect in a system that may cause an *error* during its operation. If an error affects the service to be provided by a system, a *failure* occurs. Fault-tolerant systems were built long before the advent of the digital computer, based on the use of replication, diversified design, and federation of equipment. In an article on Babbage's difference engine published in 1834, Dionysius Lardner wrote [29]: "The most certain and effectual check upon errors which arise in the process of computation is to cause the same computations to be made by separate and independent computers; and this check is rendered still more decisive if they make their computation by different methods." Early fault-tolerant computers include NASA's *Self-Testing-and-Repairing* (STAR) computer, developed for a 10-year mission to the outer planets in the 1960s, and the computers onboard the Jet Propulsion Laboratory's Voyager systems. Today, highly sophisticated fault-tolerant computing systems control the new generation of fly-by-wire aircraft, such as the Airbus and Boeing airliners, protecting against design as well as hardware faults. Perhaps the most widespread use of fault-tolerant computing has been in the area of commercial transactions systems, such as automatic teller machines and airline reservation systems.

The focus of this article is on software methods for dealing with faults that may arise in hardware or software systems. Before entering into a discussion on fault tolerance, the broader concept of *dependability* is explored below.

Dependability

Fault tolerance is one important aspect of a system's **dependability**, a property that has been defined by the IFIP 10.4 Working Group on Dependable Computing and Fault Tolerance as the "*trustworthiness of a computing system which allows reliance to be justifiably placed on the service it delivers.*" Whereas fault tolerance deals with the problem of ensuring correct system service in the presence of faults, the notion of dependability includes also methods for removing faults during system design, for example, via program verification, or to prevent faults a priori, e.g., by imposing coding rules that outlaw common design faults.

Basic Attributes of Dependability

The *attributes* of dependability specify a set of properties that can be used to assess how a system satisfies its overall requirements. A system's dependability specification needs to include the requirements for each of the individual attributes in terms of the acceptable frequency and severity of service failures for specified classes of faults and the system's operating environment. Short definitions for a typical list of attributes are provided below; a detailed discussion can be found in [3, 4, 31].

The *reliability*, $R(t)$, of a system at a time, t , is specified as the probability that the system will provide correct service up to time t . For example, the reliability required for aircraft control systems has been specified as $R(t) > 1 - 10^{-9}$ for $t = 1\text{ h}$ (this is often informally characterized as "9 nines"). The *mean time to failure (MTTF)* is the expected time that a system will operate correctly before failure. System *availability* at a time, t , is defined as the probability that the system can provide correct service at time t . The *safety* of a system is characterized by the absence of catastrophic consequences on its user and the environment it is operating in. More formally, it can be defined as the probability to fail in a *controlled*, or *safe* manner (see section "►Controlled Failure"). *Confidentiality* is a

system's capability to prevent the unauthorized disclosure of information. *Maintainability* characterizes the ability of a system to undergo modifications, including repairs: one specific aspect is the time it takes to restore a failed system to normal operation.

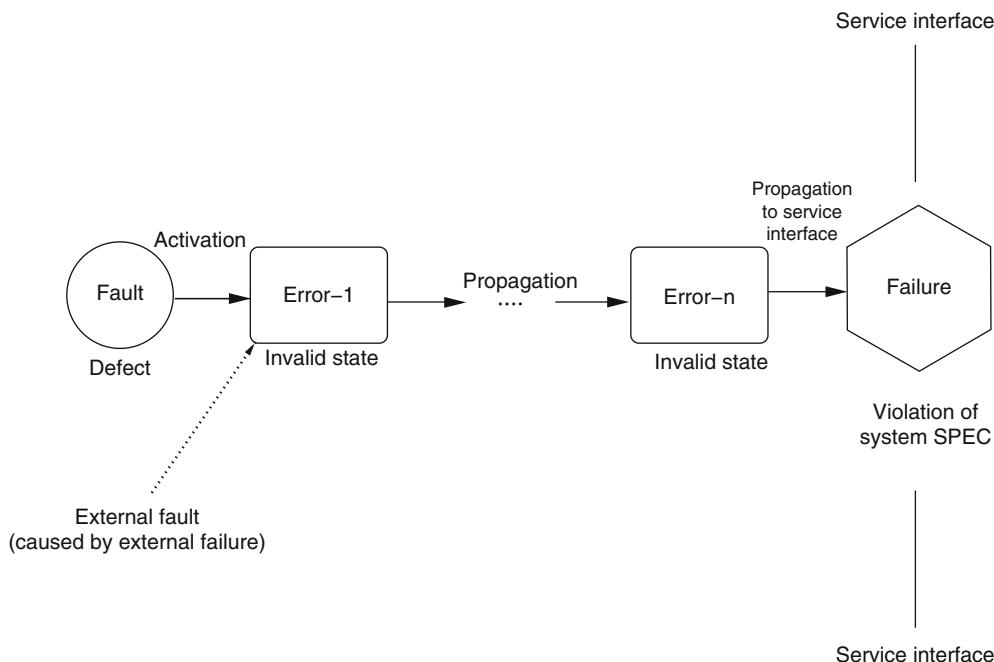

Threats

A *system* is associated with a *specification*, which describes the service the system is intended to provide to its user (a human or another system). It consists of one or more interacting *components*. A *threat* is any fact or event that negatively affects the dependability of a system. Threats can be classified as faults, errors, or failures; their relationship is illustrated by the *fault-error-failure* chain [3] shown in Fig. 1.

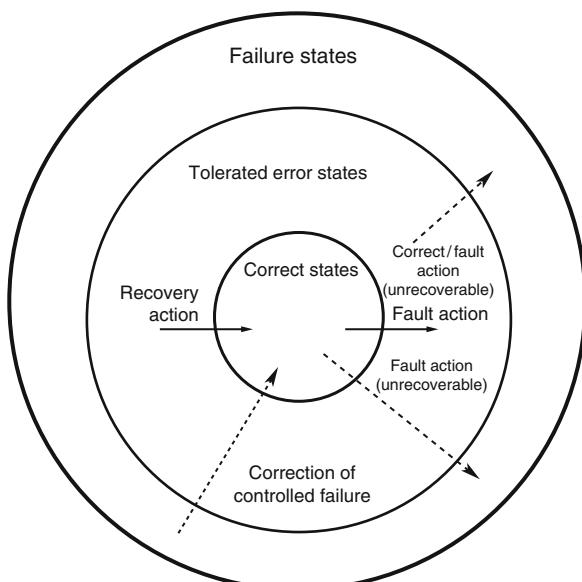

A *fault* is a defect in a system. Faults can be *dormant* – e.g., incorrect program code that is not executed – and have no effect. When *activated* during system operation, a fault leads to an *error*, which is an illegal system state. A fault inside a component is called *internal*; an *external* fault is caused by a failure propagated from another component, or from outside the system. Errors may be propagated through a system, generating other errors. For example, a faulty assignment to a variable may result in an error characterized by an illegal value for that variable; the use of the variable for the control of a for-loop can lead to ill-defined iterations and other errors, such as illegal accesses to data sets and buffer overflows. A *failure* occurs if an error reaches the service interface of a system, resulting in system behavior that is inconsistent with its specification.

The *execution* of a system can be modeled by a sequence of *states*, with state transitions being caused as the result of atomic *actions*. In a first approximation, the set of all system states can be partitioned into *correct states* and *error states*. By separating those error states that allow a recovery from those that represent system failure the set of all error states is further partitioned into *tolerated error states* and *failure states* (Fig. 2). The transitions between these state categories can be described by classifying unambiguously each action as a *correct*, *fault*, or *recovery* action [17]:

- A correct action, executed in a correct state, results in a correct state

Fault Tolerance. Fig. 1 Threats: the fault-error-failure chain

Fault Tolerance. Fig. 2 State-space partitioning

- A fault action, executed in a correct state, results in an error state (tolerated or failure)

- A correct or fault action, executed in a tolerated error state, results in an error state (tolerated or failure)
- A recovery action, executed in a tolerated error state, results in a correct state.
- For a class of systems that are referred to as *fail-controlled* recovery from failure is possible using special protocols (see section “Controlled Failure”).

A system is *fault tolerant* if it never enters a failure state: this means that errors may occur, but they never reach the service boundary of the system and always allow recovery to take place. The implementation of fault tolerance in general implies three steps: error detection, error analysis, and recovery.

The main categories of faults are physical, design, and interaction faults. A *physical fault* manifests itself by malfunctioning of hardware, which is not the result of a design fault. Examples include a *permanent fault* caused by the breakdown of a processor core due to overheating, a *transient fault* caused by radiation and resulting in a bitflip in a register or memory, or a fault caused by a human operator.

Design faults may originate in either hardware or software. An illegal condition in a while loop leading to infinite iteration or an assignment involving incompatible variable types are examples for software design errors.

Interaction faults occur during system operation and are caused by the environment in which the system operates. They include illegal input data or operator errors as well as natural faults caused by radiation hitting the system.

In addition to these main categories, faults can be characterized along a set of additional properties, often across the above classes. This includes the *domain* of a fault – hardware or software, its *intent* – accidental or malicious (e.g., faults caused by viruses, worms, or intrusion), or its *persistence* – hard or soft. A *hard fault* (such as a device breakdown) makes a component permanently unusable. In contrast, a *soft fault* is a temporary fault that can be transient or intermittent. A component affected by such a fault can be reused after the resulting error has been processed. For example, a bitflip in a register caused by a proton hitting a circuit is a transient fault referred to as a *Single Event Upset (SEU)*.

Reflecting the diversity of faults, the failures caused by them can be characterized by a broad range of nonorthogonal properties. These include their *domain* – value or timing, the capability for *control*, *signalling* – signalled or unsignalled failures, and their *consequences*, ranging from minor to catastrophic.

Fault Prevention

Fault prevention addresses methods that prevent faults to being incorporated into a system. In the software domain, such methods include restrictive coding standards that avoid common programming faults, the use of object-oriented techniques such as modularization and information hiding, and the provision of high-level programming languages and abstractions. Firewalls are mechanisms for preventing malicious faults. An example for hardware fault prevention includes shielding against radiation-caused faults [36].

Fault Removal

Despite the existence of fault tolerance methods, a software system's dependability will tend to increase with

the number of faults identified and removed during its development. *Fault removal* refers to the set of techniques that eliminate faults during the design and development process. *Verification and Validation (V&V)* are important in this context: Verification refers to methods for the review, inspection, and test of systems, with the goal of establishing that they conform to their specification. Validation checks the specification in order to determine if it correctly expresses the needs of the system's users.

Verification methods can be classified as either *dynamic* or *static*, depending on whether or not they involve execution of the underlying program. Both techniques require that a system's functional and behavioral specification be transformed into a mathematically based specification language, such as first-order logic [14]. System developers also need to specify a set of *correctness properties*, which must be satisfied. For example, a correctness property for a camera mounted on a robotic planetary exploration spacecraft would be that the camera's lens cover must be closed if the camera is pointed within a given angle of the Sun.

Static verification of a program implies a static proof – performed *before execution* of the program – that for all legal inputs the program conforms to its specification. Early techniques include Hoare's logic and Dijkstra's predicate transformers [12, 20]. Theorem provers use mathematical proof techniques to provide a rigorous argument that the correctness properties are satisfied. Some theorem provers, such as the early versions of the Boyer-Moore theorem prover [6], are designed to operate in a completely automated fashion. Others, such as the Prototype Verification System (PVS) [9], are interactive, requiring the user to "steer" the proof. *Model checkers* determine whether a system's correctness properties can be violated by exploring its computational state space. If a violation is detected, the model checker returns a counterexample describing how the violation can occur. This also means that model checkers can be used to generate test cases for the implemented system [16]. Model checkers are able to identify types of faults associated with multithreaded systems such as deadlocks, lack of progress cycles, and race conditions. The more widely used model checkers include the SPIN model checker [21], UPPAAL [2], and SMV (Symbolic Model Verifier) [32].

Although static verification techniques can identify faults early in a system's development, these techniques face a number of theoretical and practical challenges and limitations. Specifically, many decision problems are undecidable, that is, there is no general method that provides a complete solution [22]. Other problems, for which solution algorithms exist – including many graph problems, are *NP-complete*, that is, computationally intractable due to exponential complexity. Finally, methods such as model checking often need to deal with the scalability challenge, that is, an exploding state space.

Furthermore, substantial effort can be required to create the formal specifications to which these tools will be applied. Learning the specification language can require substantial effort as well; even more important is learning the skill of abstracting from nonessential details of the system's functionality and behavior. For these reasons, these techniques are usually applied only to the critical elements of a system (e.g., the fault detection, identification, and repair component of onboard spacecraft control software, or fault response systems for nuclear power plants).

Dynamic verification technologies are based on the actual execution of the program. Most important are *test* methods. The test of a program for a specific input either demonstrates correctness of the program *for this specific input*, or results in an error. Thus, a specific test execution can either prove that the program operates correctly for the selected input, or it identifies an error. Thus, as already noticed by Edsger Dijkstra in 1972, tests can prove or disprove the *existence* of a fault but never the *absence of all* faults [11].

Controlled Failure

Non-fault tolerant systems may be *fail-controlled*, meaning that they fail only in specific, predefined modes, and only to a manageable extent, avoiding complete disruption. Rather than providing the capability of resuming normal operation, a failure in such a system puts it into a state from which recovery is possible after the failure has been detected and identified.

As an example, the onboard software controlling robotic planetary exploration spacecraft for those portions of a mission during which there is no critical

activity (such as detumbling the spacecraft after launch or descent to a planetary surface) can be organized as a fail-controlled system. When a fault is detected during operation, all active command sequences are terminated, components inessential for survival are powered off, and the spacecraft is positioned into a stable, sun-pointed attitude. Critical information regarding its state is transmitted to ground controllers via an emergency link; rebooting and restoring the health of the spacecraft is then delegated to controllers on Earth.

Systems that preserve continuity of service can be significantly more difficult to design and implement than fail-controlled systems. Not only is it necessary to determine that a fault has occurred, the software must be able to determine the effects of the fault on the system's state, remove the effects of the fault, and then place the system into a state from which processing can proceed.

Fault Tolerance

General Methods for Software Fault Tolerance

Ensuring fault tolerance, that is, continuity of service in the presence of faults, requires replication of functionality. Many of the techniques used to achieve replication of functionality can be categorized as either *design diversity* or as *self-checking software*. Using *design diversity* to tolerate faults in the design of a software system requires that there be at least two *variants* of a system (i.e., different designs and/or implementations based on a common specification), a *decider* to provide an error-free result from the variants' execution, and an explicit specification of decision points in common specification (i.e., specification of when decisions have to be performed, and specification of the data upon which decisions have to be performed). Two well-known types of design diversity are *recovery blocks* and *N-version programming*.

Recovery Blocks

Recovery blocks [34] make use of sequentially applied design diversity. In this case, the decider is an acceptance test that checks the computation results against context-specific criteria to determine whether the result can be accepted as correct. If the acceptance test decides

that the result is correct, the system continues execution and does not attempt to apply any corrective action. On the other hand, if the acceptance test indicates that the result is incorrect, the result is discarded and a variant (termed an “alternate” for recovery blocks) is applied to the inputs to retry the computation. If all of the alternates have been attempted and no results have met the acceptance criteria, additional steps (such as exception handling, see section “Exception Handling”) are required to recover from the fault. A Petri-net model of a recovery block is shown in Fig. 3.

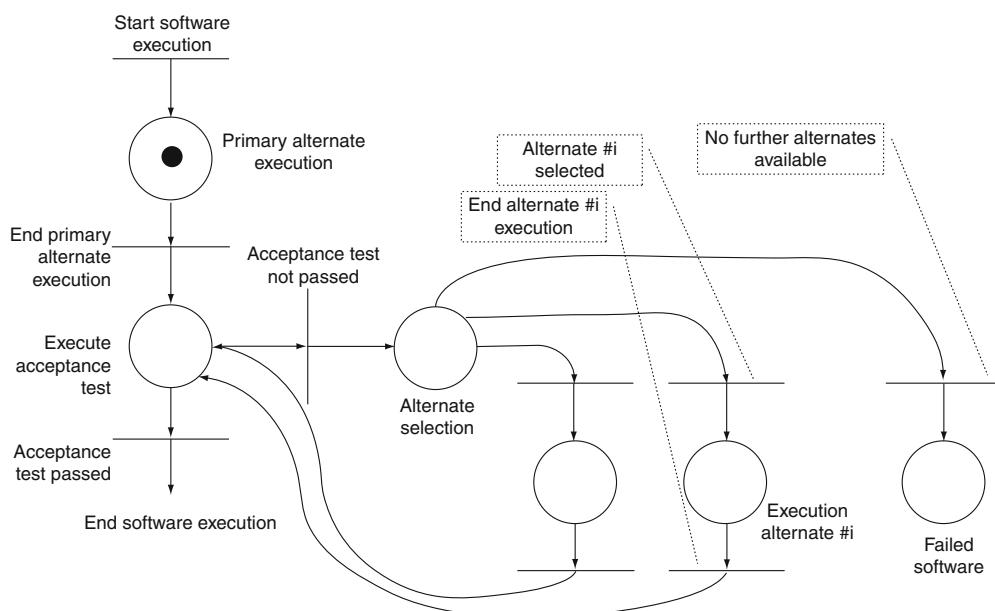

N-Version Programming

For *N-version programming* [5], design diversity is applied by executing all of the variants (termed *versions*) in parallel. The decider then votes on all of the results: if a majority of the results meet the decider’s criteria for correctness, the system is considered to be operating normally and continues execution. Otherwise, further action is required to recover from the fault. A Petri-net model for N-version programming is shown in Fig. 4. A variant of N-version programming, known as back-to-back testing [42], keeps only one of the *N* versions in the fielded system, but uses all of the versions during testing. If a defect is found in one of the *N* versions during test, the other versions are analyzed to determine

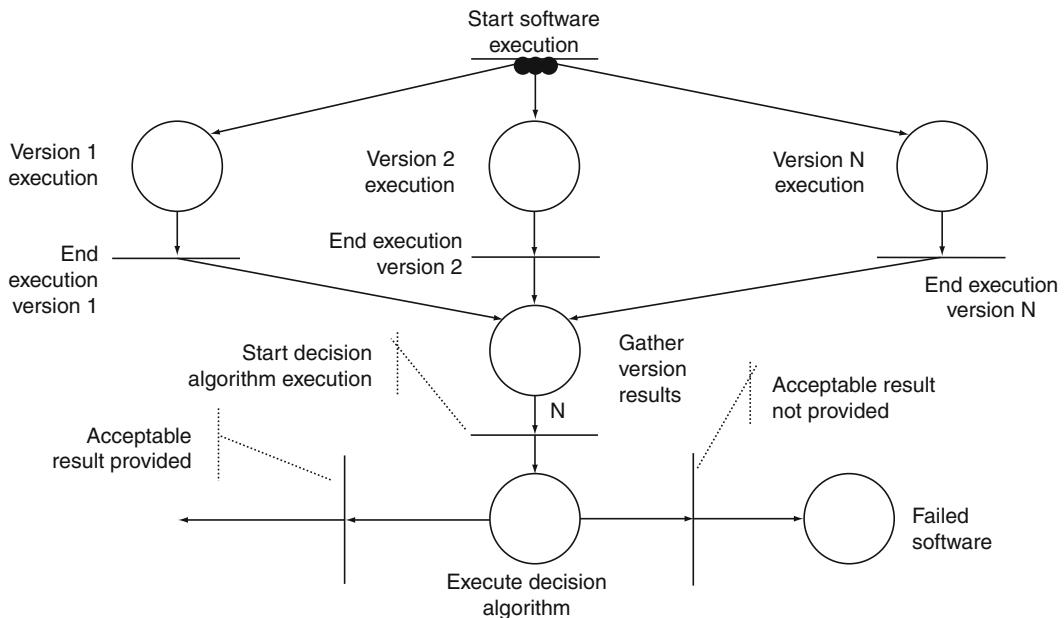

whether they also have that defect. The goal of back-to-back testing is to improve the reliability of a fielded system without incurring the memory space or execution time penalties that might be associated with *N*-version programming. However, fielding only a single version removes the fault-tolerance capability associated with *N*-version programming.

N-Self-Checking Programming

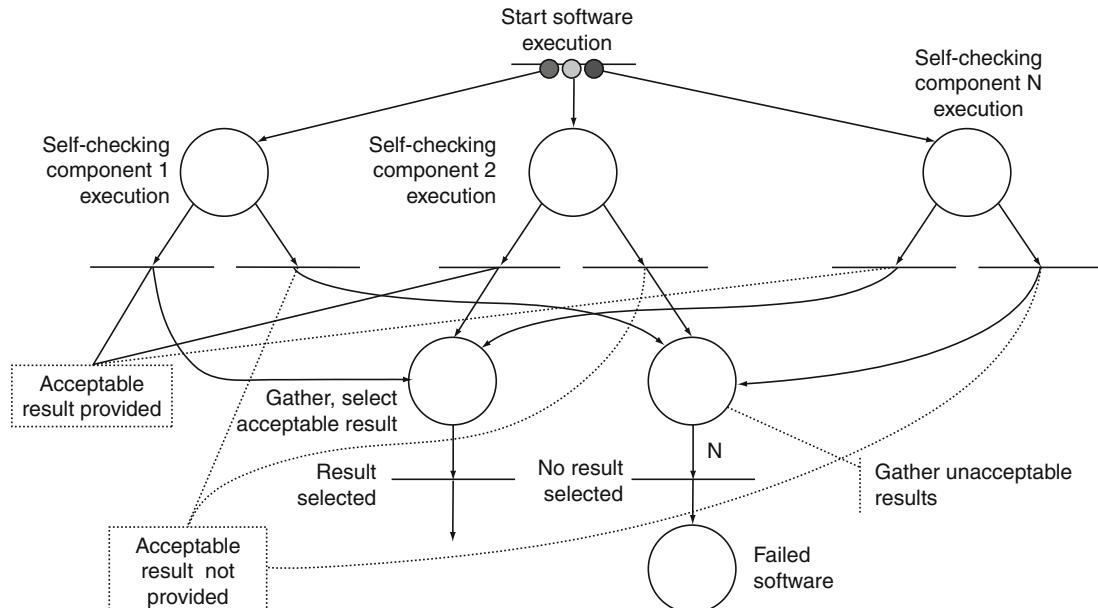

N-self-checking programming [28] combines the idea of an acceptance test from recovery blocks with the parallel execution of $N \geq 2$ variants. In this case, each of the variants has an acceptance test associated with it. The acceptance tests associated to each variant or the comparison algorithms associated to a pair of variants can be the same, or specifically derived for each of them from a common specification. As the variants are executed, the acceptance test associated with each variant determines whether the result meets the criteria for correctness. From the set of correct results, one is selected as the collective output for all the variants and execution proceeds normally. If the set of correct results is empty, the system is considered to have failed and further action is required to restore it to nominal operation. A Petri-net model for *N*-self-checking software is shown in Fig. 5.

Fault Tolerance. Fig. 3 Petri-net model for recovery block

Fault Tolerance. Fig. 4 Petri-net model for N-version programming

Fault Tolerance. Fig. 5 Petri-net model for self-checking programming

For self-checking software components that are based on the association of two variants, one variant only may be written for the purpose of fulfilling the functions expected from the component, while the other variant can be written as an extended acceptance

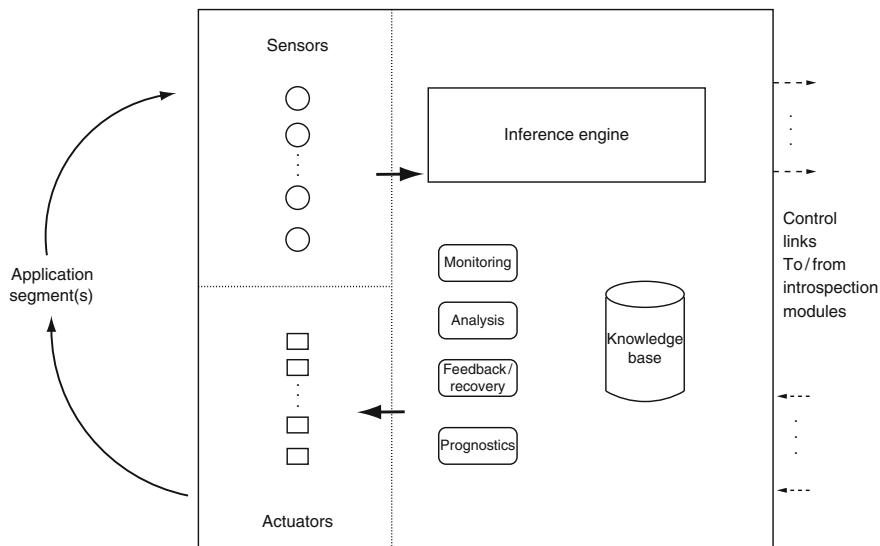

test. For example, it could perform the required computations with a different accuracy, compute the inverse function from the primary variant's results (if possible), or exploit application-specific intermediate results of the primary variant. *Algorithm-based fault tolerance*

(ABFT) belongs to this category [19]. Many of the fault-tolerant systems encountered in real life are based on self-checking software. For example, the software for the Airbus A310 and A320 flight control systems and the Swedish railways' interlocking system are based on parallel execution of two variants – in the latter case, the variants' results are compared, and operation is stopped if the results of the variants disagree.

It is important to note that the actual effectiveness of fault-tolerance techniques based on multiple versions may not be as high as the theoretical limits, because even independent programming teams may make similar errors [25]. However, recent work indicates that in spite of this limitation, N-version techniques can still be a viable way of tolerating faults [7].

systems require support for *adaptive fault tolerance*, based on a *fault model* and a characterization of applications and their components with respect to their overall importance, exposure to faults, and requirements for fault tolerance. An *introspection-based approach* can support such an environment by providing a capability for execution-time monitoring and self-checking, analysis, and feedback-oriented recovery [23]. An introspection module, as illustrated in Fig. 6, is the core element of such a system, connected to the application via a set of software *sensors* for receiving input from, and a set of *actuators* for generating feedback to an application module. An inference engine connected to a knowledge base controls the operation of the introspection module. Introspection modules are organized into an *introspection graph* that reflects the organization and fault-tolerance requirements of the application.

The application-specific error detection, analysis, and recovery actions of an introspection module can be controlled via *assertions* inserted in a program, directions for generation of specific checks, and corresponding recovery actions. This information can be provided by a user or automatically generated from the source program or a pre-existing knowledge basis characterizing properties of the application [23, 44]. A detailed analysis of the range of fault-tolerance requirements for a complex real-time environment is provided in [24].

Fault Tolerance. Fig. 6 Introspection module

Fault Tolerance in Concurrent Systems

Safety and Liveness Properties

A *concurrent system* is introduced as an interconnected collection of a finite number of autonomous *processes*. Processes can either interact via a global *shared memory*, or communicate via *message-passing* over a network. No assumptions are made about individual and relative speeds of processes and delays involved in access to shared memory or message-passing communication, except for the requirement that the speed of active processes is finite and positive, and message delays are finite. (Thus, this model does not cover real-time constraints.) An *execution* of such a system can be modeled by a sequence of system states, with a transition between successive states taking place as a result of an atomic action in a process or a communication step.

Lamport [27] introduced two key types of *correctness properties* for parallel systems: safety properties and liveness properties. A *safety* property can be described by a predicate over the state that must hold for *all* executions of the system. It rules out that “bad things happen.” An example for a safety property is the requirement of an airline reservation system to provide *mutual exclusion* for accesses to any record representing a specific flight on a given day. A more mundane example is the requirement for a system controlling the traffic lights of a street intersection that the lights for two crossing streets may never be green at the same time. A *liveness* property requires that each process, which in principle is able to work, will be able to do so after a finite time. This property can be expressed via a predicate that must be *eventually* satisfied, guaranteeing that “a good thing will finally happen.” For instance, if a set of processes compete for a resource, each of the processes should be able to acquire it after a finite amount of time. Examples for violation of liveness include the prevention of a process to reach regular termination or to provide a specified service. Another example is a *deadlock* involving two or more processes, which cyclically block each other indefinitely in an attempt to access common resources. Alpern and Schneider have shown that *every possible* property of the set of executions can be expressed as a conjunction of safety and liveness properties [1].

The manifestation of faults in a concurrent system, and related methods for their toleration depend largely

on detailed system properties and the programming model under consideration. In the next subsection, a number of typical problems in concurrent systems are shortly discussed; a comprehensive treatment of such issues can be found in [35]. In addition to the applicability of the general methods discussed in section “General Methods for Software Fault Tolerance”, fault tolerance can be often achieved using specialized techniques.

Example Problems

Mutual exclusion constrains access to a shared resource – for example, a variable, record, file, or output device – such that at any time at most one process may access the resource (a safety property). Any correct solution must also guarantee that each process requesting the resource is granted access after a finite waiting period (a liveness property). A simple method for implementing mutual exclusion in a shared memory system is via a binary semaphore [10] that controls access to the resource. The corruption of the semaphore value (by any process or as a result of a hardware fault) destroys the safety property of the algorithm. An error in the semaphore implementation may destroy the liveness property. The mutual exclusion problem is discussed in detail in [10].

State-based synchronization makes the progress of a process dependent on a condition in its environment. For example, in a simple version of the *producer-consumer problem*, the producer and consumer are autonomous processes operating asynchronously, with a cyclic buffer between them acting as a temporary storage for data items: in each cycle of the producer, it generates one data item and places it into the buffer; conversely, the consumer removes in each cycle one item from the buffer and then processes it. Wrong synchronization (as a result of a design error or a corruption of variables used for the coordination) can lead to a number of errors, including the corruption of a buffer element, an attempt of the producer to write into a full buffer, or an attempt of the consumer to read from an empty buffer. The result is a violation of the safety property, and possibly of liveness.

A *deadlock* is a system state where two or more processes block each other indefinitely in an attempt to access a set of resources. In a typical example, process p_1 holds resource r_1 and requests resource r_2 , while process p_2 holds r_2 and requests r_1 . This is a violation of the liveness requirement. It can be addressed in a number

of ways, including deadlock prevention –, by prioritizing resources and allowing access requests only in rising priority order, or by periodically checking for a deadlock and taking a recovery action if it occurs. A different example for a liveness violation is represented by the famous *dining philosophers problem*, where two processes conspire to block a third process indefinitely from accessing a common resource. Problems of this kind can be avoided by defining an upper limit for the number of unsuccessful resource requests, and prioritizing the blocked process once this limit is reached.

In a system where processes communicate over a network, a *network fault* can propagate into a number of different faults in the process system. These include (1) transmission of wrong message content, (2) sending a message to the wrong destination, and, (3) total loss of the message, resulting in a possibly indefinite delay of the intended receiver. A way to deal with the last of these faults is the use of a *watchdog timer* that regularly checks the progress of processes.

Byzantine faults are arbitrary value or timing faults that can occur as a result of radiation hitting a circuit, or of a malicious intruder. Under certain conditions, such faults can be tolerated using a sophisticated form of replication [18].

Checkpointing and Rollback Recovery in Message-Passing Systems

This section deals with fault tolerance for long-running applications in message-passing systems implemented on top of a reliable communication layer (which has to be provided by the underlying hardware and software layers of the network). The state of such systems consists of the set of local states of the participating processes, extended by the state of the communication system, which records the messages that are in-flight at any given time. Consistency of the global state implies that the dependences created between processes as a result of message transmissions must be observable in the state: more specifically, at the time a process records receipt of a message the state of the sender must reflect the previous sending of that message.

A recovery approach based on checkpointing and rollback requires a stable storage device that is not affected by faults in the system. At a *checkpoint*, a process saves recovery information to this storage device during fault-free operation; after occurrence of an error

(e.g., as a result of a failing process), the information stored at the checkpoint can be used to restart the process. Recovery can be managed by the application; here a system-supported approach is discussed.

There are two categories of recovery-based protocols. The first relies only on the use of checkpoints, whereas the second approach in addition performs logging of all nondeterministic events, which allows the *deterministic* regeneration of an execution after the occurrence of a fault (which is not possible if only checkpoints are used). This is important in applications that heavily communicate with the outside world (which cannot be rolled back!). However, from the viewpoint of today's large-scale scientific applications, the first approach, which will just be denoted as *checkpointing* is more relevant, and will be the sole focus in the rest of this section.

There are two main methods for performing checkpointing, which are characterized as uncoordinated or coordinated. In *uncoordinated checkpointing*, each process essentially decides autonomously when to take checkpoints. During recovery, a consistent global checkpoint needs to be found taking into account the dependences between the individual process checkpoints. Uncoordinated checkpointing has the advantage of allowing a process to take into account local knowledge, for example, for minimizing the amount of data that needs to be saved. However, there are serious disadvantages, including the *domino effect* that can result in rollback propagation all the way to the beginning of the computation and the need to record multiple checkpoints in each process, with the necessity of periodical cleanups via garbage collection.

As a result of these shortcomings, the dominating method used in today's systems, and particularly in supercomputers, is *coordinated checkpointing*. In this approach, a global synchronization step involving all processes is used to form a consistent global state. Only one checkpoint is needed in each process, and no garbage collection is required. A straightforward centralized two-stage protocol for the creation of a checkpoint requires blocking of all communication while the protocol executes. In a first step, a *coordinator process* broadcasts a *quiesce message* to all processes requesting them to stop. After receiving an acknowledgment for this request from all processes, the coordinator broadcasts a *checkpoint message* that requests processes to take their checkpoint and acknowledge completion. Finally,

after receipt of this acknowledgment from all processes, the coordinator broadcasts a *proceed message* to all processes, allowing them to continue their work. On a failure in a process, the whole application rolls back to the last checkpoint and resumes execution from there.

Coordinated checkpointing provides a relatively simple approach to recovery. Drawbacks include the overhead for communication in the checkpointing and recovery protocols, and the time required for storing the relevant data sets to a stable storage device, with the obvious consequences for scalability. In fact, a recent study on exascale computing [15] shows that checkpointing along the above protocol seems no longer to be feasible, due to the existence of billions of threads in such a system. A potential solution would require new storage technology for saving the recovery information.

A comprehensive treatment of rollback-recovery protocols, including log-based approaches, can be found in [13]. Coordinated checkpointing for large-scale supercomputers is discussed in detail in [43], including a study of scalability and an approach to deal with failures during the checkpointing and recovery phases.

Fault Injection Testing

Fault injection testing refers to a technique for revealing defects in a system's ability to tolerate faults [40]. Fault injection inserts faults into a system or mimicks their effects, combined with a strategy that specifies the type and number of faults to be injected into system components, the frequency at which faults are to be injected, and dependencies among fault types.

A number of fault injectors have been developed [37, 38, 40], which allow faults to be inserted into a computing system's memory or processor registers while the system is running, in a manner that is transparent to the executing application and system software. This allows developers of fault-tolerant systems to observe the system operating in an environment closely related to the expected environment during fielded use. As faults are injected into the system, system engineers are able to observe the immediate effects of each fault as well as the way in which it propagates through the system. When conducting fault injection testing, it is necessary to design test strategies that will cause the system under test to execute its fault-handling capabilities under a wide variety of conditions. One particular strategy, implemented by the Ballista automated testing

methodology [26], is to change the parameters passed to software modules and observe the result. In Ballista, a test passes if the system does not hang or crash, ignoring the validity of output values produced. The JPL Implementation of a Fault Injector (JIFI) [39] toolset is typical of modern software-controlled fault injectors. It allows automated campaigns of random uniformly distributed bitflip faults into application registers and/or memory space and registers. In order to characterize the fault injection results, it is necessary to verify the final result and classify its effect on the system with respect to its liveness properties and the functional correctness of the output. The main goal of this methodology is to characterize an application's sensitivity to transient faults. For example, it is possible to determine whether the application is more likely to crash or produce incorrect results, or which subroutines of the program are most vulnerable.

Exception Handling

An *exception* is a special event that signals the occurrence of one among a number of predetermined faults in a program. Exception handling can be considered as an additional fault-tolerance technique in that it provides a structured response to such events.

There are two types of exception handling, resumption and termination [8]. In resumption, if an exception is encountered at a given command in a program, the program is temporarily halted and control is transferred to a handler associated with that program. The handler performs the computations required to mitigate the effects of the exception and then transfers control back to the program. The handler may return to the command immediately following the one at which the exception was encountered, or to a different location that may depend on the details of the program's state when the exception was signalled. By contrast, termination simply leads to the (controlled) halting of the program in which the exception was observed.

Although resumption has a potential advantage in that the interrupted program may be resumed upon successful execution of the handler, there are also advantages associated with choosing termination [8]. For example, with termination a programmer is encouraged to recover a consistent state of a module in which an exception is detected before signalling it, so that further calls to the module's procedures find the module state consistent. With resumption, a programmer

does not know if control will come back after signalling an exception. In addition, recovering a consistent state before signalling (e.g., for example by undoing all changes made since the procedure start) defeats the purpose of resumption, which is to save the work done so far between the procedure entry and the detection of the exception. If a consistent state is not recovered, the handler may never resume execution of the module after the signalling command, and the module will remain in the intermediate, most likely inconsistent, state that existed when the exception was detected, meaning that further module calls can lead to additional exceptions and failures.

Future Directions

As computing systems become increasingly embedded in and critical to society, more effective capabilities to deal with faults induced by exceptional environmental conditions, specification and design defects, or both, will be required. As an example, consider implantable medical devices such as insulin pumps or defibrillators. These systems already execute safety-critical software; future versions of these devices intended to respond to a wider set of medical conditions will be substantially more complex than those in operation today. New challenges for fault tolerance will also come from the increased degree of automation in transportation systems (railways, airplanes, automobiles) as well as extreme-scale systems for large-scale simulation with billion-way parallelism [15]. Last but not least, future robotic space missions in our solar system and beyond will demand an unprecedented degree of autonomy when operating in environments in which direct communication with Earth will no longer be possible within practical time intervals. The additional complexity of these systems and the uncertainties of the environments in which they operate will introduce more opportunities for specification and design defects [33], for which effective fault-tolerant techniques must be developed and deployed.

Bibliographic Notes and Further Reading

The basic concepts of dependability are discussed in detail in the seminal work of Avizienis, Laprie, Randell, and Landwehr [3, 4]. A comprehensive discussion of software fault tolerance can be found in the collection of articles edited by Lyu [30]. In [31] dependability and fault tolerance are discussed with a focus on hardware issues. Faults and fault tolerance for algorithms in distributed systems, with a detailed treatment of provably solvable and unsolvable issues can be found in [41].

The premier conference on dependability is the annual *IEEE/IFIP International Conference on Dependable Systems and Networks* (DSN), with DSN-40 held in Chicago in 2010. This conference was established in 2000 by combining the IEEE-sponsored *International Symposium on Fault-Tolerant Computing* (FTCS), which had been held since 1971, with the *Working Conference on Dependable Computing for Critical Applications* (DCCA) sponsored by IFIP WG 10.4. Other conferences related to dependability include the *International Symposium on Software Reliability Engineering* (ISSRE) organized by the IEEE Computer Society and the *Reliability, Availability, and Maintainability Symposium* (RAMS) organized by the IEEE Reliability Society.

In addition to many journals discussing fault tolerance in the context of more general or related areas such as software engineering, programming languages and systems, and system security, the *IEEE Transactions on Dependable and Secure Computing* (TDSC) have a strong focus on dependability and fault tolerance. The bibliography in [17] provides a good overview of publications in the field until 1999.

Synonyms

[Fast algorithm for the discrete Fourier transform \(DFT\)](#)

Definition

A fast Fourier transform (FFT) is an efficient algorithm to compute the discrete Fourier transform (DFT) of an input vector. Efficient means that the FFT computes the DFT of an n -element vector in $O(n \log n)$ operations in contrast to the $O(n^2)$ operations required for computing the DFT by definition. FFTs exist for any vector length n and for real and higher-dimensional data. Parallel FFTs have been developed since the advent of parallel computing.

Discussion

Introduction

The discrete Fourier transform (DFT) is a ubiquitous tool in science and engineering including in digital signal processing, communication, and high-performance computing. Applications include spectral analysis, image compression, interpolation, solving partial differential equations, and many other tasks.

Given n real or complex inputs x_0, \dots, x_{n-1} , the DFT is defined as

$$y_k = \sum_{0 \leq \ell < n} \omega_n^{k\ell} x_\ell, \quad 0 \leq k < n, \quad (1)$$

with $\omega_n = \exp(-2\pi i/n)$, $i = \sqrt{-1}$. Stacking the x_ℓ and y_k into vectors $x = (x_0, \dots, x_{n-1})^T$ and $y = (y_0, \dots, y_{n-1})^T$ yields the equivalent form of a matrix-vector product:

$$y = \text{DFT}_n x, \quad \text{DFT}_n = [\omega_n^{k\ell}]_{0 \leq k, \ell < n}. \quad (2)$$

Computing the DFT by its definition (2) requires $\Theta(n^2)$ many operations. The first fast Fourier transform algorithm (FFT) by Cooley and Tukey in 1965 reduced the runtime to $O(n \log(n))$ for two-powers n and marked the advent of digital signal processing. (It was later discovered that this FFT had already been derived and used by Gauss in the nineteenth century but was largely forgotten since then [9].) Since then, FFTs have been the topic of many publications and a wealth of different algorithms exist. This includes $O(n \log(n))$ algorithms for any input size n , as well as numerous variants optimized for various computing platform and computation requirements. The by far most commonly used DFT is for two-power input sizes n , partly because these sizes permit the most efficient algorithms.

The first FFT explicitly optimized for parallelism was the Pease FFT published in 1968. Since then specialized FFT variants were developed with every new type of parallel computer. This includes FFTs for data flow machines, vector computers, shared and distributed memory multiprocessors, streaming and SIMD vector architectures, digital signal processing (DSP) processors, field-programmable gate arrays (FPGAs), and graphics processing units (GPUs). Just like Pease's FFT, these parallel FFTs are mainly for two-powers n and are adaptations of the same fundamental algorithm to structurally match the target platform.

On contemporary sequential and parallel machines it has become very hard to obtain high-performance DFT implementations. Beyond the choice of a suitable FFT, many other implementation issues have to be addressed. Up to the 1990s, there were many public FFT implementations and proprietary FFT libraries available. Due to the code complexity inherent to fast implementations and the fast advances in processor design, today only a few competitive open source and vendor FFT libraries are available in the parallel computing space.

FFTs: Representation

Corresponding to the two different ways (1) and (2) of representing the DFT, FFTs are represented either as sequences of summations or as factorizations of the transform matrix DFT_n . The latter representation is adopted in Van Loan's seminal book [18] on FFTs and used in the following. To explain this representation, assume as example that DFT_n in (2) can be factored into four matrices

$$DFT_n = M_1 M_2 M_3 M_4. \quad (3)$$

Then (2) can be computed in four steps as

$$t = M_4 x, u = M_3 t, v = M_2 u, y = M_1 v.$$

If the matrices M_i are sufficiently sparse (have many zero entries) the operations count compared to a direct computation is decreased and (3) is called an FFT. For example, DFT_4 can be factorized as

$$DFT_4 = \begin{bmatrix} 1 & 1 \\ 1 & 1 \\ 1 & -1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} 1 & \\ 1 & \\ i & \\ & 1 \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 1 & -1 \\ 1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} 1 & \\ 1 & \\ 1 & \\ 1 & \end{bmatrix}, \quad (4)$$

where omitted values are zero. This example also demonstrates why the matrix-vector multiplications in (3) are not performed using a generic sparse linear algebra library, but, since the M_i are known and fixed, by a specialized program.

Conversely, every FFT can be written as in (3) (with varying numbers of factors). The matrices M_i in FFTs are not only sparse but also structured, as a glimpse on (4) illustrates. This structure can be efficiently expressed using a formalism based on matrix algebra and also clearly expresses the parallelism inherent to an FFT.

Matrix formalism and parallelism. The $n \times n$ identity matrix is denoted with I_n , and the *butterfly matrix* is a DFT of size 2:

$$DFT_2 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}. \quad (5)$$

The *Kronecker product* of matrices A and B is defined as

$$A \otimes B = [a_{k,\ell} B], \quad \text{for } A = [a_{k,\ell}].$$

It replaces every entry $a_{k,\ell}$ of A by the matrix $a_{k,\ell} B$. Most important for FFTs are the cases where A or B is the identity matrix. As examples consider

$$I_4 \otimes DFT_2 = \begin{bmatrix} 1 & 1 & & & \\ 1 & -1 & & & \\ & & 1 & 1 & \\ & & 1 & -1 & \\ & & & 1 & 1 \\ & & & 1 & -1 \\ & & & & 1 & 1 \\ & & & & 1 & -1 \end{bmatrix},$$

$$DFT_2 \otimes I_4 = \begin{bmatrix} 1 & & & & 1 & & & \\ & 1 & & & & 1 & & \\ & & 1 & & & & 1 & \\ & & & 1 & & & & 1 \\ \hline 1 & & & & 1 & & & \\ & 1 & & & & -1 & & \\ & & 1 & & & & -1 & \\ & & & 1 & & & & -1 \end{bmatrix},$$

with the corresponding dataflows shown in Fig. 1. Note that the dataflows are from right to left to match the order of computation in (3). $I_4 \otimes DFT_2$ clearly expresses block parallelism: four butterflies computing on contiguous subvectors; whereas $DFT_2 \otimes I_4$ expresses vector parallelism: four butterflies operating on interleaved subvectors which is the same as one *vector butterfly* operating on *vectors* of length four as emphasized in Fig. 1(b). More precisely, consider the code for DFT_2 (i.e., $y = DFT_2 x$):

```
y[0] = x[0] + x[1];
y[1] = x[0] - x[1];
```

Then code for $\text{DFT}_2 \otimes I_4$ is obtained by replacing every scalar operation by a four-way vector operation:

```
y[0:3] = x[0:3] + x[4:7];
y[4:7] = x[0:3] - x[4:7];
```

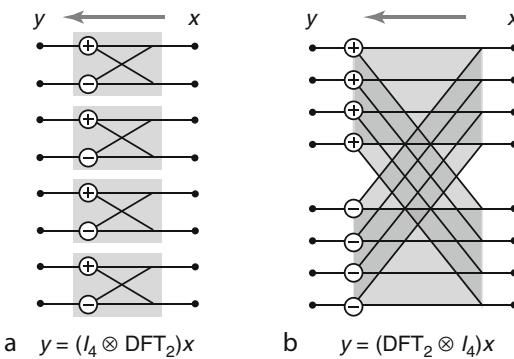

Here, $x[a:b]$ denotes (Matlab or FORTRAN style) the subvector of x starting at a and ending at b . These examples illustrate how the tensor product captures parallelism. To summarize:

block parallelism (n blocks): $I_n \otimes A$, (6)

vector parallelism (n -way): $A \otimes I_n$, (7)

where A is any matrix.

The *stride permutation* matrix L_m^{mn} permutes the elements of the input vector as $in + j \mapsto jm + i$, $0 \leq i < m$, $0 \leq j < n$. If the vector x is viewed as an $n \times m$

FFT (Fast Fourier Transform). Fig. 1 Dataflow (right to left) of a block parallel and its “dual” vector parallel construct (figure from [5])

matrix, stored in row-major order, then L_m^{mn} performs a transposition of this matrix. Further, if P is a permutation (matrix), then $A^P = P^{-1}AP$ is the *conjugation* of A with P .

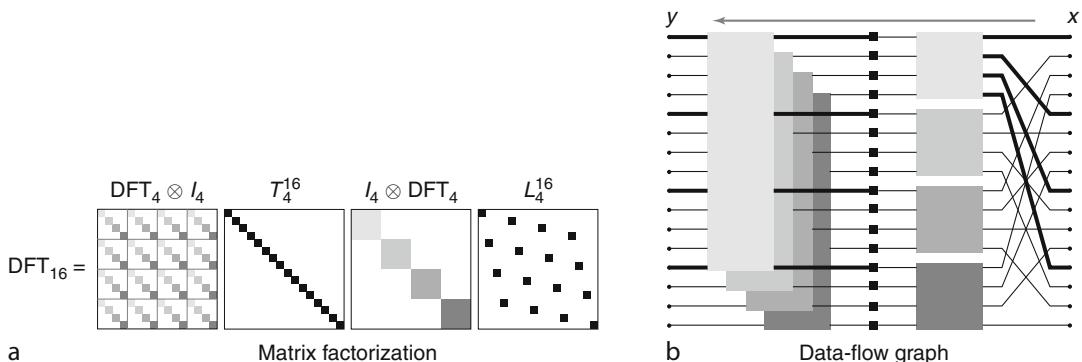

Cooley–Tukey FFT. The fundamental algorithm at the core of the most important parallel FFTs derived in the literature is the general-radix decimation-in-time Cooley–Tukey type FFT expressed as

$$\text{DFT}_n = (\text{DFT}_k \otimes I_m) T_m^n (I_k \otimes \text{DFT}_m) L_k^n, \quad n = km. \quad (8)$$

Here, k is called the radix and T_m^n is a diagonal matrix containing the *twiddle factors*. The algorithm factors the DFT into four factors as in (4), which shows the special case $n = 4 = 2 \times 2$. Two of the four factors in (8) contain smaller DFTs; hence the algorithm is divide-and-conquer and has to be applied recursively. At each step of the recursion the radix is a degree of freedom. For two-power sizes $n = 2^\ell$, (8) is sufficient to recurse up to $n = 2$, which is computed by definition (5).

Figure 2 shows the special case $16 = 4 \times 4$ as matrix factorization and as corresponding data-flow graph (again to be read from right to left). The smaller DFTs are represented as blocks with different shades of gray.

A straightforward implementation of (8) suggests four steps corresponding to the four factors, where two steps call smaller DFTs. However, to improve locality, the initial permutation L_k^n is usually not performed but interpreted as data access for the subsequent computation, and the twiddle diagonal T_m^n is fused with the

FFT (Fast Fourier Transform). Fig. 2 Cooley–Tukey FFT (8) for $16 = 4 \times 4$ as matrix factorization and as (complex) data-flow graph (from right to left). Some lines are bold to emphasize the strided access (figure from [5])

subsequent DFTs. This strategy is chosen, for example, in the library FFTW 2.x and the code can be sketched as follows:

```
void dft(int n, complex *y, complex *x) {
    int k = choose_factor(n);
    // t1 = (I_k tensor DFT_m)L(n,k)*x
    for(int i=0; i < k; ++i)
        dft_iostride(m, k, 1, t1 + m*i, x + i);
    // y = (DFT_k tensor I_m)diag(d(j))*t1
    for(int i=0; i < m; ++i)
        dft_scaled(k, m, precomp_d[i], y + i,
                   t1 + i);
}
// DFT variants needed
void dft_iostride(int n, int istride,
                  int ostride, complex *y, complex *x);
void dft_scaled(int n, int stride,
                complex *d, complex *y, complex *x);
```

The DFT variants needed for the smaller DFTs are implemented similarly based on (8). There are many additional issues in implementing (8) to run fast on a nonparallel platform. The focus here is on mapping (8) to parallel platforms for two-power sizes n .

Parallel FFTs: Basic Idea

The occurrence of tensor products in (8) shows that the algorithm has inherent block and vector parallelism as explained in (6) and (7). However, depending on the platform and for efficient mapping, the algorithm should exhibit one or both forms of parallelism throughout the computation to the extent possible. To achieve this, (8) can be formally manipulated using well-known matrix identities shown in Table 1.

The table makes clear that there is a virtually unlimited set of possible variants of (8), which also explains the large set of publications on FFTs. These variants hardly differ in operations count but in structure, which is crucial for parallelization. The remainder of this entry introduces the most important parallel FFTs derived in the literature. All these FFTs can be derived from (8) using Table 1. The presentation is divided into iterative and recursive FFTs. Each FFT is visualized for size $n = 16$ in a form similar to (1) (and again from right to left) to emphasize block and vector parallelism. In these visualizations, the twiddle factors are dropped since they do not affect the dataflow and hence pose no structural problem for parallelization.

FFT (Fast Fourier Transform). Table 1 Formula identities to manipulate FFTs. A is $n \times n$, and B and C are $m \times m$. A^T is the transpose of A

$(BC)^T$	$= C^T B^T$
$(A \otimes B)^T$	$= A^T \otimes B^T$
I_{mn}	$= I_m \otimes I_n$
$A \otimes B$	$= (A \otimes I_m)(I_n \otimes B)$
$I_n \otimes (BC)$	$= (I_n \otimes B)(I_n \otimes C)$
$(BC) \otimes I_n$	$= (B \otimes I_n)(C \otimes I_n)$
$A \otimes B$	$= L_n^{mn}(B \otimes A)L_m^{mn}$
$(L_m^{mn})^{-1}$	$= L_n^{mn}$
L_n^{kmn}	$= (L_n^{kn} \otimes I_m)(I_k \otimes L_n^{mn})$
L_{km}^{kmn}	$= (I_k \otimes L_m^{mn})(L_k^{kn} \otimes I_m)$
L_k^{kmn}	$= L_{km}^{kmn} L_{kn}^{kmn}$

Iterative FFTs

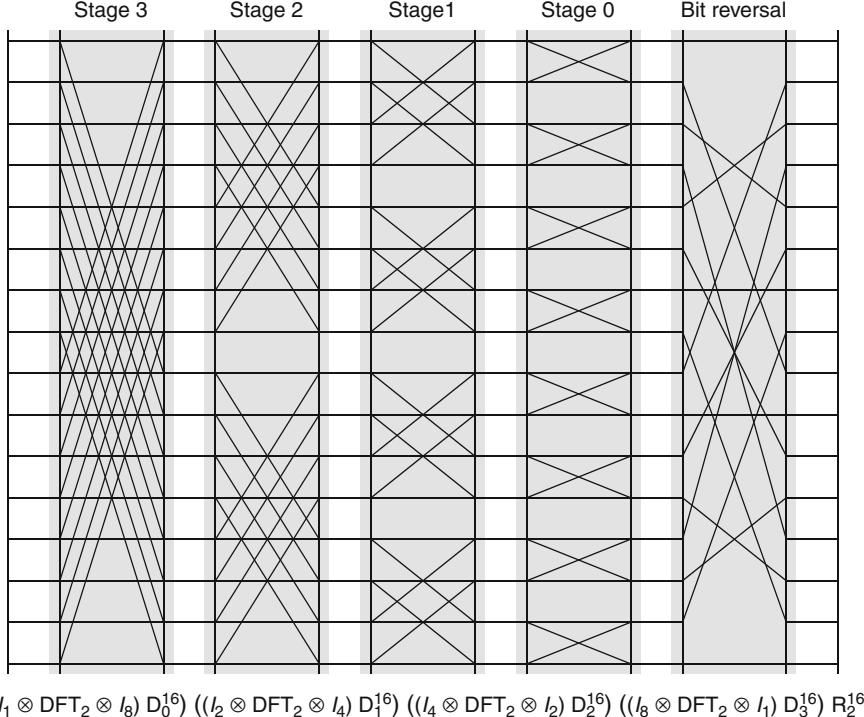

The historically first FFTs that were developed and adapted to parallel platforms are iterative FFTs. These algorithms implement the DFT as a sequence of nested loops (usually three). The simplest are *radix-r* forms (usually $r = 2, 4, 8$), which require an FFT size of $n = r^\ell$; more complicated mixed-radix radix variants always exist. They all factor DFT_n into a product of ℓ matrices, each of which consists of a tensor product and twiddle factors. Iterative algorithms are obtained from (8) by recursive expansion, flattening the nested parentheses, and other identities in Table 1.

The most important iterative FFTs are discussed next, starting with the standard version, which is not optimized for parallelism but included for completeness. Note that the exact form of the twiddle factors differs in these FFTs, even though they are denoted with the same symbol.

Cooley–Tukey iterative FFT. The radix- r *iterative decimation-in-time FFT*

$$DFT_{r^\ell} = \left(\prod_{i=0}^{\ell-1} (I_{r^i} \otimes DFT_r \otimes I_{r^{\ell-i-1}}) D_i^{r^\ell} \right) R_r^{r^\ell}, \quad (9)$$

is the prototypical FFT algorithm and shown in Fig. 3. $R_r^{r^\ell}$ is the radix- r digit reversal permutation and the diagonal $D_i^{r^\ell}$ contains the twiddle factors in the i th stage. The radix-2 version is implemented by Numerical Recipes using a triple loop corresponding to the two tensor products (inner two loops) and the product (outer loop).

FFT (Fast Fourier Transform). Fig. 3 Iterative FFT (9) for $n = 2^4$ and $r = 2$

Formal transposition of (9) yields the *iterative decimation-in-frequency FFT*:

$$\text{DFT}_{r^\ell} = R_r^{r^\ell} \prod_{i=0}^{\ell-1} D_i^{r^\ell} (I_{r^{\ell-i-1}} \otimes \text{DFT}_r \otimes I_{r^i}). \quad (10)$$

Both (9) and (10) contain the bit reversal permutation $R_r^{r^\ell}$. The parallel and vector structure of the occurring butterflies depends on the stage. Thus, even though every stage is data parallel, the algorithm is neither well suited for machines that require block parallelism nor vector parallelism. For this reason, very few parallel triple-loop implementations exist and compiler parallelization and vectorization tend not to succeed in producing any speedup when targeting the triple-loop algorithm.

Pease FFT. A variant of (9) is the *Pease FFT*

$$\text{DFT}_{r^\ell} = \left(\prod_{i=0}^{\ell-1} L_r^{r^\ell} (I_{r^{\ell-i-1}} \otimes \text{DFT}_r) D_i^{r^\ell} \right) R_r^{r^\ell}, \quad (11)$$

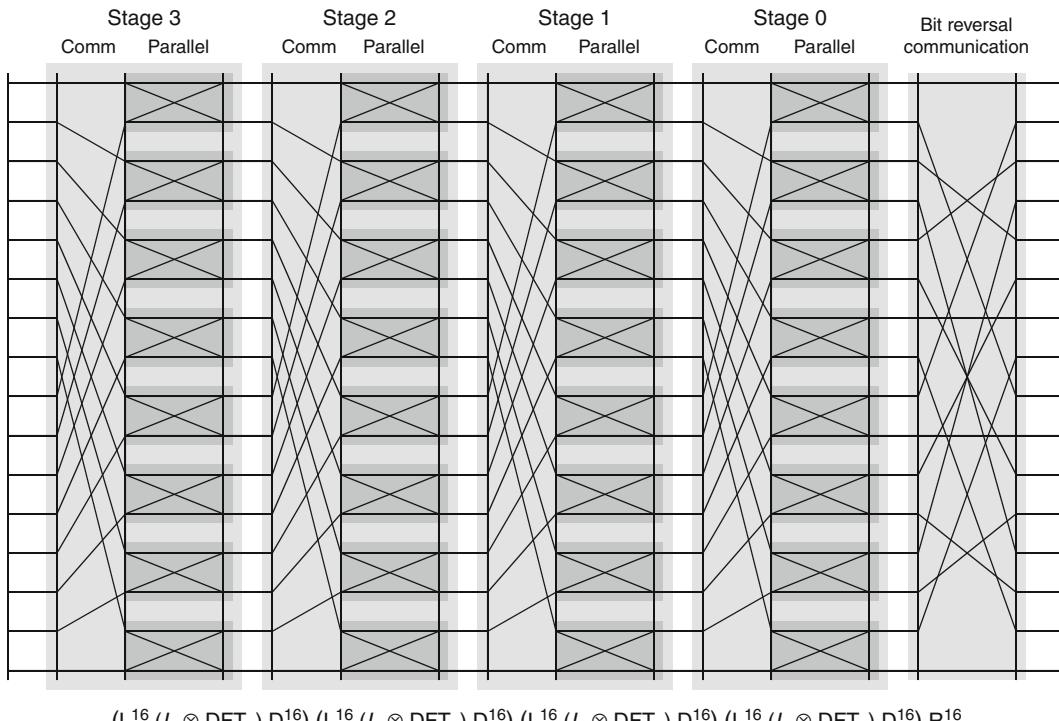

shown in Fig. 4 for $r = 2$. It has constant geometry, that is, the control flow is the same in each stage, and maximizes block parallelism by reducing the block sizes to r on which single butterflies are computed. However,

the Pease FFT also requires the digit reversal permutation. Each stage of the Pease algorithm consists of the twiddle diagonal and a parallel butterfly block, followed by the same data exchange across parallel blocks specified through a stride permutation. The Pease FFT was originally developed for parallel computers, and its regular structure makes it a good choice for field-programmable gate arrays (FPGAs) or ASICs. Formal transposition of (11) yields a variant with the bit-reversal in the end.

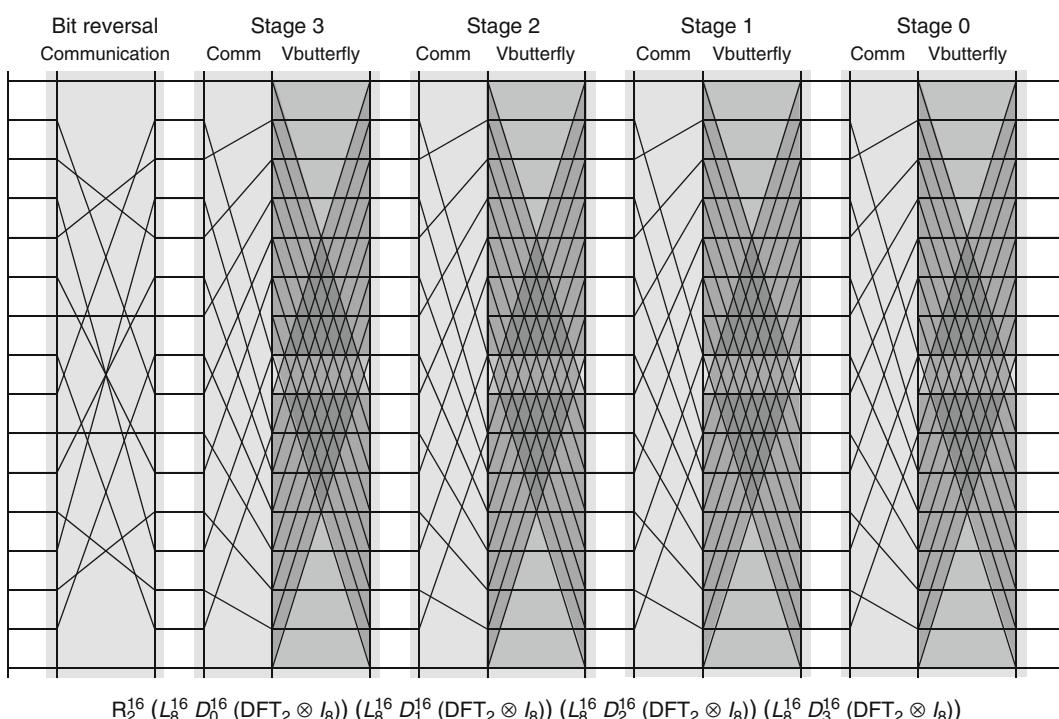

Korn–Lambiotte FFT. The *Korn–Lambiotte FFT* is given by

$$\text{DFT}_{r^\ell} = R_r^{r^\ell} \left(\prod_{i=0}^{\ell-1} L_{r^{\ell-i-1}}^{r^\ell} D_i^{r^\ell} (\text{DFT}_r \otimes I_{r^{\ell-i-1}}) \right), \quad (12)$$

and is the algorithm that is dual to the Pease FFT in the sense used in Fig. 1. Namely, it has also constant geometry, but maximizes vector parallelism as shown in Fig. 5 for $r = 2$. Each stage contains one vector butterfly operating on vectors of length n/r , and a twiddle diagonal. As last step it performs the digit reversal permutation. The Korn–Lambiotte FFT was developed for early vector computers. It is derived from the Pease

FFT (Fast Fourier Transform). Fig. 4 Pease FFT in (11) for $n = 2^4$ and $r = 2$

FFT (Fast Fourier Transform). Fig. 5 Korn-Lambiotte FFT in (12) for $n = 2^4$ and $r = 2$. Vbutterfly = vector butterfly

algorithm through formal transposition followed by the translation of the tensor product from a parallel into a vector form.

Stockham FFT. The Stockham FFT

$$\text{DFT}_{r^\ell} = \prod_{i=0}^{\ell-1} (\text{DFT}_r \otimes I_{r^{\ell-i}}) D_i^{r^\ell} (L_r^{r^{\ell-i}} \otimes I_{r^i}), \quad (13)$$

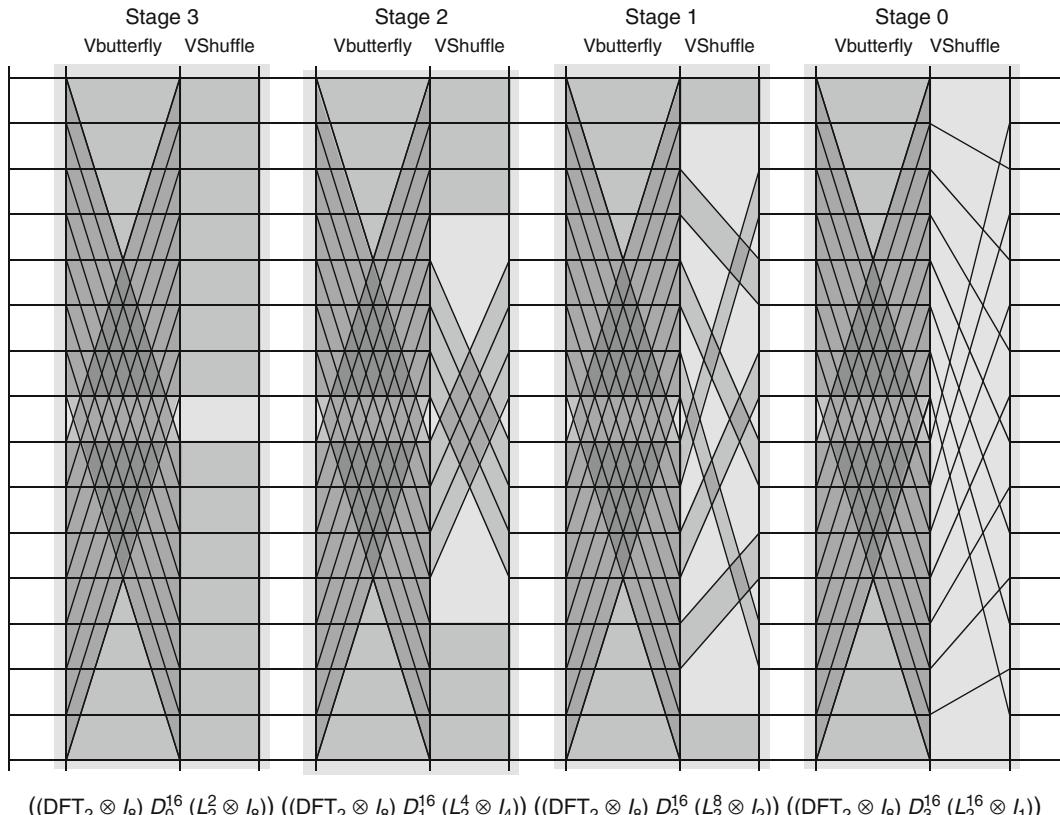

is *self-sorting*, that is, it does not have a digit reversal permutation. It is shown in Fig. 6 for $r = 2$. Like the Korn–Lambiotte FFT, it exhibits maximal vector parallelism but the permutations change across stages. Each of these permutations is a vector permutation, but the vector length increases by a factor of r in each stage (starting with 1). Thus, for most stages a sufficiently long vector length is achieved. The Stockham FFT was originally developed for vector computers. Its structure is also suitable for graphics processors (GPUs), and indeed most current GPU FFT libraries are based on the

Stockham FFT. The formal transposition of (13) is also called Stockham FFT.

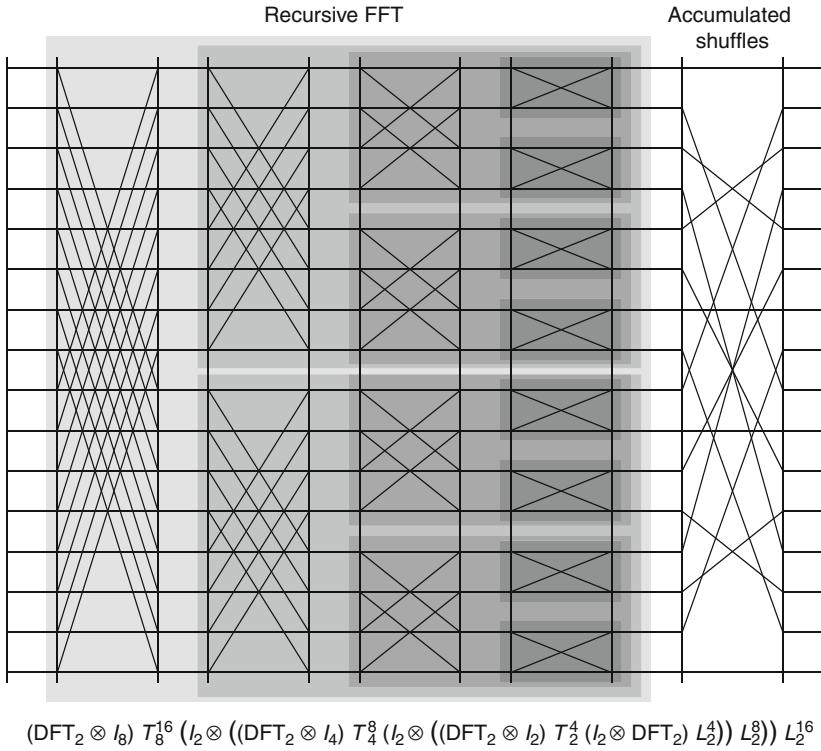

Recursive FFT Algorithms

The second class of Cooley–Tukey-based FFTs are recursive algorithms, which reduce a DFT of size $n = km$ into k DFTs of size m and m DFTs of size k . The advantage of recursive FFTs is better locality and hence better performance on computers with deep memory hierarchies. They also can be used as kernels for iterative algorithms. For parallelism, recursive algorithms are derived, for example, to maximize the block size for multicore platforms, or to obtain vector parallelism for a fixed vector length for platforms with SIMD vector extensions. The most important recursive algorithms are discussed next.

Recursive Cooley–Tukey FFT. The recursive, general-radix decimation-in-time Cooley–Tukey FFT was shown before in (8). Typically, k is chosen to be

FFT (Fast Fourier Transform). Fig. 6 Stockham FFT in (13) for $n = 2^4$ and $r = 2$. Vbutterfly = vector butterfly, VShuffle = vector shuffle

FFT (Fast Fourier Transform). Fig. 7 Recursive radix-2 decimation-in-time FFT for $n = 2^4$

small, with values up to 64. If (8) is applied to $n = r^\ell$ recursively with $k = r$ the algorithm is called radix- r decimation-in time FFT. As explained before, the initial permutation is usually not performed but propagated as data access into the smaller DFTs. For radix-2 the algorithm is shown in Fig. 7. Note that the dataflow is equal to Fig. 3, but the order of computation is different as emphasized by the shading.

Formal transposition of (8) yields the *recursive decimation-in-frequency FFT*

$$DFT_n = L_m^n (I_k \otimes DFT_m) T_m^n (DFT_k \otimes I_m), \quad n = km. \quad (14)$$

Recursive application of (8) and (14) eventually leads to prime sizes k and m , which are handled by a special prime-size FFT. For two-powers n the butterfly matrix DFT_2 terminates the recursion.

The implementation of (8) and (14) is more involved than the implementation of iterative algorithms, in particular in the mixed-radix case. The divide-and-conquer nature of (8) and (14) makes them good choices for machines with memory hierarchies, as at some

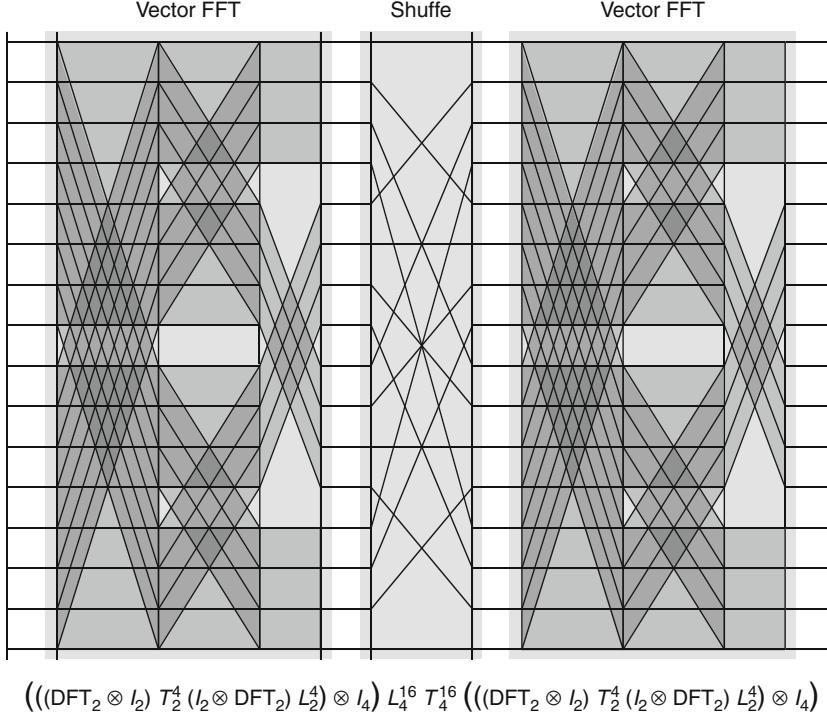

recursion level the working set will be small enough to fit into a certain cache level, a property sometimes called *cache oblivious*. Both (8) and (14) contain both vector and parallel blocks and stride permutations. Thus, despite their inherent data parallelism, they are not ideal for either parallel or vector implementations. The following variants address this problem.

Four-step FFT. The *four-step FFT* is given by

$$DFT_n = (DFT_k \otimes I_m) T_m^n L_k^n (DFT_m \otimes I_k), \quad n = km, \quad (15)$$

and shown in Fig. 8. It is built from two stages of vector FFTs, the twiddle diagonal and a transposition. Typically, $k, m \approx \sqrt{n}$ is chosen (also called “square root decomposition”). Then, (15) results in the longest possible vector operations except for the stride permutation in the middle.

The four-step FFT was originally developed for vector computers and the stride permutation (or transposition) was originally implemented explicitly while the smaller FFTs were expanded with some other FFT—typically iterative. The transposition can

FFT (Fast Fourier Transform). Fig. 8 Four-step FFT for $n = 2^4$ and $k = m = \sqrt{n} = 4$

be implemented efficiently using blocking techniques. Equation (15) can be a good choice on parallel machines that execute operations on long vectors well and on which the overhead of a transposition is not too high. Examples includes vector computers and machines with streaming memory access like GPUs.

Six-step FFT. The *six-step FFT* is given by

$$\text{DFT}_n = L_k^n (I_m \otimes \text{DFT}_k) L_m^n T_m^n (I_k \otimes \text{DFT}_m) L_k^n, \quad n = km, \quad (16)$$

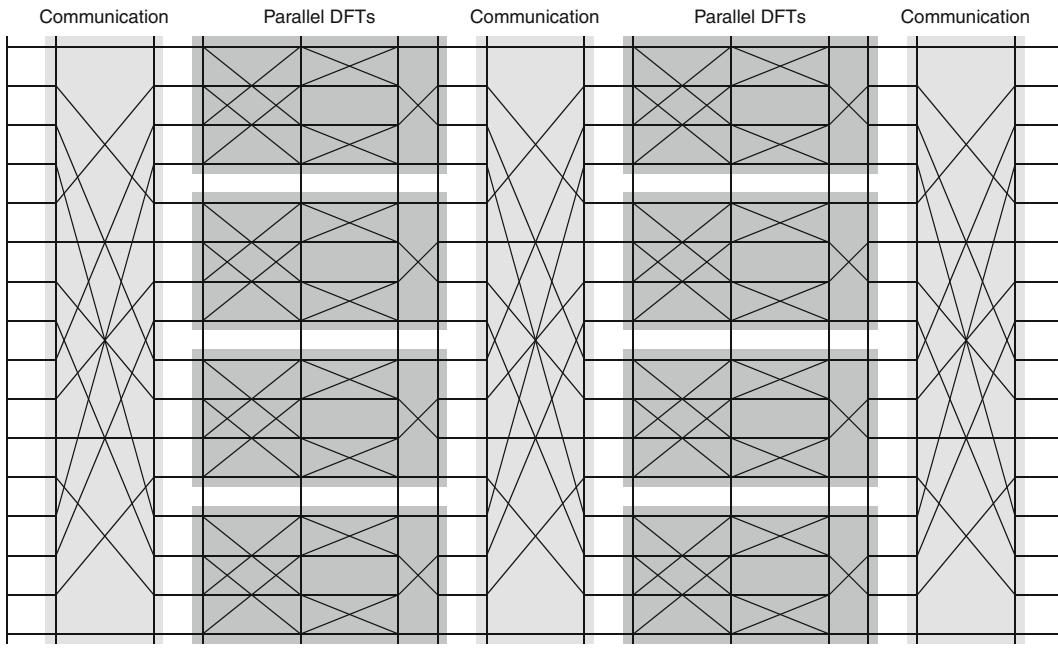

and shown in Fig. 9. It is built from two stages of parallel butterfly blocks, the twiddle diagonal, and three global transpositions (all-to-all data exchanges). (16) was originally developed for distributed memory machines and out-of-core computation. Typically, $k, m \approx \sqrt{n}$ is chosen to maximize parallelism. The transposition was originally implemented explicitly as all-to-all communication while the smaller FFTs were expanded with some other FFT algorithm—typically iterative. As in (15), the required matrix transposition can be blocked for more efficient data movement. (16) can be a good choice on parallel machines that have

multiple memory spaces and require explicit data movement, like message passing, off-loading to accelerators (GPUs and FPGAs), and out-of-core computation.

Multicore FFT. The *multicore FFT* for a platform with p cores and cache block size μ is given by

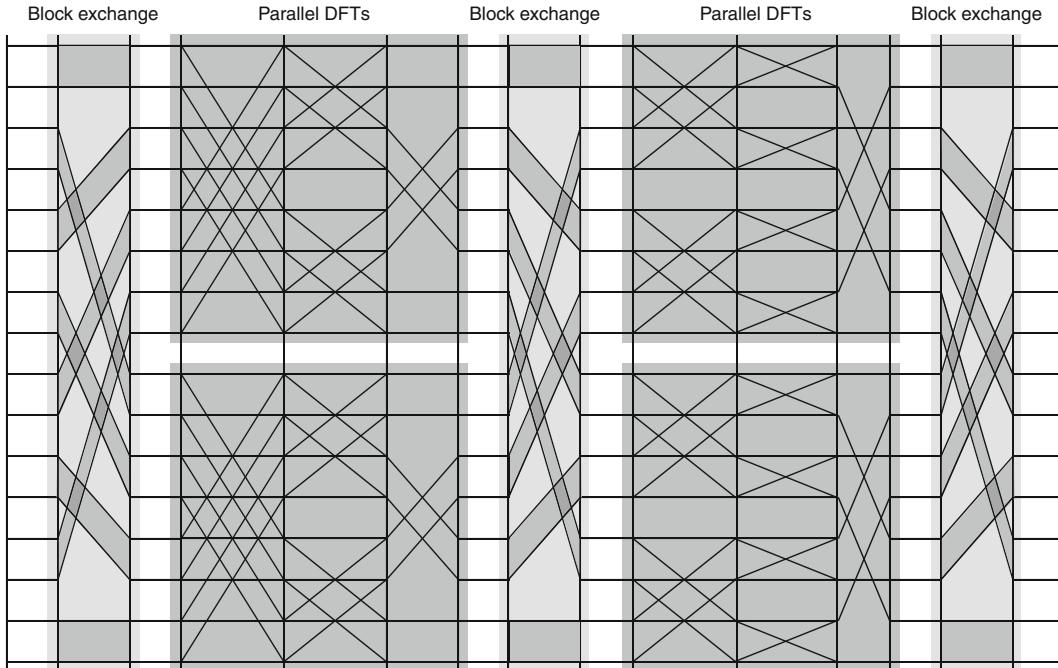

$$\begin{aligned} \text{DFT}_n = & \left(I_p \otimes (\text{DFT}_k \otimes I_{m/p}) \right)^{\left((L_p^{kp} \otimes I_{m/p\mu}) \otimes I_\mu \right)} T_m^n \\ & \times \left(I_p \otimes (I_{k/p} \otimes \text{DFT}_m) L_{k/p}^{n/p} \right) \\ & \times \left((L_p^{pm} \otimes I_{k/p\mu}) \otimes I_\mu \right), \quad n = km, \end{aligned} \quad (17)$$

and is a version of (8) that is optimized for homogeneous multicore CPUs with memory hierarchies. An example is shown in Fig. 10. (17) follows the recursive FFT (8) closely but ensures that all data exchanges between cores and all memory accesses are performed with cache block granularity. For a multicore with cache block size μ and p cores, (17) is built solely from permutations that permute entire cache lines and p -way parallel compute blocks. This property allows for parallelization of small problem sizes across a moderate

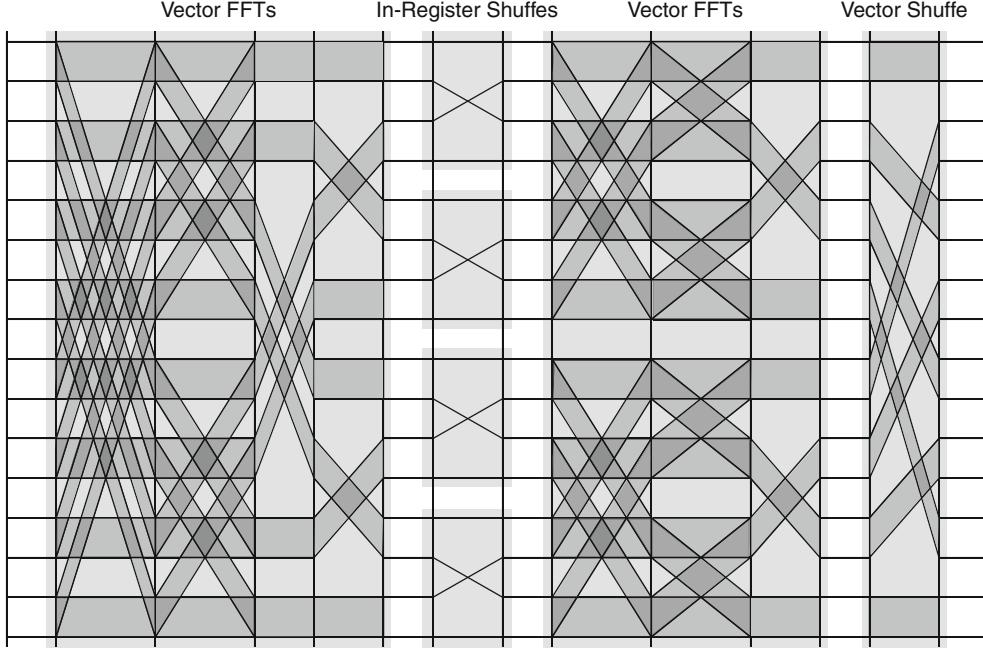

$$L_4^{16} \left(I_4 \otimes ((DFT_2 \otimes I_2) T_2^4 (I_2 \otimes DFT_2) L_2^4) \right) L_4^{16} T_4^{16} \left(I_4 \otimes ((DFT_2 \otimes I_2) T_2^4 (I_2 \otimes DFT_2) L_2^4) \right) L_4^{16}$$

FFT (Fast Fourier Transform). Fig. 9 Six-step FFT for $n = 2^4$ and $k = m = \sqrt{n} = 4$

$$(L_4^8 \otimes I_2) (I_2 \otimes ((DFT_2 \otimes I_2) T_2^4 (I_2 \otimes DFT_2) L_2^4) \otimes I_2) (L_2^8 \otimes I_2) T_4^{16} (I_2 \otimes (I_2 \otimes (DFT_2 \otimes I_2) T_2^4 (I_2 \otimes DFT_2)) R_2^8) (L_2^8 \otimes I_2)$$

FFT (Fast Fourier Transform). Fig. 10 Multicore FFT for $n = 2^4$, $k = m = 4$, $p = 2$ cores, and cache block size $\mu = 2$

$$\left(\left((\text{DFT}_2 \otimes I_2) T_2^4 (I_2 \otimes \text{DFT}_2) L_2^4 \right) \otimes I_2 \right) T_4^{16} \left(I_2 \otimes (L_2^4 \otimes I_2) (I_2 \otimes L_2^4) \left(\left((\text{DFT}_2 \otimes I_2) T_2^4 (I_2 \otimes \text{DFT}_2) L_2^4 \right) \otimes I_2 \right) (L_2^8 \otimes I_2) \right)$$

FFT (Fast Fourier Transform). Fig. 11 Short vector FFT in (18) for $n = 2^4$, $k = m = 4$, and (complex) vector length $v = 2$

number of cores. Implementation of (17) on a cache-based system relies on the cache coherency protocol to transmit cache lines of length μ between cores and requires a global barrier. Implementation on a scratchpad-based system requires explicit sending and receiving of the data packets, and depending on the communication interface additional synchronization may be required.

The smaller DFTs in (17) can be expanded, for example, with the short vector FFT (discussed next) to optimize for vector extensions.

SIMD short vector FFT. For CPUs with SIMD v -way vector extensions like SSE and AltiVec and a memory hierarchy, the *short vector FFT* is defined as

$$\begin{aligned} \text{DFT}_n = & \left((\text{DFT}_k \otimes I_{m/v}) \otimes I_v \right) T_m^n \left(I_{k/v} \otimes (L_v^m \otimes I_v) \right. \\ & \times \left. (I_{m/v} \otimes L_v^{v^2}) (\text{DFT}_m \otimes I_v) \right) \left(L_{k/v}^{n/v} \otimes I_v \right), \quad n = km, \end{aligned} \quad (18)$$

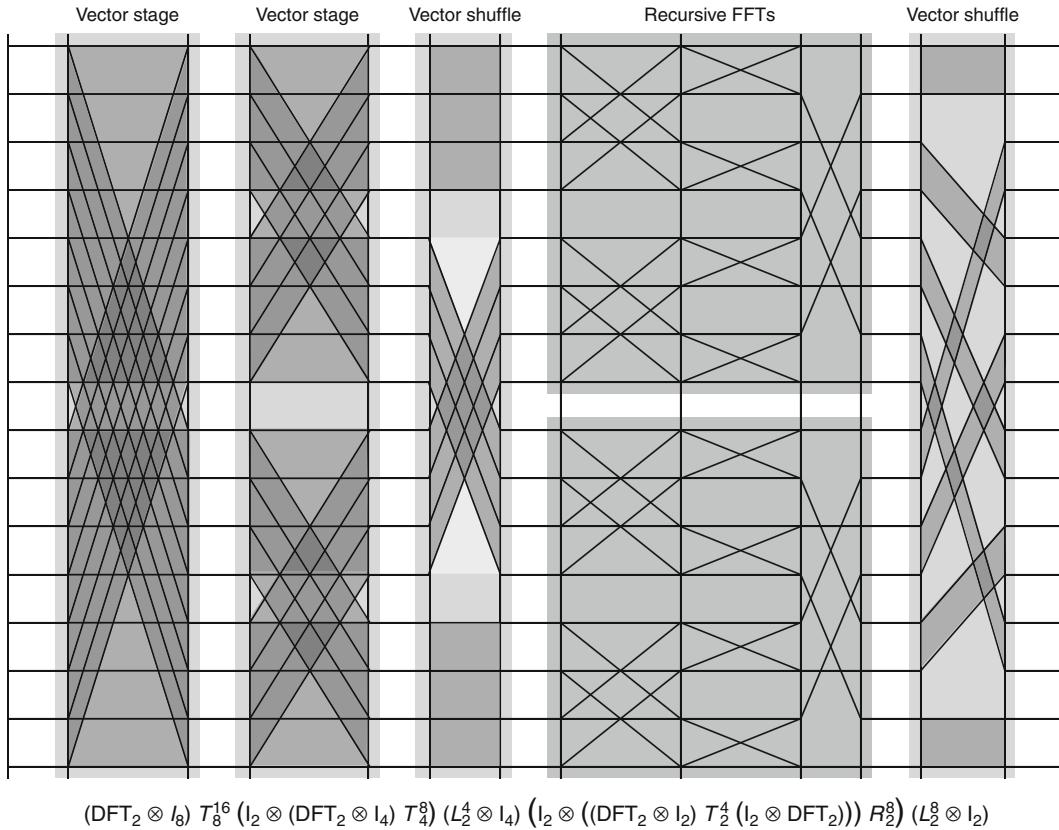

and can be implemented using solely vector arithmetic, aligned vector memory access, and a small number of vector shuffle operations. An example is shown in Fig. 11. All compute operations in (18) have complex v -way vector parallelism. The only operation that is not

v -way vectorized is the stride permutations $L_v^{v^2}$, which can be implemented efficiently using in-register shuffle instructions. (18) requires the support or implementation of complex vector arithmetic and packs v complex elements into a machine vector register of width $2v$. A variant that vectorizes the real rather than the complex dataflow exists.

Vector recursion. The *vector recursion* performs a locality optimization for deep memory hierarchies for the first stage $(I_k \otimes \text{DFT}_m)L_k^n$ of (8). Namely, in this stage DFT_m is further expanded using again (8) with $m = m_1 m_2$ and the resulting expression is manipulated to yield

$$\begin{aligned} (I_k \otimes \text{DFT}_m)L_k^n = & \left(I_k \otimes (\text{DFT}_{m_1} \otimes I_{m_2}) T_{m_2}^m \right) \\ & \times \left(L_k^{km_1} \otimes I_{m_2} \right) \left(I_{m_1} \otimes (I_k \otimes \text{DFT}_{m_2}) L_k^{km_2} \right) \\ & \times \left(L_{m_1}^m \otimes I_k \right). \end{aligned} \quad (19)$$

While the recursive FFT (8) ensures that the working set will eventually fit into any level of cache, large two-power FFTs induce large 2-power strides. For caches with lower associativity these strides result in a high number of conflict misses, which may impose

FFT (Fast Fourier Transform). Fig. 12 Vector recursive FFT for $n = 2^4$. The vector recursion is applied once and yields vector shuffles, two recursive FFTs, and two iterative vector stages

a severe performance penalty. For large enough two-power sizes, in the first stage of (8) every single load will result in a cache miss. The vector recursion alleviates this problem by replacing the stride permutation in (8) by stride permutations of vectors, at the expense of an extra pass through the working set. Since (19) matches $(I_k \otimes DFT_n) L_k^{kn}$, it is recursively applicable and will eventually produce child problems that fit into any cache level. The vector recursion produces algorithms that are a mix of iterative and recursive as shown in Fig. 12.

Other FFT Topics

So far the discussion has focused on one-dimensional complex two-power size FFTs. Some extensions are mentioned next.

General size recursive FFT algorithms. DFT algorithms fundamentally different from (8) include prime-factor (n is a product of coprime factors), Rader (n is

prime), and Bluestein or Winograd (any n). In practice, these are mostly used for small sizes < 32 , which then serve as building blocks for large composite sizes via (8). The exception is Bluestein's algorithm that is often used to compute large sizes with large prime factors or large prime numbers.

DFT variants and other FFTs. In practice, several variants of the DFT in (2) are needed including forward/inverse, interleaved/split complex format, for complex/real input data, in-place/out-of-place, and others. Fortunately, most of these variants are close to the standard DFT in (2), so fast code for the latter can be adapted. An exception is the DFT for real input data, which has its own class of FFTs.

Multidimensional FFT algorithms. The Kronecker product naturally arises in 2D and 3D DFTs, which respectively can be written as

$$DFT_{m \times n} = DFT_m \otimes DFT_n, \quad (20)$$

$$DFT_{k \times m \times n} = DFT_k \otimes DFT_m \otimes DFT_n. \quad (21)$$

For a 2D DFT, applying identities from Table 1 to (20) yields the row-column algorithm

$$\text{DFT}_{m \times n} = (\text{DFT}_m \otimes I_n)(I_m \otimes \text{DFT}_n). \quad (22)$$

The 2D vector-radix algorithm can also be derived with identities from Table 1 from (20):

$$\begin{aligned} \text{DFT}_{mn \times rs} &= (\text{DFT}_{m \times r} \otimes I_{ns})^{I_m \otimes L_r^m \otimes I_s} (T_n^{mn} \otimes T_s^{rs}) \\ &\times (I_{mr} \otimes \text{DFT}_{n \times s})^{I_m \otimes L_r^m \otimes I_s} (L_m^{mn} \otimes L_r^{rs}). \end{aligned} \quad (23)$$

Higher-dimensional versions are derived similarly, and the associativity of \otimes gives rise to more variants.

Bibliographic Notes and Further Reading

The original Cooley–Tukey FFT algorithm can be found in [2]. The Pease FFT in [13] is the first FFT derived and represented using the Kronecker product formalism. The other parallel FFTs were derived in [10] (Korn–Lambiotte FFT), [16] (Stockham FFT), [11] (four-step FFT), [1] (six-step FFT). The vector-radix FFT algorithm can be found in [8], the vector recursion in [7], the short vector FFT in [3], and the multicore FFT in [4]. A good overview on FFTs including the classical parallel variants is given in Van Loan’s book [18] and the book by Tolimieri, An and Lu [17]; both are based on the formalism used here. Also excellent is Nussbaumer FFT book [12]. An overview on real FFTs can be found in [20].

At the point of writing the most important fast DFT libraries are FFTW by Frigo and Johnson [6, 7], Intel’s MKL and IPP, and IBM’s ESSL and PESSL. FFTE is currently used in the HPC Challenge as *Global FFT* benchmark reference implementation. Most CPU, GPU, and FPGA vendors maintain DFT libraries. Some historic DFT libraries like FFTPACK are still widely used. Numerical Recipes [14] provides C code for an iterative radix-2 FFT implementation. BenchFFT provides up-to-date FFT benchmarks of about 60 single-node DFT libraries. The Spiral system is capable of generating parallel DFT libraries directly from the tensor product-based algorithm description [15, 19].

Fast Algorithm for the Discrete Fourier Transform (DFT)

- [FFT \(Fast Fourier Transform\)](#)

FFTW

FFTW is a C library for computing the Discrete Fourier Transform (DFT). It was originally developed at MIT by Matteo Frigo and Steven G. Johnson. FFTW is an example of autotuning in two ways. First, the library is adaptive by allowing for different recursion strategies. The best one is chosen at the time of use by a feedback-driven search. Second, the recursion is terminated by small optimized kernels (called codelets) that are generated by a special purpose compiler. The library continues to be maintained by the developers and is widely used due to its excellent performance. The name FFTW stands for the somewhat whimsical “Fastest Fourier Transform in the West.”

Definition

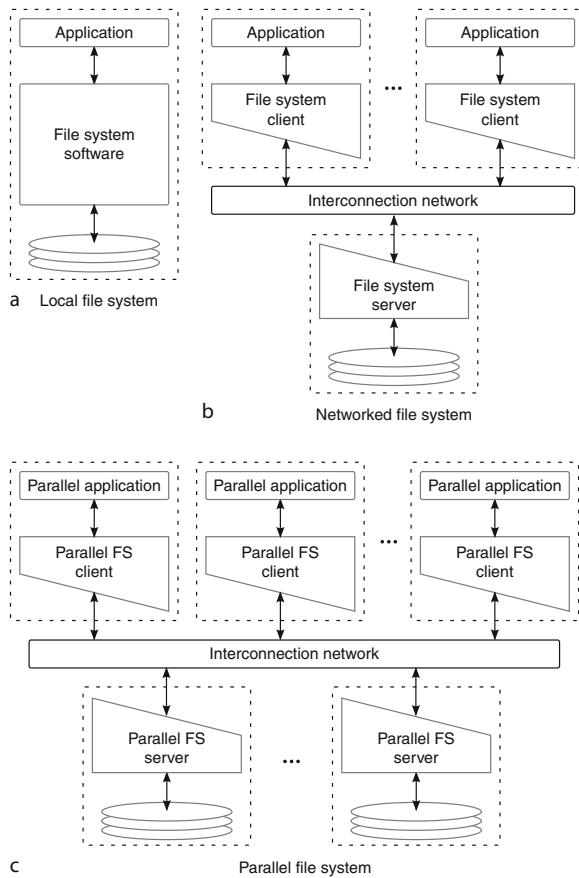

A parallel file system (PFS) is a system software component that organizes many disks, servers, and network links to provide a file system name space that is accessible from many clients; distributes data across many devices to enable high aggregate bandwidth; and coordinates changes to file system data so that clients' views of the data are kept coherent.

Discussion

Introduction

File systems are the traditional mechanism for reading and writing data on persistent storage. The current standard interface for file systems, part of the Portable Operating System Interface (POSIX) standard, was first defined in 1988 [14]. As networking of computers became common, sharing storage between multiple computers became desirable. In 1989 [15], the Network File System (NFS) standard was created, allowing a file system stored locally on one computer to be accessed by other computers. With the advent of NFS, *shared file name spaces* were possible – many computers could see and access the same files at the same time.

Figures 1a and b show a high-level view of a local and network file system, respectively. In the local file system case, a single software component manages local storage resources (typically one or more disks) and allows processes running on that computer to store and retrieve data organized as files and directories. In the network file system case, the software allowing access to storage is split from the software managing the storage. The file system client presents the traditional view of files and directories to processes on a computer, while the file system server software manages the storage and coordinates access from multiple clients.

File Systems. Fig. 1 Local, network, and parallel file systems

As distributed-memory parallel computers became popular, the utility of a shared file name space became obvious as a way for parallel programs to store and retrieve data without concern for the actual location of files and file data. However, accessing data stored on a single server quickly became a bottleneck, driving the implementation of parallel file systems – file systems that opened up many concurrent paths between computers and persistent storage.

Figure 1c depicts a parallel file system. With multiple network links, servers, and local storage units, high degrees of concurrent access are possible. This enables very high aggregate I/O rates for the parallel file system as a whole when it is accessed by many processes on different nodes in the system, especially when those accesses are relatively evenly distributed across the storage servers. A wide variety of network configurations

and technologies are used in PFS deployments, from storage area networks and InfiniBand to Gigabit Ethernet and TCP/IP.

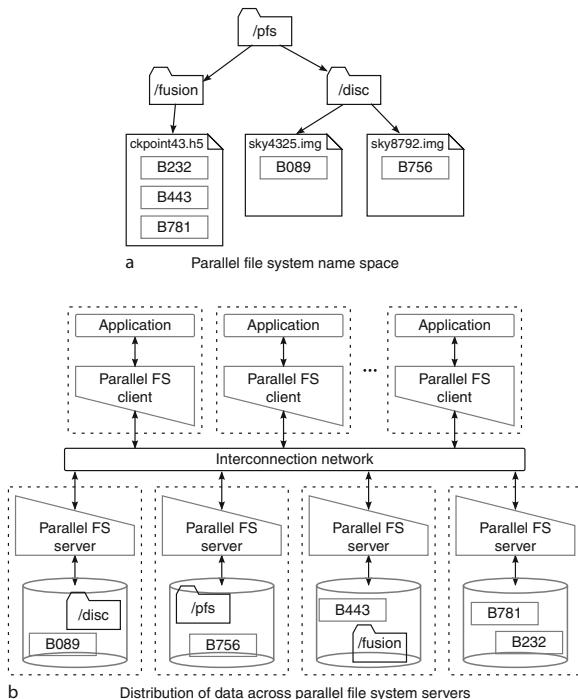

This discussion focuses on parallel file system deployments where processes accessing the file system are on compute nodes distinct from the nodes that manage storage of data (storage nodes). This model is the most common in high-performance computing (HPC) deployments, because (a) there are typically many more compute nodes than needed to provide storage services, (b) placing disks in all compute nodes has an impact on their reliability and power consumption, (c) servicing I/O operations for some other process on a node executing an HPC application can perturb performance of that application, and (d) keeping storage nodes distinct enables higher-reliability components to be used and helps collocate storage resources in the machine room.

That said, Beowulf-style commodity clusters and clusters used for Data Intensive Scalable Computing (DISC) applications are typically configured with local drives, and organizing those drives with a parallel file system can be an effective way to provide a low-cost, high-performance, cluster-wide storage resource.

Data Distribution

A number of approaches are used for managing data distribution in parallel file systems. Figures 2a and b show a simple example file system name space and a distribution of that name space onto multiple storage nodes, respectively. In the name space, two HPC applications have generated three files. A fusion code has written a large checkpoint, while a DISC application is analyzing a pair of relatively small images from observations of the night time sky. The checkpoint has been split into a set of blocks distributed across multiple storage nodes, while the data for each of the smaller images resides on a single server. In addition to distributing the file data across storage nodes, in this example the file system *metadata* has also been distributed, as depicted by directory data residing on different storage nodes. File system metadata is the data that represents the directory tree as well as information such as the owners and permissions of files.

File data is typically divided into fixed-size units called *stripe units* and distributed in a round-robin manner over a fixed set of servers. This approach is similar

File Systems. Fig. 2 Data distribution in a parallel file system (PFS)

to the way in which data is distributed over disks in a disk array. How PFSes keep track of where data is stored will be covered in the section on Metadata Storage and Access.

In a configuration such as the one shown here, the file system deployment is said to be *symmetric*, meaning that metadata and data are both distributed and stored on the same storage nodes. Not all parallel file systems operate this way, and those that keep metadata on separate servers are considered *asymmetric*. There are advantages to both approaches. The symmetric approach provides a high degree of concurrency for metadata operations, which can be important for applications that generate and process many files. On the other hand, storing metadata on a smaller set of nodes leads to greater locality of access for metadata and simplifies fault tolerance for the name space. Both approaches are commonly used, and some parallel file systems, such as GPFS [1] and PVFS [2], can be deployed with either configuration depending on workload expectations.

Access Patterns

The designs of parallel file systems have been heavily influenced by the characteristics and access patterns of HPC applications. These applications execute at very large scale, with current systems allowing over 128,000 application processes to execute at once. Potentially all of those processes might initiate an I/O operation at any time, including all at once. Additionally, HPC applications are primarily scientific simulations [CROSSREF](#). These codes operate on complex data models, such as regular or irregular grids, and these data models are reflected in the data that they store. The end result is that HPC access patterns are often highly concurrent and complex, including noncontiguity of access [3]. This often arises from access to subarrays of large global arrays.

A primary use case for parallel file systems in HPC environments is for *checkpointing*. Checkpointing is the writing of application state to persistent storage for the purpose of enabling an application to restart at some point in the event of a system failure. This state is typically referred to as a “checkpoint.” If a node on which the application is running crashes, then the application can be restarted using the checkpoint to avoid having to recalculate early results. Typically an application will compute for some amount of time, and then all the processes will pause and write their checkpoint so that the checkpoint represents the same point in time across all the processes.

Users are often surprised that their serial workloads are not faster when run on a parallel file system. The cost of coordination in the PFS in conjunction with different caching policies and the latency of communicating with file servers can result in performance no different from, or even worse than, that of local storage. Serial workloads are simply not the primary focus of PFS designs.

Consistency

In the context of PFSes, *consistency* is about the guarantees that the file system makes with respect to concurrent access by processes, particularly processes on different compute nodes. The stronger these guarantees, the more coordination is generally necessary, inside the PFS, to ensure the guarantees.

For example, most parallel file systems ensure that data written by one process is visible to all other processes immediately following the completion of the write operation. If no other copies of file data are kept in the system, then this is easy to enforce: the server owning the data simply always returns data from the most recent completed write.

Some parallel file systems make a stronger guarantee, that of *atomicity* of writes. This means that other processes accessing the PFS will always see either all, or none, of a write operation. This guarantee requires coordination, because if a write spans multiple servers, then the servers need to agree on which data to return in reads if reading is allowed while a write is in progress. Alternatively, the PFS could force readers to wait when a write is ongoing. Many parallel file systems do guarantee atomicity of writes, and this approach of delaying reading when writes are ongoing is commonly used to provide this guarantee. These PFSes include a distributed locking component. Distributed locking systems in parallel file systems are typically single-writer, multi-reader, meaning that they allow many client nodes to simultaneously read a resource but permit only a single client node access when writing is in progress. Scalable parallel file systems perform locking on ranges of bytes in files, usually rounded to some block size. This allows concurrent writes to different ranges from different compute nodes.

The use of distributed locking in parallel file systems has two significant impacts on designs that rely on them. First, the granularity of locking places a limit on concurrency and leads to *false sharing* during writes. False sharing occurs when two processes on different compute nodes attempt to write to different bytes of a file that happen to map to a single lock. While the two processes are not really performing shared access to the same bytes, the locking system behaves as if they were, serializing their writes. Given the nature of HPC access patterns, false sharing is common. Second, availability is impacted. If a compute node fails while holding a lock, access to the locked resource is halted until the lock can be reclaimed. Determining the difference between a busy compute node and a failed one can be difficult at large scale, especially in the presence of lightweight, non-preemptive kernels. For these reasons, some PFS designs eschew the use of distributed

locking, instead slightly relaxing consistency guarantees to a level that may be supported without locking infrastructure [4].

Parallel File System Design

Five major mechanisms shape a PFS design:

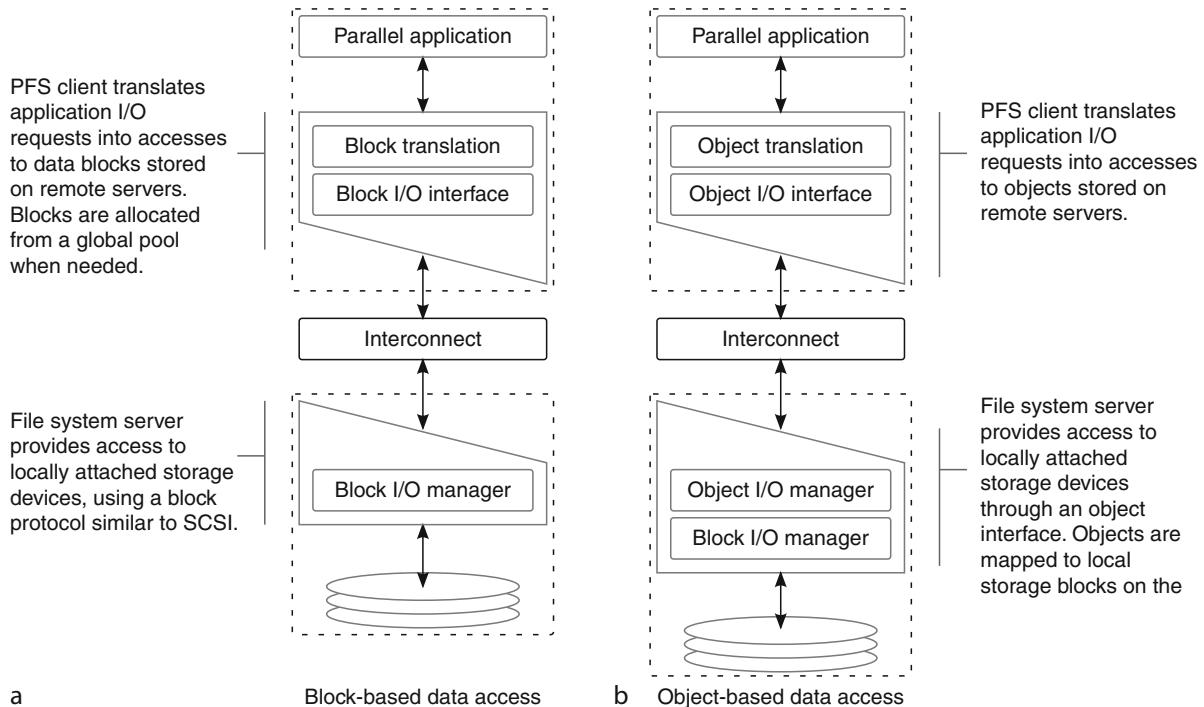

- Underlying storage abstraction
- Metadata storage and access
- Caching
- Tolerance of failures
- Enforcement of consistency semantics

Consistency semantics have been discussed. The other four topics are covered next.

Underlying Storage Abstraction

Some early parallel file systems relied on storage area networks (SANs) to provide shared access to physical drives. In that approach, data was accessed directly by block locations on drives or logical volumes. Eventually designers realized that interposing storage servers had some advantages, but this block access model was retained. IBM's General Parallel File System (GPFS) uses this model, with software on the server side providing access to storage over an interconnection network such as Gigabit Ethernet. Figure 3a shows the division of functionality in such a parallel file system. On the client side, PFS software translates application I/O operations directly into block accesses on specific file servers and obtains permission to access those blocks. File servers receive block access requests and perform them on locally accessible storage.

An important development that shaped more recent PFS designs was the concept of *object storage devices*. Object storage devices (OSDs) are storage devices (e.g., disks, disk arrays) that allow users to store data in logical containers called objects. By abstracting away block locations, file systems built using this abstraction are simpler to build, and blocks can be managed locally, at the device itself. Recently developed parallel file systems, such as Lustre [5], PVFS [2], and PanFS [6], all use object-based access. Figure 3b shows how functionality is divided in such a design. Application accesses are translated into accesses to objects stored on file

File Systems. Fig. 3 The two most common approaches to data storage in parallel file systems are block-based (*left*) and object-based (*right*)

servers. File servers translate these accesses into locations on locally accessible storage and manage allocation of space when needed.

A less obvious advantage of the object-based approach is the possibility of *algorithmic distribution* of file data. This relates to file system metadata.

Metadata Storage and Access

There are three major components of PFS metadata: directory contents, file and directory attributes, and file data locations. Directory contents are simply the listing of files and directories residing in a single directory. Typically the contents for a single directory are stored on a single server. This can become a bottleneck for workloads that generate a lot of files in a single directory, so some parallel file systems will split the contents of a single directory across multiple servers (e.g., GPFS [1]).

File and directory attributes are pieces of information such as the owner, group, modification time, and permissions on a file or directory. Some of this information changes infrequently (e.g., owner), while

other information can change rapidly (e.g., modification time). Some parallel file systems keep all these attributes on a single server, while others distribute the attributes for different files to different servers to allow concurrent access.

File data locations are the metadata necessary to map a logical portion of a file to where it is stored in the file system. For a block-based PFS, this information generally consists of a list of blocks or (server, block) pairs, similar to the traditional inode structure in a local file system. For an object-based PFS, a list of objects or (server, object) pairs is kept along with some parameters that define how data is mapped from the logical file into the objects. In a typical round-robin distribution, a stripe unit parameter defines how much data is placed in each object for a single stripe, and this pattern is repeated as necessary over the set of objects. This algorithmic approach to data distribution has the advantages that file data location metadata does not grow over time and does not need to be modified as the file grows.

Updates to metadata are usually handled in one of two ways. First, if the PFS already implements a distributed locking system, that system might be used to synchronize access to metadata by clients. Clients can then read, modify, and write metadata themselves in order to make updates. This approach has the advantage of allowing caching of metadata as well. Second, the PFS might implement a set of atomic operations that allow clients to update metadata without locks. For example, a special “insert directory entry” operation can be used by a client to add a new file. The server receiving this message is then responsible for ensuring atomicity of the operation, blocking read operations, or returning previous state until it completes its modifications. This approach reduces network traffic for modifications, but it does not lend itself to caching of modifiable data on the compute node side.

Caching

Caching of file system data contributes greatly to the observed performance of local file systems, in part because access patterns on local file systems (e.g., editing files, compiling code, surfing the Internet) often focus on a relatively small subset of data with multiple accesses to the same data in a short period of time. Implementing caching of file system data in the local file system context is also fairly straightforward, because the file system code sees all accesses and can ensure that the cache is kept consistent with what is on storage without any communication.

Caching in the context of a parallel file system is more complex when consistency semantics are taken into account. Keeping multiple copies of file system data and metadata consistent across multiple compute nodes requires the same sort of infrastructure as needed to enforce serialization of changes to file data and to ensure notification of changes. Typically parallel file systems that allow caching of data on compute nodes rely on a distributed locking system to ensure that all cached copies are the same, or *coherent*. Thus the caches are organized much the same as a software distributed memory system.

The benefits of caching in parallel file systems are highly dependent on the applications using the system. Checkpointing operations do not typically benefit from caching, because the amount of data written usually exceeds data cache sizes, and the data is not accessed

again soon after. Likewise, large analysis applications that read datasets in parallel often exhibit access patterns that confuse typical cache read-ahead algorithms. Nevertheless, if the parallel file system is also used for home directory storage, or if applications access many small files, then caching can be beneficial.

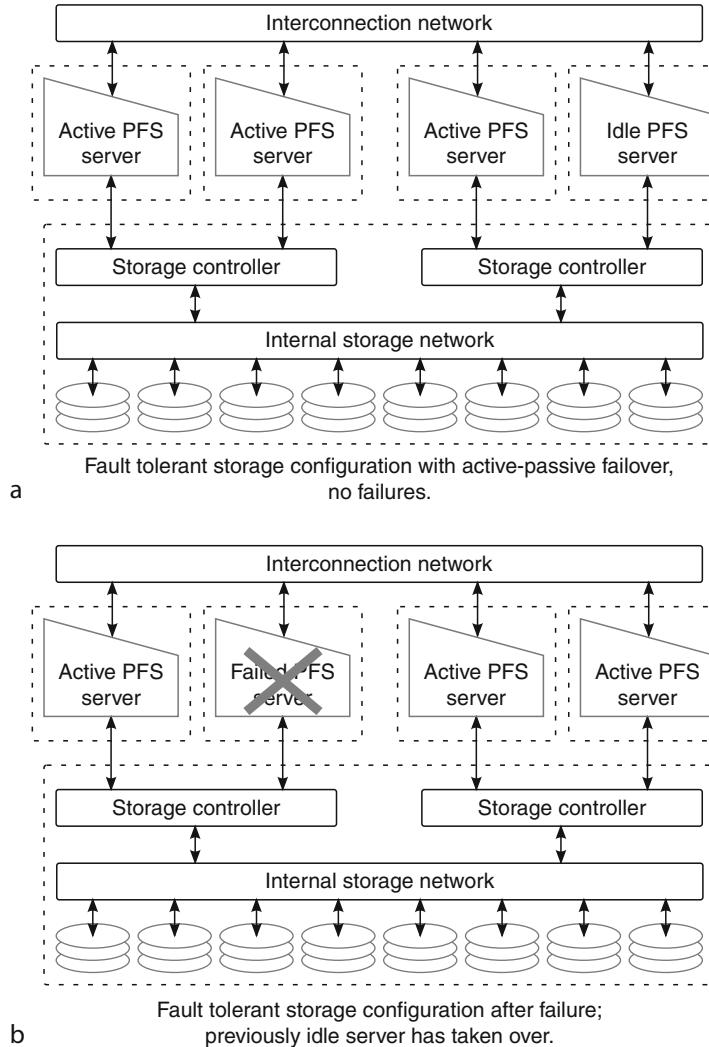

Fault Tolerance

Leading HPC systems use parallel file systems with hundreds of servers and thousands of drives. With that many components, failures are inevitable. In order to ensure that data is not lost, and that the file system remains available in the event of component failures, parallel file systems rely on a collection of fault tolerance techniques.

Nearly all parallel file systems rely on redundant array of independent disk (RAID) techniques to cope with drive failures, usually employed only on drives directly accessible by servers (i.e., not between multiple servers). These techniques use parity or erasure codes to allow data to be reconstructed in the event of a failure using the data that remains. Typically, RAID is performed on blocks of storage, but some systems perform RAID on an object-by-object basis [6].

Server failures are often handled through the use of *failover* techniques. Figures 4a and 4b depict a set of PFS servers configured with shared storage to allow for failover. In Fig. 4a, no failures have occurred. The system is running in an active-passive configuration, meaning that an additional server is sitting idle in case a failure occurs. When a server does fail (Fig. 4b), the idle server is brought into active service to take over where the previous server failed. The active-passive configuration allows for a certain number of failures to occur without degrading service. Alternatively, in an active-active configuration all servers are active all the time, with some server “doubling up” and handling the workload of a failed server when a failure occurs. This can lead to a significant degradation of performance.

While not depicted in the figures, this configuration can also tolerate storage controller failures, because all drives are accessible through either of the storage controllers. If a storage controller were to fail, the servers on the remaining functional storage controller would take over the responsibilities of the servers that could

File Systems. Fig. 4 Typical PFS configuration using shared backend storage to enable server failover, before (a), and after (b) a server failure. Compute nodes have been omitted from the figure

no longer see storage, maintaining accessibility but with obvious performance penalties.

Designs exist that do not share access to storage on the back-end [6, 7]. As opposed to the approach described above, these designs apply RAID techniques across multiple servers. This approach eliminates the need for expensive enterprise storage on the back-end, but it requires additional coordination between clients and servers in order to correctly update erasure code blocks. In the presence of concurrent writers to the same file region (e.g., writing to different portions of the same file stripe), performance can be significantly reduced.

Parallel File System Interfaces

Most applications access parallel file systems through the same interface provided for local file systems, and the industry standard for file access is the POSIX standard. As mentioned previously, the POSIX standard was developed primarily with local file systems and single-user applications in mind, and as a result it is not an ideal interface for parallel I/O. One reason is its use of the open model for translating a file name into a reference for use in I/O. This model forces name translation to take place on every process, which can be expensive at scale.

Additionally, the POSIX `read` and `write` I/O calls allow for description only of contiguous I/O regions. Thus, complex I/O patterns cannot be described in a single call, leading instead to a long sequence of small I/O operations. Moreover, the POSIX consistency semantics require atomicity of writes and immediate visibility of changes on all nodes. These semantics are stronger than are needed for many HPC applications, and require communication to enforce. An effort is underway to define a set of extensions to the POSIX standard for HPC I/O. This effort includes a set of new function calls that address the three issues outlined here. Implementations of these calls have not yet begun to appear in operating systems, but a few custom implementations do exist in specific parallel file systems, and early results are encouraging.

The MPI-IO interface standard is the only current alternative to POSIX for low-level file system access.

Bibliographic Notes and Further Reading

Early Parallel File Systems

The Vesta parallel file system [8, 9] was a file system built at the user level (i.e., not in the kernel) and tested on IBM SP systems. AIX Journaled File System volumes were used for storage by file system servers. Vesta is notable for using an algorithmic distribution of data, exposing a two-dimensional view of files, and providing numerous collective I/O modes and control over consistency semantics.

The Frangipani [10] parallel file system and Petal [11] virtual block device were originally developed at Digital Equipment Corporation and are well-documented examples of one way of organizing a block-based parallel file system. The Petal system combines a collection of block devices into a single, large, replicated pool that the Frangipani system uses as its underlying storage.

Current Parallel File Systems

Currently the largest HPC systems tend to use one of four parallel file systems: IBM's General Parallel File System (GPFS); Sun's Lustre; Panasas's PanFS; and the Parallel Virtual File System (PVFS), a community-built parallel file system whose development is led by Argonne National Laboratory and Clemson University.

GPFS [1] grew out of the Tiger Shark multimedia file system. It uses a block-based approach, and can operate either with clients physically attached to a storage area network or, more typically, with clients accessing storage attached to file system servers via a shared disk model. A lock-based approach is used for coordinating access to blocks of data, and through its locking system GPFS is able to cache data on the client side and provide full POSIX semantics.

Lustre [5] is an asymmetric parallel file system that uses software-based object storage servers (OSSes) to provide data storage. It is the file system chosen by Cray for use on the Cray XT3/4/5 systems. File data is striped across objects stored on multiple OSSes for performance. A locking subsystem is used to coordinate file access by clients and allows for coherent, client-side caching. Failure tolerance is provided by using shared storage and traditional server failover.

PanFS [6] is an asymmetric parallel file system that uses a clustered metadata system in conjunction with lightweight data storage blades that provide data access via the ANSI T-10 object storage device (OSD) protocol [12, 13]. It is the file system used on the IBM Roadrunner system at Los Alamos National Laboratory. PanFS is notable in that it does not rely on shared storage on the back-end; instead clients compute and update parity information directly on data storage blades. Parity is calculated on a perfile basis, and objects in which file data is stored are spread across all storage blades to enable declustering of rebuilds in the event of a failure.

The PVFS [2] design team chose to specifically target HPC workloads with their design. It is one of the two parallel file systems deployed on the IBM Blue Gene/P system at Argonne National Laboratory; GPFS is the other. Coordinated caching and locking were not used, eliminating false sharing and locking overheads, and API extensions are available that allow complex non-contiguous accesses to be described with single I/O operations. Data is distributed algorithmically across a user-specifiable number of servers, and an object-based model is used that allows servers to locally allocate storage space. Failure tolerance is provided via shared storage between file system servers.

[SIMD \(single instruction, multiple data\) machines](#)

Definition

FPS AP-120B was the first commercially successful attached array processor product designed and manufactured by Floating Point Systems Inc., in 1976. It is designed to be attached to a host computer, such as the DEC PDP-11, as a number crunching accelerator. The key innovation behind this family of array processors is the horizontal micro-coding of the wide instruction set architecture with pipelined execution units to achieve high parallelism. Floating Point Systems Inc., later introduced several derivative products to 64-bit arithmetic and floating point calculations, by employing higher speed silicon technology, VLSI, and multiple floating point coprocessors.

Discussion

Introduction

Floating Point Systems (FPS) Inc. was founded in 1970 by former Tektronix engineer C. Norm Winningstad in Beaverton, Oregon, to manufacture low-cost, high performance attached floating point accelerators, mainly, for minicomputers, targeting signal processing applications.

FPS AP-120B was the first attached processor product marketed under the company's own brand. It was co-designed by George O'Leary and Alan Charlesworth, first delivered in 1976. Its pipelined architecture gave it a peak performance of 12 MFLOPS (Million Floating-point Operations Per Second), with 38-bit floating point calculations. By 1985, roughly 4,400 machines had been delivered [1]. Since FPS-120B

was designed for mini-computer host machines, such as the DEC PDP-11, a larger memory version, FPS-190L, was also introduced for mainframe hosts such as the IBM-370 series.

In order to expand to more general purpose scientific and engineering applications, FPS announced the FPS-164 system in 1981. The word length was extended from 38-bit to 64-bit. The addressing capability was expanded from 16-bit to 24-bit, and the memory size grew to 7.25 MW (Million 64-bit Words). Even though the peak speed went down a bit, from 12 MFLOPS to 11 MFLOPS, the size of the problem and the precision of the calculations have both increased. The silicon technology remained the same, TTL.

In 1984, FPS announced the first 64-bit machine at higher speed with enhanced architecture, which is the FPS-164/MAX. This was the first VLSI design which incorporated matrix accelerator (MAX) boards. This is a SIMD (Single Instruction stream and Multiple Data stream) design that can incorporate up-to 15 MAX boards, each board having computation power equivalent to that of two FPS-164 processors. With a total of 31 FPS-164 CPU's, the peak computational power reached 341 MFLOPS.

In 1995, FPS announced the first ECL version, FPS-264, with a peak speed of 38 MFLOPS. In the meantime, FPS-164 also went through a makeover with the new VLSI technology, which can now be attached to both the MicroVAX or the Sun workstations.

Another derivative of the FPS-120B system is a MIMD (Multiple Instruction and Multiple Data streams) version called FPS-5000, announced in 1983. It incorporated a shared-memory bus architecture among a control processor, three arithmetic coprocessors and an I/O processor, connected to a host. The control processor is the traditional AP-120B, and the arithmetic coprocessors, XP32, were a new design, but by employing the same concept as AP-120B. Since this MIMD architecture approach digressed from the array concept, we will not go into any length in this discussion.

One word of clarification regarding AP. In the high performance computing circle, AP stands for Array Processors, even though, unlike the ICL DAP family, there was not necessarily any "array" of processors presented in the architecture. So, realistically, AP can be viewed as Attached Processors, or, we can interpret "array processor" as the attached processor designed

especially for efficient array operations. For this family of systems, the common grounds are the horizontal micro-coding concept (each instruction contains multiple fields of micro-instructions, and are decoded in parallel) and the pipelined architecture.

FPS AP-120B

Hardware

The FPS AP-120B was a micro-coded, pipelined, array processor design, attached to host computers such as the DEC PDP-11/34. Data transfer between host and AP was done via MDA (Direct Memory Access). Its cycle time was 167 ns (6 MHz), with a peak speed (multiple-add) of 12 MFLOPS. For a detailed architecture block diagram, please consult with Hockney and Jesshope's book, Fig. 2.39, p. 210, in [1].

The whole idea of micro-coding was based on the concept of the (synchronous) parallel execution of multiple execution units. A single 64-bit instruction word was divided into arithmetic field (address calculation), floating point fields, and two data pad register fields, all under the control of the decoding and execution unit. The address and logic unit (ALU) was 16-bit wide. There were 16 of 16-bit S-registers for the ALU. The floating point units (FMUL and FADD) were 38-bit wide. There were two 32 data pad registers (DX and DY), each was 38-bit wide. They were both for receiving data from memory and used as operands in floating point calculations. The FADD was a two-stage adder, and FMUL was a three-stage multiplier. In order to keep the pipelines moving, they need to be explicitly “pushed.” For example, in order to push the result of a FADD operation into its destination register, we need to add another FADD operation in the next cycle, either with a valid floating add of another pair of operands (FADD DX, DY), or with another FADD operation (FADD) without any operands. The same principle is true with FMUL.

There were three kinds of memory units, the program memory, the main (data) memory, and the table memory. The program memory was $4K \times 64$ -bit. The table memory was $64K \times 38$ -bit. It contained approximations for sine/cosine and other special functions, and was used to calculate intrinsic function values. The main memory was interleaved into two banks, odd and even. For fast memory option (333 ns access time), each bank was capable of producing one result every other cycle

(two cycle latency to data pad register). Hence, in the case of fast memory, sequential accesses could be done at each cycle with no delay. For slow memory, access time 500 ns, each bank can only deliver one result every three cycles.

The floating point format of the 38-bit data was a bit unconventional in its word length. The exponent field had 10-bits in Radix-2, and the mantissa had 28-bits in 2's complement format. Thus, the exponent had a dynamic range of 10 to the power ± 153 , and the mantissa had 8-digit of accuracy. Hence, it provided much better range and accuracy compared to the IBM 32-bit format. Extra guard bits were also kept in the calculation in order to improve precision. Format conversion between host and array was done on the fly during the data move.

Data moving into, or out of, AP-120B were performed by I/O-port (IOP) or a general programmable I/O port (GPIO) by DMA operations, by stealing cycles if necessary. There were two data width, 16-bit and 38-bit. The bandwidth of moving into AP memory was 1.5 MW/s, and that of moving out was 1.3 MW/s. Special features to support real-time audio and video processing were also provided.

Software and Performance

In order to achieve optimal performance on pipelined and horizontally micro-coded machines, it was best to write compact loops, based on skillful arrangement of the critical path. If done right, it was truly a thing of beauty.

In carrying out matrix-vector type of operations, for example, the main loop body sometimes could be written in an one-line (single instruction) loop structure. Within that one line, there could be a floating multiple-add pair (might be unrelated ops, but typically “chained” together), indexing, memory ops, and conditional test and branch. Sometimes, an extra cycle could even be saved by storing/accessing some temp data in the table memory, since table memory had an independent data path. Of course, once the loop body was set, the programmer needed to wrap the initialization part and the winding-down code around the loop in order to complete the whole execution. The whole philosophy was very much like coding for vector machines, except that there were multiple instruction fields in the horizontally micro-coded instruction set.

There was no hardware support for divide in the machine. The loop body for a vector divide was three-cycles, for example. A scalar divide was much longer.

Initially, in order to use the array processor, users had to use library procedures from the main program running on the host machine. Users use library procedures to transfer data to-and-from the attached machine, and then library procedures to do the computation. Library procedures mainly were used to execute vector (array) operations including intrinsic functions, basic arithmetic operations, signal processing library, image processing library (including 2D FFT, convolution, filtering), and advanced math library (inc. sparse matrix solution and eigenvalues, Runge-Kutta integration).

The next step was the availability of cross Fortran compiler on the host machine, to compile Fortran IV code into object code for the AP, and executed on the array processor side. With this offering, the AP became much more versatile.

But, since AP-120B did not provide a real time clock, most timing analyses were done on the host side, through APSIM, a timing simulator. Of course, with the use of a simulator, which was 1,000 times slower, it could only be useful for shorter running codes.

FPS-164

The FPS-164, announced in 1981, was a 64-bit enhancement from the 38-bit AP-120B. It incorporated some VLSI components in its design. The cycle time was at 182 ns, a bit slower than its predecessor. It made for 11 MFLOPS peak speed. Other than the double precision design, there are other improvements as well. First, the instruction memory (program memory) and the data memory were merged into one large main memory. Instruction cache was loaded automatically from the instruction memory as needed. Hence this instruction cache (size: 1,024 64-bit) replaced the program memory of the AP-120B. There was also a stack memory, consisting of 256 32-bit entries used to store subroutine return addresses, to expedite procedure calls. The table memory, also called auxiliary memory, has primarily become random access memory, used to store intermediate data from registers (e.g., register overflow area). However,

the first 8K or memory space was read-only, used to store commonly used constants and table values.

The main memory consisted of 12 memory modules. Each module had two boards (hence two banks). The memory size ranged from the initial 1.5 MW (with 16K-bit dynamic NMOS) to 7.25 MW later (with 64K-bit dynamic NMOS). All memory accesses were done in a pipelined fashion, both for main memory and table memory. Memory mapping and protections were also available.

The FPS-164 did provide programmable real-time clock and a CPU timer, which enabled accurate timing of program executions.

FPS-164/MAX

The FPS-164/MAX was introduced in 1984. The “MAX” here stood for matrix algebra accelerator. The machine consisted of one FPS-164 processor, and up-to 15 MAX boards. Each board was capable of two FPS-164 CPU. Besides, four vector registers were added, each with 2,048 elements, at each CPU. In total, the computing power consisted of 31 164-CPUs, and had a peak performance of 341 MFLOPS.

The MAX boards could execute just a handful of vector operations (SDOT, vector multiple, vector add, scalar vector multiple add, etc.). The logic was implemented with CMOS VLSI technology. The vector registers were memory mapped with the top 1 MW of the 16 MW main memory. That means, vector operations were executed simply by reading from, or writing to, appropriate memory locations.

Of course, in order to take advantage of the extra computing power, the arrays had to be very long. Hence, this type of SIMD architecture was more of a special purpose machine.

FPS-264

The FPS-264, announced in 1985, was an (custom air-cooled Fairchild 100K) ECL implementation of the (Schottky TTL technology) FPS-164. It increased the clock cycle time from 182 to 53 ns, a speed up of more than three times. Other improvements in the instruction cache and data memory (static NMOS) boasted a total improvement of 4x to 5x over the FPS-164 generation.

Bibliographic Notes and Further Reading

For interested readers, the best textbook that covers the complete family of FPS products can be found in [1]. For a complete history of all parallel computers, please find it in [2].

In 1985, FPS brought to market its long anticipated T-Series product, a hypercube, distributed memory, message passing multicomputer, with Occam software. Because of its arcane software environment, and non-general-purpose nature, it was not very successful in the marketplace. Since then, it changed direction, and brought FPS-500 product family to the market. These developments are beyond the scope of this entry. Interested readers can find more details from: "FPS Computing: A History of Firsts," by Howard Thraikill, former President and CEO of FPS, in [3].

Definition

Flow control is a synchronization protocol for transmitting and receiving units of information. It determines the advance of information between a sender and a receiver, enabling and disabling the transmission of information. Since messages are usually buffered at intermediate switches, flow control also determines how resources in a network are allocated to messages traversing the network.

Discussion

Flow control is defined, in its broad sense, as a synchronization protocol that dictates the advance of information from a sender to a receiver. Flow control determines how resources in a network are allocated to packets traversing the network. First, basic definitions and types of flow control are introduced. Then, differentiation between flow control and switching is highlighted. Finally, basic flow control mechanisms are described and briefly compared.

Messages, Packets, Flits, and Phits

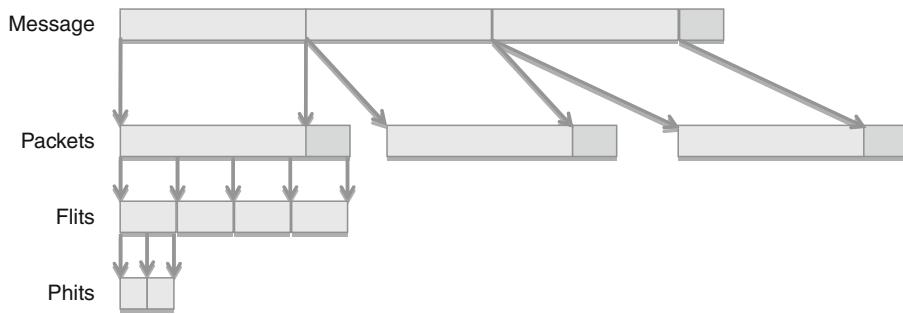

Usually, the sender needs to transmit information to the receiver. To do this, the sender transmits blocks of information, referred to as messages, through a path. A header including the routing information is prepended to the message. Depending on the switching technique used (see below and the "switching" entry), the message may be further divided into packets. A packet is made up of a header (with the proper information to route the packet through the network) and a payload.

Every message or packet is then further split into *flits*. The *flit* (flow control bit) term is defined as the minimum amount of information that is flow controlled. *Flits* can then be divided into smaller data units called *phits* (physical units). A *phit* is usually the amount of information that is forwarded in a cycle through a network link. Depending on the link width a certain number of *phits* will be required to transmit a *flit*. *Phits* are not flow controlled, they only exist because of the link width. Figure 1 shows the breakdown of a message into packets, *flits*, and *phits*.

Not all the communication systems use these four types of data units. Indeed, in some networks, packets are not needed and the entire message is transmitted (see *Wormhole Switching* in *Switching Techniques* entry). Also, in some networks, the *flit* size equals the *phit* size, and thus, there is no need to split a *flit* into smaller *phits*. In addition, as will be highlighted later, the *flit* size can span from few bits to the entire packet size.

Types of Flow Control

The sender and receiver can be connected in different ways, for instance they can be directly connected through a link, or they can be connected through a

Flow Control. Fig. 1 Messages, packets, flits, and phits

network (made of routers, switches, and links) where several routers/switches are visited, and links traversed, prior to reaching the receiver. In both cases, a flow control protocol is defined to set up the proper transmission of information. Therefore, different levels of flow control can be used at the same time: end-to-end flow control and link-level flow control.

Bufferless Flow Control Versus Buffered Flow Control

Usually, flow control is used to prevent the overflow of buffering resources when transmitting information. When the queue at the receiver gets full then the flow control must stop the transmission of information at the sender. Once there is room at the queue the flow control resumes the transmission of information. Therefore, flow control is closely related to buffer management.

However, there are cases where buffers (or queues) are not used along the transmission path of messages. In that case a bufferless flow control is defined. This is the simplest form of flow control. In that case information is simply forwarded, and potentially the information gets discarded or misrouted (due to contention along the path from the sender to the receiver). A bufferless flow control is also used in the so-called lossy networks where packets may be dropped (discarded) at receiver when the buffer fills up. In such networks, the sender will need to retransmit the packet (via time-out or a NACK control packet sent back from the receiver from upper communication layers, e.g., transport layer). However, in buffered networks, some flow control mechanism is usually used to prevent packet dropping, and such networks are known as lossless (or flow controlled) networks. This is an important distinction of types of networks with huge implications. Indeed,

the type of network (lossy or lossless) constrains the solutions for packet routing, congestion management, and deadlock issues. Also, network performance will be significantly different. Typically, storage/system-area networks (SAN) used in parallel systems and on-chip networks are lossless and local area networks (LAN) and wide area networks (WAN) are lossy.

Flow Control Versus Switching

Flow control is also closely related to switching. Switching determines when and how the information advances through a switch or router. Nowadays, the most frequently used switching mechanisms are *wormhole* and *virtual cut-through*. One of the key differences between *wormhole* switching and *virtual cut-through* switching lies in the size of buffers and messages. In *wormhole* switching buffers at routers are usually smaller than message sizes, having slots for only a few *flits* (and messages can be tens of *flits* in size or even much larger). However, in *virtual cut-through* switching, buffers must be larger than packets so as to store an entire packet in a router. Indeed, in *virtual cut-through*, whenever a packet blocks in the network the packet needs to be stored completely at the blocking router. On the contrary, in *wormhole* switching the message is spread along its paths across several routers. This fact greatly affects the flow control mechanism and, indeed, affects the *flit* size of the flow control protocol. In *wormhole* switching, the *flit* size is a small part of the message, whereas in *virtual cut-through*, the *flit* size is the size of the packet. Because original messages from the sender could be larger than buffers, packetization (splitting a message into bounded packets) is required in *virtual cut-through*.

As information may travel across multiple routers, the switching inside a router is also seen as a means of flow control. Indeed, some authors do not distinguish between flow control and switching [1], and they describe most used flow control mechanisms as *worm-hole* flow control and *virtual cut-through* flow control. However, a basic distinction exists depending on where the flow control is applied. If applied inside a router or switch then switching mechanism is used and if applied over a link connecting two nodes then flow control is used. Keep in mind also the end-to-end flow control as a third possibility. **Figure 2** shows a pair of connecting devices (source and destination nodes) connected through a series of switches and links. The figure illustrates the different levels of flow control (end-to-end and link-level) and where switching is performed (inside the switches). Taking into account this basic differentiation between flow control and switching, the following sections describe the most frequently used link-level flow control mechanisms. They are described linked to the suitable switching mechanisms they usually work with.

Another key property that distinguishes flow control from switching is that flow control is used as a means to provide backpressure not to overflow receiving buffers. Instead, switching is related to decide when and how information is switched from input ports of a switch/router to output ports of the switch/router.

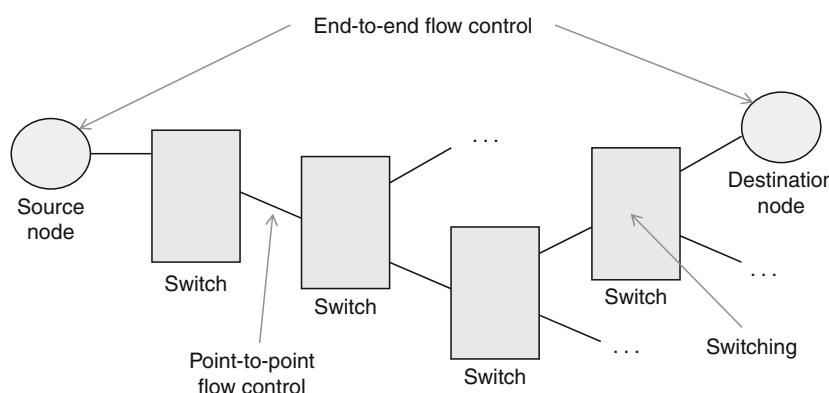

Impact of Flow Control and Buffer Size

Flow control is a key component in a network. An optimized flow control protocol will keep a fraction

of the buffers used most of the times and will minimize the time *flits* are seated waiting at queues, thus achieving high performance in the network. However, a suboptimal flow control protocol may keep resources underutilized and *flits* blocked most of the time waiting at buffers, thus ending up in a network with low performance (low throughput and high latencies).

In a flow control protocol, the buffer resources at the receiver end must be efficiently used to keep maximum performance. To do this, the buffer depth must be sized according to the latency of the path between the transmitter and the receiver (the time it takes for a flit to travel from the transmitter to the receiver). As both receiver and transmitter will exchange flow control information, the buffer must be sized, at minimum, to allow for the round-trip time of the link. This value is the path latency multiplied by two (two way transmission) plus the time it takes to generate and process the flow control command at both sides. Notice that this is needed in any type of flow-controlled transmission, either link-level or end-to-end.

Flow control is also highly related to congestion management. Congestion management deals with high levels of blocking in the network among different messages. To solve such a situation, a congestion management technique may reduce the injection of traffic from a router or from an end node, thus resembling flow control methods (as they dictate when flows advance). However, the reader must be aware that in a congestion management technique the goal is to reduce the blocking experienced in the network, whereas in a flow control method the goal is not to overrun a buffer.

Flow Control. Fig. 2 Different levels of flow control

Link-Level Flow Control

The most commonly used link-level flow control protocols are Xon/Xoff, credit-based, and Ack/Nack. However, there are other solutions that, although basic and probably low in performance, help to better understand the concept. This is the case for a handshake protocol. Next, each of these flow control protocols is described.

Handshake protocol. The most straightforward method to implement flow control among two devices is by setting a handshake protocol. As an example, a sender may assert a request signal to the receiver thus notifying it has a *flit* to send. The receiver (depending on its availability for storing new flits) may assert a grant signal to let the transmitter know that there is slot at the queue. Then, the transmission of the *flit* may begin. For the next *flit* the handshake protocol needs to be repeated (the handshake works at the *flit* granularity). Although such protocol is correct and ensures that no queue will overrun, the problem is the low performance achieved in the transmission. Indeed, the delay incurred in the control signal exchange is not overlapped with the transmission of *flits*, and therefore, there are bubbles introduced along the transmission path. Another potential problem is the excessive exchange of control information (request, grant signals) between the transmitter and the receiver for every transmitted *flit*. The following link-level flow control methods reduce such overhead.

Xon/Xoff flow control. Xon/Xoff flow control is also known as Stop&Go. It is mostly used in networks with *wormhole* switching. Basically, the receiver notifies the sender either to stop or to resume sending *flits* once high and low buffer occupancy levels are reached, respectively. To do this, two queue thresholds are set at the receiving side. When the queue fills and passes the Xoff threshold, then the receiver side sends an *off* flow control signal to the transmitter to stop transmission (in order to prevent buffer overrun). At the transmitter side, when the *off* control signal is received the transmission is stopped and the sender enters the *off* mode. Transmission will be resumed only when notified by the receiver. Indeed, when the queue drains and reaches the Xon threshold, then the receiver sends an *on* flow control signal to the transmitter. The transmitter enters again the *on* mode and resumes transmission.

Xon and Xoff thresholds are critical from the performance point of view. Indeed, Xoff threshold must be set not to overrun the receiving queue, and the Xon threshold must be set not to introduce bubbles along the transmission path (once forwarding of flits is resumed). Therefore, the round-trip time must be taken into account when setting the thresholds. In addition, Xoff and Xon thresholds must be away enough so as not to send many *off* and *on* control signals unnecessarily. It is common to set the Xoff threshold at 2/3 and the Xon threshold at 1/3 of buffer capacity. Control signals may be sent back to the sender either by using special control signals (thus not using the link data path) or using special control packets through the link data path. With appropriate thresholds, Xon/Xoff significantly reduces the amount of flow control information exchange. However, it requires large buffer memories to avoid buffer overruns.

However, there are other approaches to set up the thresholds that may be beneficial. This is the case for the Prizma switch [6] where both thresholds are set to the same value. This is efficient if the link length is short enough (round trip time is short) as is the case for the Prizma switch. The benefit in this case is the use of a single control signal that when set means a Go, and when reset means a Stop.

Credit-based flow control. Credit-based flow control is usually linked to networks using *virtual cut-through* switching. Indeed, the flit size is the packet size and, therefore, packet size is limited to a maximum (buffer size needs to be larger or equal than packet size). In credit-based flow control the sender has a counter of credits. The counter is initially set to the number of *flits*/slots available at the receiver side. Typically, a credit means a slot for a *flit* is granted at the receiver side. There are, however, systems where the credit means a chunk of bytes not necessarily the size of the packet (e.g., in InfiniBand network the credit means a slot for 64 bytes).

The sender transmits a *flit* whenever it has credits available. If the credit counter is different from zero, then a *flit* can be transmitted, and the counter is decremented by one. If the counter reaches zero then the transmitter cannot send more *flits* to the receiver.

The receiver keeps track of receptions and transmissions. Whenever a *flit* is consumed the receiver sends a new credit upstream. This is notified by a flow

control signal (again this info can travel decoupled from the transmission link or as a control packet through the transmission link). Alternatively, and to reduce the overhead in transmitting control information, the receiver may collect credits and send them in a batch. However, in that case, performance may suffer since forwarding of *flits* may be delayed.

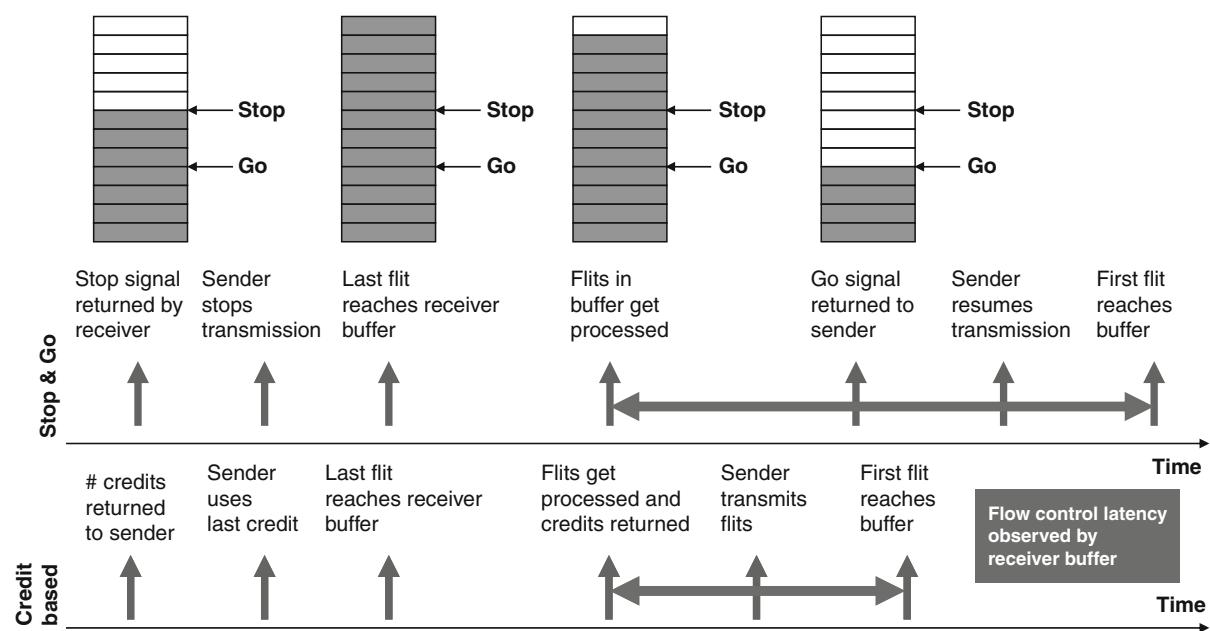

Credit-based flow control requires less than half the buffer size required by Xon/Xoff flow control, thus being more effective regarding resource requirements. In addition, the link reaction time is shorter in credit-based flow control. When the sender runs out of credits then it stops sending *flits*. When a single credit is returned from the receiver then the transmission is resumed. In Xon/Xoff the go threshold needs to be reached before sending the go signal, thus incurring higher transmission latencies. **Figure 3** shows a comparison between the Stop&Go flow control protocol (Xon/Xoff) and the credit-based flow control. As can be seen, the credit-based flow control protocol is able to resume forwarding flits sooner than Stop&Go.

Ack/Nack flow control. Flow control is also linked to fault-tolerance in message transmissions. Indeed, the

Ack/Nack flow control allows the receiver to notify the sender that the last *flit* sent was correct (received without error) or erroneous (due to a failure or even because there was no buffer available). There is no state information at the transmitter side. Indeed, the transmitter is optimistic and keeps sending *flits* to the receiver. In this sense, Ack/Nack protocol is also known as optimistic flow control.

This flow control method, although it reduces the latency (the sender just transmits the *flit* when it is available) has a poor bandwidth utilization (sending flits that are dropped). In addition, the transmitter needs logic to deal with timeouts in order to trigger retransmissions (in the absence of either an ACK or NACK signal). Also, it needs to keep a copy of the *flit* until it receives an ACK signal. Thus, the protocol incurs in an inefficient buffer utilization.

Xon/Xoff and credit-based flow control methods do not support failures. Indeed, these protocols only care about buffer flooding. When using such protocols and in the face of a failure, the system needs to rely on a higher-level flow control protocol, most of the time being an end-to-end flow control protocol.

Flow Control. Fig. 3 Flow control comparison (Xon/Xoff vs credits)

Other Specific Flow Control Protocols

Depending on the type of network used, other flow control protocols may be used trying to add new functionalities, like higher performance, lower *flit* latencies, fault coverage, etc. One example is T-ERR [5] flow control protocol, proposed for on-chip networks. T-ERR increases the operating frequency of a link with respect to a conventional design. In such situations, timing errors become likely on the link. These faults are handled by a repeater architecture leveraging upon a second clock to resample input data, so as to detect any inconsistency. Therefore, T-ERR obtains higher link throughput at the expense of introducing timing errors.

Flow Control and Virtual Channels

An important issue related to flow control is how to deal with virtual channels (► [Switch Architecture](#)). Flow control can be instantiated for each virtual channel so that individual virtual channels do not get overflowed. However, this leads to the assumption that buffer resources are statically assigned to each virtual channel, leading to low memory utilization. The problem with this approach comes from the fact that every virtual channel must be deep enough to cover the round-trip time of the link and avoid introducing bubbles in the transmission line. To reduce such overhead, it is common to design a single (and shared) landing pad at the input port of the switch. The landing pad is flow controlled. Flits arriving to the landing pad are then moved to the appropriate virtual channel.

More interesting approaches rely on the dynamic assignment of memory resources to virtual channels. Thus virtual channels may grow in depth depending on the traffic demands. In order to cope with such dynamicity, it is common to combine two flow control mechanisms. One example is the use of the Stop&Go flow control protocol per virtual channel and the credit-based flow control protocol for the entire memory at the input port of the switch. Thus, whenever a switch wants to forward a flit to the next switch, it needs to check whether there are global credits available at the input port and whether the receiving virtual channel is in go state. Notice that with the proper setting of thresholds a particular

virtual channel will not consume the entire memory resources, thus leaving room for other virtual channels.

End-to-End Flow Control

Link-level flow control protocols can, in principle, be applied in end-to-end scenarios. Indeed, nothing impedes them to work. This is the case for the Ack-/Nack protocol implemented at end nodes, in order to guarantee the reception of messages at destination. However, since the round trip time is longer, large buffers are required at both sides to transmit multiple messages while waiting for ACK signals. Usually this is not a major problem, since end nodes implement much larger buffer resources than routers and switches.

There are, however, other protocols designed at that level. Indeed, these flow control protocols are known also as message protocols. Two examples are the eager protocol and the rendezvous protocol.

The eager protocol just assumes the receiver will have enough allocated space at its buffers to store the transmitted message. In case the receiver was not expecting the message then it has to allocate more buffering and copy the message. During that time, the network may fill up. Thus, the eager protocol may impact performance.

In contrast, the rendezvous protocol does not send a message unless the receiver is aware of it. This is of particular interest when the amount of information to send is large. When using the rendezvous protocol, the transmitter first sends a single short message requesting buffer storage at the reception so as to allocate a large buffer. The receiver, after allocating the buffer, sends an acknowledgment to the sender. Upon reception, the sender injects all the messages, which include a sequence number in their header. The receiver just stores every incoming message at the correct buffer slot, depending on the sequence number the message has. Upon reception of all the messages the data info is at the receiver and ordered.

The use of the eager or the rendezvous protocol may also affect the way programs are coded. This is the case for MPI programming where different commands can be implemented with different end-to-end flow control protocols. Also, out of order delivery of

messages can be avoided with the rendezvous protocol. As there are applications that do not work in networks with unordered delivery of messages (e.g., using adaptive routing), then the choice of the rendezvous protocol may be a good choice for exploiting the benefits of adaptive routing without suffering out-of-order delivery.

Bibliographic Notes and Further Reading

There are several books that cover the field of interconnection networks. High-performance interconnection networks (used in Massively Parallel Systems and/or clusters of computers) are covered in the books of Duato [2] and Dally [1]. Both offer a good text for flow control and in some cases complementary views. In particular, Dally's book couples flow control with switching providing a common text for both terms. In Duato's book the term is clearly differentiated and is more focused on switching (rather than flow control).

For more specific and emerging scenarios, like on-chip networks, the book by De Micheli and Benini [3] provides alternative flow control protocols (link-level flow control in Chap. 4 and end-to-end flow control protocols in Chap. 5). For computer networks (LANs and WANs) the reader should focus on books like Tanenbaum [4] (Chap. 6 for the transport layer and Chap. 3 for the data link layer).

Flynn's Taxonomy

MICHAEL FLYNN

Stanford University, Stanford, CA, USA

Synonyms

SIMD (single instruction, multiple data) machines

Definition

Flynn's taxonomy is a categorization of forms of parallel computer architectures. From the viewpoint of the assembly language programmer, parallel computers are classified by the concurrency in processing sequences (or streams), data, and instructions. This results in four classes SISD (single instruction, single data), SIMD (single instruction, multiple data), MISD (multiple instruction, single data), and MIMD (multiple instruction, multiple data).

Discussion

Introduction

Developed in 1966 [1] and slightly expanded in 1972 [2], this is a methodology to classify general forms of parallel operation available within a processor. It was proposed as an approach to clarify the types of parallelism either supported in the hardware by a processing system or available in an application. The classification is based on the view of either the machine or the application by the machine language programmer. It implicitly assumes that the instruction set accurately represents a machine's micro-architecture.

At the instruction level, parallelism means that multiple operations can be executed concurrently within a program. At the loop level, consecutive loop iterations are ideal candidates for parallel execution provided that there is no data dependency between subsequent loop iterations. Parallelism available at the procedure level depends on the algorithms used in the program. Finally, multiple independent programs can obviously execute in parallel. Different instruction set (or instructions set architectures or simply, computer architectures) have been built to exploit this parallelism. In general, an instruction set architecture consists of instructions each

of which specifies one or more interconnected processor elements that operate concurrently, solving a single overall problem.

The Basic Taxonomy

The taxonomy uses the stream concept to categorize the instruction set architecture. A stream is simply a sequence of objects or actions. There are both instruction streams and data streams, and there are four simple combinations that describe the most familiar parallel architectures [3]:

1. SISD – single instruction, single data stream; this is the traditional uniprocessor (Fig. 1) which includes pipelined, superscalar, and VLIW processors.
2. SIMD – single instruction, multiple data stream, which includes array processors and vector processors (Fig. 2 shows an array processor).
3. MISD – multiple instruction, single data stream, which includes systolic arrays, GPUs, and dataflow machines (Fig. 3).
4. MIMD – multiple instruction, multiple data stream, which includes traditional multiprocessors (multi-core and multi-threaded) as well as the newer work of networks of workstations (Fig. 4).

As the stream description of instruction set architecture is the programmer's view of the machine, there are limitations to the stream categorization. Although it serves as useful shorthand, it ignores many subtleties of

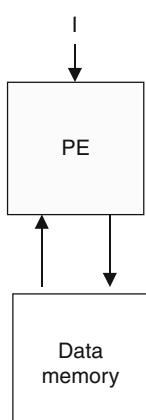

an architecture or an implementation. As pointed out, the original work in 1966 even an SISD processor can be highly parallel in its execution of operations. This parallelism need not be visible to the programmer at the assembly language level, but generally becomes visible at execution time through improved performance and, possibly, programming constraints.

SISD: Single Instruction, Single Data Stream

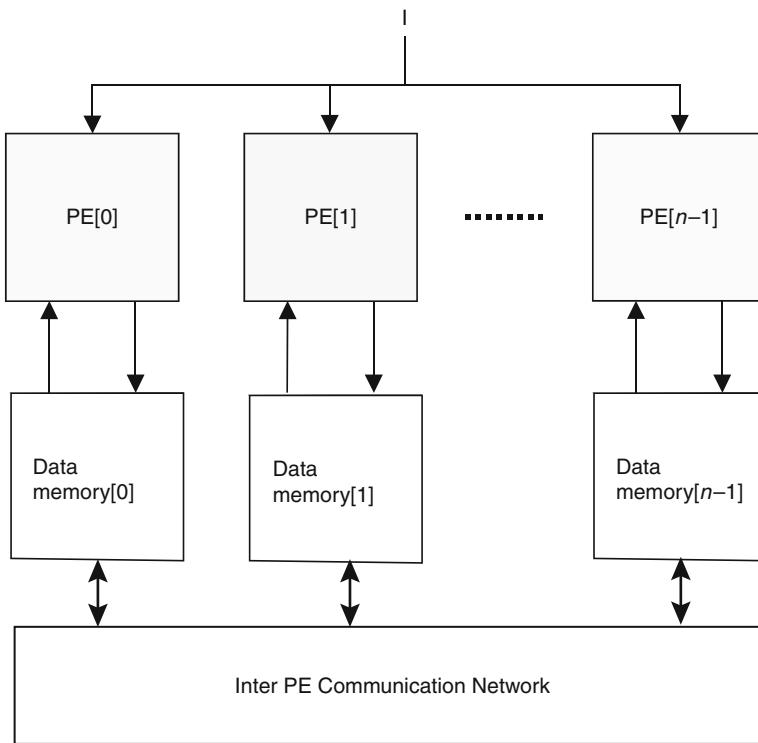

The SISD class of processor architecture includes most commonly available workstation type computers. Although a programmer may not realize the inherent parallelism within these processors, a good deal of concurrency can be present. Obviously, pipelining is a powerful concurrency technique and was recognized in the 1966 original work. Indeed, in that work, the idea of simultaneously decoding multiple instructions was mentioned but was regarded as infeasible for the technology of the time. (That paper referred to the issuance of more than one instruction at a time as a bottleneck and later publications sometimes refer to this problem as *Flynn's bottleneck*). Of course by now almost all machines use pipelining and many machines use one or another form of multiple instruction issue. These multiple issue techniques aggressively exploit parallelism in executing code whether it is declared statically or determined dynamically from an analysis of the code stream. During execution, a SISD processor executes one or more operations per clock cycle from the instruction stream. Strictly speaking, the instruction stream consists of a sequence of instruction words. An instruction word is a container that represents the smallest execution packet visible to the programmer and executed by the processor.

One or more operations are contained within an instruction word. In some cases, the distinction between instruction word and operations is crucial to distinguish between processor behaviors. When there is only one operation in an instruction word, it is simply referred to as an instruction.

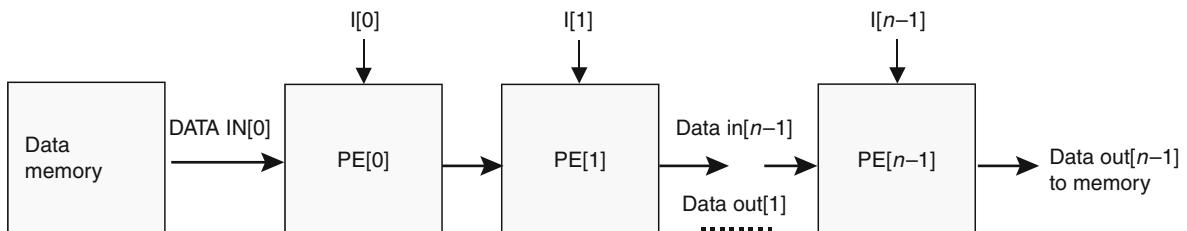

Scalar and superscalar processors execute one or more instructions per cycle where each instruction contains a single operation. VLIW processors, on the other hand, execute a single instruction word per cycle where this instruction word contains multiple operations.

Flynn's Taxonomy. Fig. 1 SISD – single instruction operating on a single data unit

Flynn's Taxonomy. Fig. 2 SIMD – array processor type using PEs with local memory

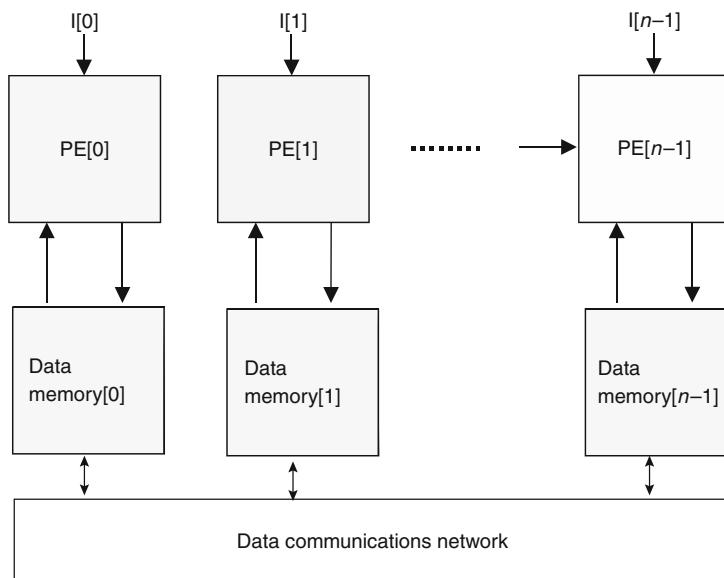

Flynn's Taxonomy. Fig. 3 MISD – a streaming processor example

The amount and type of parallelism achievable in a SISD processor has four primary determinates:

1. The number of operations that can be executed concurrently on a sustainable basis.
2. The scheduling of operations for execution. This can be done statically at compile time, dynamically at execution, or possibly both.
3. The order that operations are issued and retired relative to the original program order – these operations can be in order or out of order.
4. The manner in which exceptions are handled by the processor – precise, imprecise, or a combination.

On the occurrence of an exception (or interrupt), a precise exception handler will (usually) complete processing of the current instruction and immediately process the exception. An imprecise handler may have already completed instructions that followed an instruction that caused the exception and will simply signal that the exception has occurred and it is left to the operating system to manage the recovery.

Most SISD processors implement precise exceptions, although a few high-performance architectures allow imprecise floating-point exceptions.

Flynn's Taxonomy. Fig. 4 MIMD – ►multiple instruction

Scalar (Including Pipelined) Processors

A scalar processor is a simple (usually pipelined) processor that processes a maximum of one instruction per cycle and executes a maximum of one operation per cycle. These processors process instructions sequentially from the instruction stream. The next instruction is not processed until the execution for the current instruction is complete, and its results have been stored. The semantics of the instruction determines that a sequence of actions that must be performed to produce the desired result (instruction fetch, decode, data or register access, operation execution, and result storage). These actions can be overlapped but the result must appear in the specified serial order. This sequential execution behavior describes the sequential execution model that requires each instruction executed to completion in sequence. In the sequential execution model, execution is instruction-precise if the following conditions are met:

1. All instructions (or operations) preceding the current instruction (or operation) have been executed and all results have been committed.
2. All instructions (or operations) after the current instruction (or operation) are unexecuted or no results have been committed.
3. The current instruction (or operation) is in an arbitrary state of execution and may or may not have completed or had its results committed.

For scalar and superscalar processors with only a single operation per instruction, instruction-precise and operation-precise executions are equivalent. The traditional definition of sequential execution requires instruction-precise execution behavior at all times, mimicking the execution of a nonpipelined sequential processor.

Most scalar processors directly implement the sequential execution model. The next instruction is not processed until all execution for the current instruction is complete and its results have been committed.

Pipelining is based on concurrently performing different phases (instruction fetch, decode, execution, etc.) of processing an instruction, with a maximum of one instruction being decoded each cycle. Ideally, these phases are independent between different operations and can be overlapped; when this is not true, the processor stalls the process to enforce the dependency. Thus, multiple operations can be processed simultaneously with each operation at a different phase of its processing.

For a simple pipelined machine, only one operation occurs in each phase at any given time. Thus, one operation is being fetched, one operation is being decoded, one operation is accessing operands, one operation is in execution, and one operation is storing results. The most rigid form of a pipeline, sometimes called the

static pipeline, requires the processor to go through all stages or phases of the pipeline whether required by a particular instruction or not. Dynamic pipeline allows the bypassing of one or more of the stages of the pipeline depending on the requirements of the instruction.

There are at least two basic types of dynamic pipeline processors:

1. Dynamic pipelines that require instructions to be decoded in sequence and results to be executed and stored in sequence. This type of dynamic pipeline provides a small performance over a static pipeline. In-order execution requires the actual change of state to occur in order specified in the instruction sequence.
2. Dynamic pipelines that require instructions to be decoded in order, but the execution stage of operation need not be in order. In these organizations, the address generation stage of the load and store instructions must be completed before any subsequent ALU instruction does a write back. The reason is that the address generation may cause a page fault and affect the execution sequence of following instructions. This type of pipeline can result in imprecise exceptions mentioned earlier without the use of special order-preserving hardware.

Superscalar Processors

Even the most sophisticated scalar dynamic pipelined processor is limited to decoding a single operation per cycle. Superscalar processors decode multiple instructions in a cycle and use multiple functional units and a dynamic scheduler to process multiple instructions per cycle. These processors can achieve execution rates of several instructions per cycle (usually limited to 2 or 3, but more is possible in favorable application). A significant advantage of a superscalar processor is that processing multiple instructions per cycle is done transparently to the user and provide binary code compatibility. Compared to a dynamic pipelined processor, a superscalar processor adds a scheduling instruction window that analyzes multiple instructions from the instruction stream each cycle. Although processed in parallel, these instructions are treated in the same manner as in a pipelined processor. Before an instruction is

issued for execution, dependencies between the instruction and its prior instructions must be checked by hardware. Advanced superscalar processors usually include order-preserving hardware to insure precise exception handling, simplifying the programmer's model. Because of the complexity of the dynamic scheduling logic, high-performance superscalar processors are usually limited to processing four to eight instructions per cycle.

VLIW Processors

VLIW processors also decode multiple operations per cycle and use multiple functional units. A VLIW processor executes operations from statically scheduled instruction words that contain multiple independent operations. In contrast to superscalar which uses hardware-supported dynamic analyses of the instruction stream to determine which operations can be executed in parallel, VLIW processors rely on static analyses by the compiler. VLIW processors are thus less complex than superscalar processors, and have, at least, the potential for higher performance.

For applications that can be effectively scheduled statically, VLIW implementations offer high performance. Unfortunately, not all applications can be so effectively scheduled as execution does not proceed exactly along the path defined by the compiler code scheduler.

Two classes of execution variations can arise and affect the scheduled execution behavior:

1. Delayed results from operations whose latency differs from the assumed latency scheduled by the compiler.
2. Exceptions or interrupts, which change the execution path to a completely different and unanticipated code schedule.

While stalling the processor can control delayed result, this can result in significant performance penalties. The most common execution delay is a data cache miss. Most VLIW processors avoid all situations that can result in a delay by avoiding data caches and by assuming worst-case latencies for operations. However, when there is insufficient parallelism to hide the worst-case operation latency, the instruction schedule can have many incompletely filled or empty operation slots in the instructions, resulting in degraded performance.

SIMD: Single Instruction, Multiple Data Stream

The SIMD class of processor architecture includes both array and vector processors. The SIMD processor is created around the use of certain regular data structures, such as vectors and matrices. From the reference point of an assembly-level programmer, programming SIMD architecture appears to be very similar to programming a simple SISD processor except that some operations perform computations on these aggregate data structures. As these regular structures are widely used in scientific programming, the SIMD processor has been very successful in these environments.

Array processor and the vector processor differ both in their implementations and in their data organizations.

An array processor consists of interconnected processor elements with each having its own local memory space. A vector processor consists of a single processor that references a single global memory space and has special functional units that operate specifically on vectors.

Array Processors

The array processor consists of multiple processor elements connected via one or more networks, possibly including local and global inter element communications and control communications. Processor elements operate in lockstep in response to a single broadcast instruction from a control processor. Each processor element has its own private memory, and data is distributed across the elements in a regular fashion that is dependent on both the actual structure of the data and also on the computations to be performed on the data. Direct access to global memory or another processor element's local memory is expensive, so intermediate values are propagated through the array through local interprocessor connections, which requires that the data be distributed carefully so that the routing required to propagate these values is simple and regular. It is sometimes easier to duplicate data values and computations than it is to affect a complex or irregular routing of data between processor elements.

As instructions are broadcast, there is no means local to a processor element of altering the flow of the instruction stream; however, individual processor elements can conditionally disable instructions based on local status information – these processor elements are

idle when the specified condition occurs. Often implementation consist of an array processor coupled to a SISD general-purpose control processor that executes scalar operations and issues array operations that are broadcast to all processor elements in the array. The control processor performs the scalar sections of the application, interfaces with the outside world, and controls the flow of execution; the array processor performs the array sections of the application as directed by the control processor.

The programmer's reference point for an array processor is typically the high-level language level; the programmer is concerned with describing the relationships between the data and the computations but is not directly concerned with the details of scalar and array instruction scheduling or the details of the inter processor distribution of data within the processor. In fact, in many cases, the programmer is not even concerned with size of the array processor. In general, the programmer specifies the size and any specific distribution information for the data and the compiler maps the implied virtual processor array onto the physical processor elements that are available and generates code to perform the required computations.

Vector Processors

A vector processor is a single processor that resembles a traditional SISD processor except that some of the function units (and registers) operate on vectors – sequences of data values that are processed as a single entity. These functional units are deeply pipelined and have a high clock rate; although the vector pipelines have a long or longer latency than a normal scalar function unit, their high clock rate and the rapid delivery of the input vector data elements results in a significant throughput that cannot be matched by scalar function units. Early vector processors processed vectors directly from memory. The primary advantage of this approach was that the vectors could be of arbitrary lengths and were not limited by processor registers or resources; however, the high startup cost, limited memory system bandwidth, and memory system contention were significant limitations.

Modern vector processors require that vectors be explicitly loaded into special vector registers and stored back into memory from these registers, the same course that modern scalar processors have taken for similar reasons. The vector register file consists of several sets of

vector registers (with perhaps 64 registers in each set). Vector processors have several features that enable them to achieve high performance. One feature is the ability to concurrently load and store values between the vector registers and main memory while performing computations on values in the vector register file. This feature is important because the limited length of vector registers requires that long vectors be processed in segments. Not being able to overlap memory accesses and computations would pose a significant performance bottleneck. Just like SISD processors, vector processors support a form of result bypassing – in this case called chaining – that allows a follow-on computation to commence as soon as the first value is available from the preceding computation. Thus, instead of waiting for the entire vector to be processed, the follow-on computation can be largely overlapped with the preceding computation that it is dependent on. Sequential computations can be efficiently compounded and behave as if they were a single operation with a total latency equal to the latency of the first operation with the pipeline and chaining latencies of the remaining operations but none of the start-up overhead that would be incurred without chaining.

As with the array processor, the programmer's reference point for a vector machine is the high-level language. In most cases, the programmer sees a traditional SISD machine; however, as vector machines excel on vectorizable loops, the programmer can often improve the performance of the application by carefully coding the application, in some cases explicitly writing the code to perform register memory overlap and chaining, and by providing hints to the compiler that help to locate the vectorizable sections of the code. As languages are defined (such as Fortran 90 or High-Performance Fortran) that make vectors a fundamental data type, the programmer is exposed less to the details of the machine and to its SIMD nature.

MISD: Multiple Instruction, Single Data Stream

The MISD architecture is a pipelined ensemble where the function of the individual stages are determined by the programmer before execution is begun; then data is streamed through the pipeline, forwarding results from one (stage) function unit to the next. On the micro-architecture level this is exactly what the vector processor does. However, in the vector pipeline

the programmer initially organizes the data into suitable data structure, then streams the data elements into stages where the operations are simply fragments of an assembly-level operation, as distinct from being a complete operation. Surprisingly, some of the earliest attempts in the 1940s could be seen as the MISD computers (they were actually programmable calculators; as they were not “stored program machines” in the sense that the term is now used). They used plug boards for programs, where data in the form of a punched card was introduced into the first stage of a multistage processor. A sequential series of actions was taken where the intermediate results were forwarded from stage to stage until, at the final stage, a result would be punched into a new card.

While the MISD term is not commonly used, there are interesting uses of the MISD organization. A frequently used synonym for MISD is “streaming processor.” Some of these processors are commonly available. One example is the GPU (graphics processing unit); early and simpler GPUs provided limited programmer flexibility in selecting the function or operation of a particular stage (ray tracing, shading etc.). More modern GPGPUs (general purpose GPU) are more truly MISD with a more complete operational set at the individual stage in the pipeline. Indeed, many modern GPGPU incorporate both MISD and MIMD as these systems offer multiple MISD cores.

Other MISD style architectures include dataflow machines. In these machines, the source program is converted into a data flow graph, each node of which is a required operation. Data then is streamed across the implemented graph. Each path through the graph is a MISD implementation. If the graph is relatively static for particular data sequences, then the path is strictly a MISD if multiple paths are invoked during program execution then each path is MISD and there are MIMD instances in the implementation. Such dataflow machines have been realized by FPGA implementations.

MIMD: Multiple Instruction, Multiple Data Stream

The MIMD class of parallel architecture consists of multiple processors (of any type) and some form of interconnection. From the programmer's point of view each processor executes independently but to cooperatively execute to solve a single problem although some

form of synchronization is required to pass information and data between processors. Although no requirement exists that all processor elements be identical, most MIMD configurations are homogeneous with all processor elements identical. There have been heterogeneous MIMD configurations that use different kinds of processor elements to perform different kinds of tasks, but these configurations are usually for special-purpose applications.

From a hardware perspective, there are two types of homogeneous MIMD: multi-threaded and multi-core processors; frequently implementations use both.

Multi-Threaded Processors

In multi-threaded MIMD, a single base processor is extended to include multiple sets of program and data registers. In this configuration, separate threads or programs (instruction streams) occupy each register set. As resources are available, the threads continue execution. Since the threads are independent so is their resource usage. So ideally, the multiple threads make better use of resources such as floating point units and memory ports resulting in a higher number of instructions executed per cycle. Multi-threading is a quite useful complement to large superscalar implementations as these have relative extensive set of expensive floating point and memory resources. Critical threads (tasks) can be given priority to insure short execution while less critical tasks avail of the underused resources. As a practical matter, these designs must insure a minimum service for every task to avoid a type of task lockout. Otherwise, the implementation is straightforward since all tasks can share data caches and memory without any interconnection network.

Multi-Core and Multiple Multi-Core Processor Systems

At the other end of the MIMD spectrum are multiple multi-core processors. These implementations must communicate results through an interconnection network and coordinate task control. Their implementation is significantly more complex than the simpler MIMD or even more complex SIMD array processor.

The interconnection network in the multiprocessor passes data between processor elements and synchronizes the independent execution streams between processor elements. When the memory of the

processor is distributed across all processors and only the local processor element has access to it, all data sharing is performed explicitly using messages and all synchronization is handled within the message system.

When communications between processor elements are performed through a shared memory address space – either global or distributed between processor elements (called distributed shared memory to distinguish it from distributed memory) – there are two significant problems that arise. The first is maintaining memory consistency: the programmer-visible ordering effects on memory references, both within a processor element and between different processor elements. This problem is usually solved through a combination of hardware and software techniques. The second is cache coherency – the programmer invisible mechanism to ensure that all processor elements see the same value for a given memory location. This problem is usually solved exclusively through hardware techniques.

The primary characteristic of a large MIMD multiprocessor system is the nature of the memory address space. If each processor element has its own address space (distributed memory), the only means of communication between processor elements is through message passing. If the address space is shared (shared memory), communication is through the memory system.

The implementation of a distributed memory machine is easier than the implementation of a shared memory machine, when memory consistency and cache coherency are taken into account, while programming a distributed memory processor can be more difficult.

In recent times, large-scale (more than 1,000 cores) multiprocessors have used the distributed memory model based on implementation requirements.

Bibliographic Notes and Further Reading

Parallel processors have been implemented in one form or another almost as soon as the first uniprocessor implementation. Most early implementations were straightforward MIMD multiprocessors. With the advent of SIMD array processors, such as Illiac IV [4], the need for a distinction became clear. Because the taxonomy is simple, numerous extensions have been proposed; some fairly general such as those of Handler [5], Kuck [6], and El-Rewini [7]. Other extensions were of more specialized nature such as Göhringer [8], Chemij [9].

Additional comments on the taxonomy and elaborations can be found in the standard texts on parallel architecture such as Hwang [10], Hockney [11], and El-Rewini [7]. Xavier [12] and Quinn [13] are helpful texts which view the taxonomy from the programmer's view point.

Synonyms

Interactive parallelization; Parallelization; Vectorization; Whole program analysis

Definition

FORGE is an interactive program analysis package built on top of a database representation of an application. FORGE was the first commercial package that addressed the issue of performing interprocedural analysis for Program Consistency, Shared and Distributed Parallelization, and Vectorization. FORGE was developed by a team of computer scientists employed by Pacific Sierra Research and later Applied Parallel Research.

Discussion

Introduction

When FORGE was marketed in 1995, whole program parallelization was not quick, easy, or convenient. Vectorization was a mature user and compiler art. Many users could write vectorizable loops that a compiler could translate to efficient vector instructions. Distributed and shared memory multiprocessors could be treated as vector processors and parallelized in the same manner. This is frequently very inefficient. Parallelization introduces much more overhead than vectorization. To overcome overhead parallelization requires a much higher granularity than vectorization. Parallelization of outer loops containing nested subroutine calls is usually the best approach. Achieving this high granularity was very difficult for a user to do by hand, and practically impossible for a compiler to accomplish automatically. FORGE was created to bridge

this gap, allowing the user to interactively initiate compiler analysis and view the results. The user controlled the parallelization process using high-level program knowledge. FORGE performed the time-consuming, tedious analysis that computers are better at than programmers.

At the time, a group at Rice University, under the direction of Ken Kennedy, were developing a “Whole Program Analysis” software called Parascope. At the same time, a few of the developers of the VAST vectorizing pre-compiler began a project to develop FORGE, based on a database representation of the input application. In addition to the source code, runtime statistics could be entered into the database to identify important features derived during the execution of the application. Upon this database representation of the program an interactive, windows-based environment was built that allowed the user to interactively:

1. Peruse the database to find inconsistencies in the program
 - a. COMMON block analysis
 - b. Tracing of variable through the call chain showing aliases from subroutine calls, equivalences, and COMMON blocks
 - c. Identification of variables that are used and not set
 - d. Identification of variables that are set and not used
 - e. Queries to identify variables that satisfied certain user-defined templates
2. Interactively Vectorize Application
 - a. Perform loop restructuring
 - i. Loop splitting
 - ii. Routine inlining – pull routine into a loop
 - iii. Routine outlining – push loop into a routine
 - iv. Loop inversion
3. Interactive Shared Memory Parallelization
 - a. Array scoping
 - b. Storage conflicts due to COMMON blocks
 - c. Identification of Reduction function variables
 - d. Identification of Ordered regions due to data dependencies
4. Interactive Distributed Memory Parallelization
 - a. User-directed loop parallelization
 - b. User-directed array distribution

- c. Automatic loop parallelization based on array distribution
- d. Automatic array distribution based on parallel loop access
- e. Iteration of c. and d. for whole program parallelization
- f. Generate HPF
5. Interactive Program Restructuring
 - a. Loop Inversion
 - b. Loop splitting
 - c. Array index reordering
 - d. Routine inlining
 - e. Routine outlining
 - f. TASK COMMON generation
6. Interactive CACHE View tool
 - a. Given a hardware’s Level 1 and Level 2 Cache sizes and runtime statistics
 - i. Instrument code
 - ii. Identify Cache alignment issues
 - iii. Identify Cache overflows
 - iv. Propose Blocking strategies

General Structure

Forge was written in the C programming language. The parser was constructed using the compiler-compiler tools LEX and YACC. The windowing system used was originally a custom interface written for SUN, APOLLO, and DEC workstations. Later a MOTIF based X-Windows system was used.

The Database

To perform the aforementioned functions, FORGE needed significant information concerning the input application. At the end of the development of FORGE in 1998, the database could input the application source code (Only Fortran 77) and runtime statistics.

From the source code, the following data was extracted:

1. For each routine
 - a. Variable information
 - i. Aliasing from COMMON, EQUIVALENCE, SUBROUTINE arguments
 - ii. Read and Write references
 - iii. Data type and size
 - iv. Array dimensions
 - v. Array indexing information

- b. Control structures within the routine – IF's and DO's
- 2. Call chain information
 - a. Static Call chain – all possible calling sequences
 - b. Dynamic Call chain – derived from the runtime statistics
- 3. Variable Aliasing through call chain, both static and dynamic

Done

- 4. Basic Block (control flow) information for the entire application
 - a. All IF constructs controlling the execution of the basic block
 - b. All reaching definitions for variables used in the basic block
 - c. All uses of variable set in the basic block
- 5. Array section analysis
 - a. Information on every looping structure
 - i. Section of array that is accessed by each DO loop
- 6. Integer value information (FACTS) for array index and data dependency analysis

Database Design

The FORGE database was designed and implemented by the developers. An off-the-shelf database was not used. In design of the database, the generation of the database was performed incrementally with the ability to automatically update the database when the source code was modified. The intent was to spend the time building the database so the interactive analysis within the FORGE environment could be performed quickly.

FORGE stored a program as a Package. Each package contained a list of the source files in a program, along with other information such as directories to search, compiler options to use, and target hardware.

Brute force whole program analysis using the hardware available at the time was very time consuming for convenient interactive program analysis. For that reason, a database was created containing only data needed for parallelization of a program. Each program unit (subroutine, function, main program) was analyzed and stored separately in the database, on disk. Last modified dates were saved for each file. A checksum was saved for each program unit in a file. When the modification date for a file indicated that the database was out of date, the file was rescanned and the checksums for each routine compared to the checksums saved with the database. The database was regenerated only for modified routines. Building the initial database for a large program could take an hour. After the initial creation, updating the database for source file changes usually took a few seconds.

When the user selected a package for analysis, tables were built in memory combining the databases for called and calling routines. This process typically took

a few seconds. The efficiency of the incremental update of database and the handling of called routines in memory are the key features that made interactive whole program analysis feasible.

The database was designed to quickly supply information to the Vectorizer and Parallelizer when performing array section and scalar dependency analysis.

All of the analysis features used by the parallelization analysis were made available to the user for program browsing. This only required the implementation of menus, since all the analysis was already implemented. The browser ended up as one of the most popular and powerful features of FORGE.

Users could develop templates to define routines that were called from the application and whose source was not available. These templates simply supplied the information about variables that were either passed into the routine through the argument list or through COMMON blocks.

Runtime Statistics

FORGE had an option to instrument the application to gather information about important routines, DO loops, IF constructs, and Cache utilization. The instrumented program could then be run with an impor-

tant dataset and an ASCII output would be generated that could be fed into the database to assist in performing analysis. There was an option to ignore static information in favor of the dynamic information when performing the aforementioned analysis. The following runtime statistics were gathered.

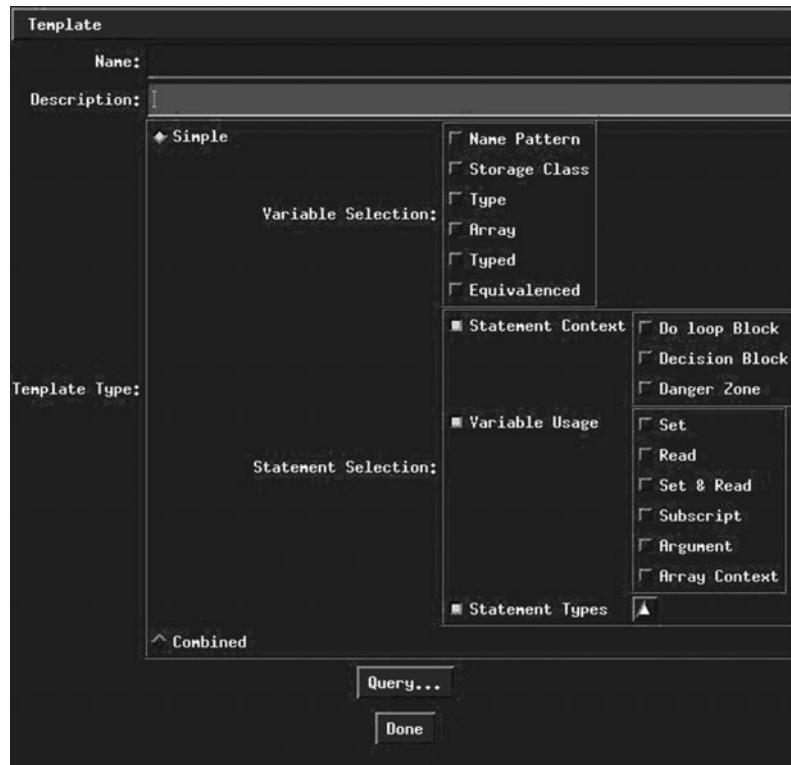

- CPU time of each routine, inclusive and exclusive
- Lengths of DO loops
- CPU time of each DO loop, inclusive and exclusive
- Frequency of IF constructs (optional)
- Array addresses (optional)

Interactive Tools available to the User

Query Database

A popular tool named Query allowed the user to find all variables in a program that matched criteria defined in templates. Templates specified criteria for:

- Variable name
- Variable type
- Variable storage
- Statement context
- Statement type

Many common templates were supplied or the user could create their own templates.

- Show all variables read into the program
- Show all variables written out
- Show all variables used within particular DO loop
- Show all variables set under a condition and used unconditionally

Cache Vu Tool

Cache Vu tool, another tools within the FORGE system, was extremely powerful and informative. The runtime statistics to support this feature was very large and had to be collected in a controlled manner. FORGE was able to visually show the user which arrays were overlapping in the cache and being evicted from cache due to cache associativity.

COMMON Block Grid

A grid was displayed with routines down the side and COMMON blocks across the top. When a COMMON block was selected, variables within that COMMON block were shown across the top showing how each variable was referenced in each routine.

USE-DEF and DEF-USE

This was extremely useful in debugging an application. Plans to attach FORGE to a debugger never materialized.

- User could click on a variable in the source and drop down a menu to select, show reaching definition, or show subsequent uses. The uses and/or sets were shown within the control structures controlling the execution of the line.

Tracing Variables Through the Call Chain

All occurrences of a variable were shown interspersed within the call chain, including IF constructs. Aliasing was shown where occurs due to EQUIVALENCE, COMMON block, or SUBROUTINE call.

Shared Memory Parallelizer

If runtime statistics were available, the window would present the user with the highest level DO loop that is a potential candidate for parallelization. If the DO loop

contained I/O or unknown routine, the user would be alerted to that. The user would then say:

1. Parallelize Automatically
2. Parallelize Interactively

The automatic mode would complete without interaction and show the user if there were any dependency regions, storage conflicts, or other inhibitors. The Interactive mode would converse with the user, showing each inhibitor as encountered. The users could then instruct the parallelizer to ignore dependencies, if appropriate, and continue.

Finally, the user could output the parallelized code in OpenMP, Cray Micro-tasking, or as a parallelized routine to be run with FORGE's shared memory runtime library. The latter was accomplished by outlining the DO loop into a subroutine call that got called in parallel. Shared variables were passed as arguments and private variables made local to the outlined routine.

Distributed Memory Parallelizer

The user could select a set of arrays to decompose, decompose the arrays through a menu – only single index decomposition was supported. FORGE would then identify every DO loop that accessed the decomposed dimension and the user could have FORGE distribute the loop iterations using the owner execute rule automatically. During the loop parallelization, FORGE searched for additional arrays to decompose and loops to parallelize. This cycle of array decomposition and loop distribution continued until no new transformations were found.

Parallelization was saved in internal format between sessions. The user could choose to save the parallelization in a new copy of the source program with HPF directives.

Executable parallel code could be generated either with the interactive parallelizer or a batch translator named XHPF. The translated code contained calls to a runtime library. Storage for distributed arrays was allocated at runtime as determined by the size of the array and the number of distributed CPUs used. Ghost cells were allocated as needed. Parallel loop bounds were computed at runtime. Internode communication was performed pre and post loop as required. Communication was inserted in serial code as required. One node was used to perform all IO operations.

Program Restructurer

The parallelized code was available to the user for all the program transformations executed by FORGE. When the source code was modified, it would be presented to the user and the user could accept the new version and the database would be updated accordingly.

Parallel Program Generation

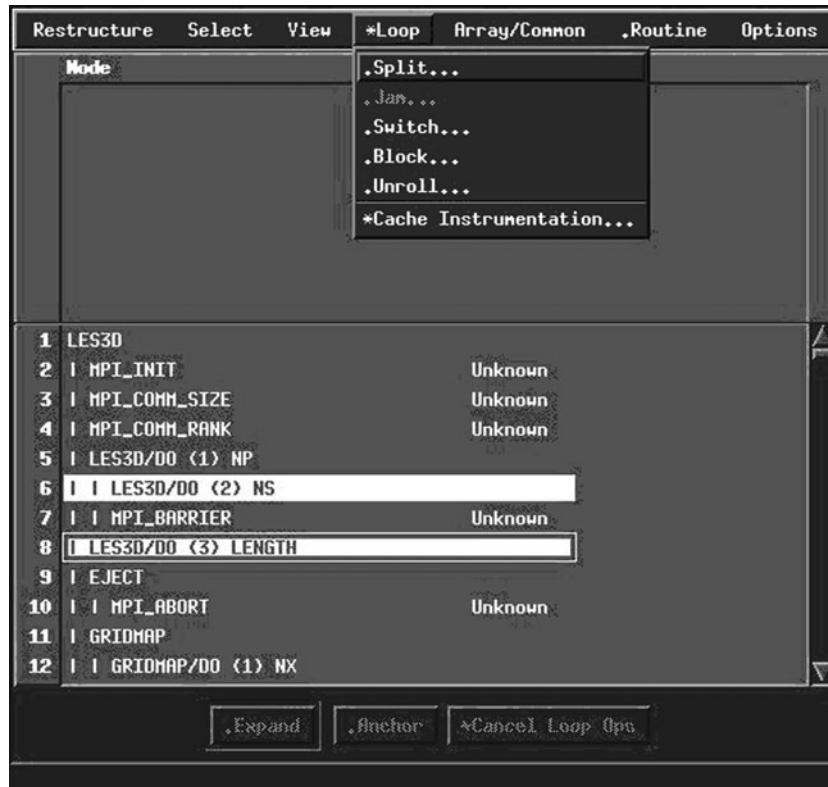

FORGE used the result of analysis to generate parallel programs. It performed source-to-source translation. The input could contain compiler parallelization directives. Syntax defined by most major vendors of the time (IBM, NEC, FUJITSU, DEC, INTEL, NCUBE) were supported, as well as HPF and OMP standards. FORGE could take any of these as input, combine them with interactive or automatic analysis, and generate directives. FORGE could also generate a parallel program containing calls to a FORGE runtime library. Versions of the library existed for shared and distributed memory parallelization for the major vendors. The user would compile the FORGE output with the vendor supplied F77 compiler, link with the appropriate FORGE library, and run the parallel application.

Instrumented versions of the FORGE parallel libraries were provided. When linked with the instrumented libraries and run, timing data was created. The timing data could be viewed interactive with FORGE, superimposed on a dynamic callchain. Efficiencies and “hotspots” were identifiable and correctable.

Batch tools, SPF – shared memory parallelizer, and XHPF (translate HPF) performed the same translation functions as FORGE. A user could modify program directives with a conventional editor and run these tools as precompilers as part of the normal compilation stack.

Future Directions

There were three major deficiencies in Forge. First, Forge handled only a subset of Fortran 90. Second, Forge was developed with Unix Xwindows interface. A convenient native MS Windows interface was needed. Last, the display of parallel loop inhibitors due to loop carried dependencies often contained many false

dependencies. The minimization of the false dependencies and a convenient method for the user to view and ignore dependencies were problems for Forge, as well as all other parallelization tools then and now. Work continued in these areas through the year 2001 when Applied Parallel Research went out of business.

Formal Methods-Based Tools for Race, Deadlock, and Other Errors

PETER MÜLLER
ETH Zurich, Zurich, Switzerland

Definition

Formal methods-based tools for parallel programs use mathematical concepts such as formal semantics, formal specifications, or logics to examine the state space of a program. They aim at proving the absence of common concurrency errors such as races, deadlocks, livelocks, or atomicity violations for all possible executions of a program. Common techniques applied by formal methods-based tools include deductive verification, model checking, and static program analysis.

Discussion

Introduction

Concurrent programs are notoriously difficult to test. Their behavior depends not only on the input but also on the scheduling of threads or processes. Many concurrency errors occur only for very specific schedulings, which makes them extremely hard to find and reproduce.

An alternative to testing is to apply formal methods. Formal methods use mathematical concepts to examine all possible executions of a program. Therefore, they are able to guarantee certain properties for all inputs and all possible schedulings of a program. Most formal methods-based tools for concurrent programs focus on races and deadlocks, the two most prominent concurrency errors. Some of them also detect other errors such as livelocks, atomicity violations, undesired non-determinism, and violations of specifications provided by the user.

This entry covers tools based on three kinds of formal methods. (1) Tools for deductive verification use mathematical logic to construct a correctness proof for the input program. (2) Tools for state space exploration (model checkers) check properties of a program by exploring all its executions. (3) Tools for static program analysis approximate the possible dynamic behaviors of a program and then check properties of these approximations. This entry summarizes the

foundations and applications of these approaches, discusses their strengths and weaknesses, and names a few representative tools for each approach.

The evaluation of the three approaches focuses on the following criteria:

Soundness. A verification or analysis tool is sound if it produces only results that are valid with respect to the semantics of the programming language. In other words, a sound tool does not miss any errors. Soundness is the key property that distinguishes formal methods from testing. However, some formal methods-based tools sacrifice soundness in favor of reducing false positives or improving efficiency.

Completeness. A verification or analysis tool is complete if it does not produce false positives, that is, each error detected by the tool can actually occur according to the semantics of the programming language. Minimizing the number of false positives is crucial for the practical applicability of a tool because each reported error needs to be subjected to further investigation, which usually involves human inspection.

Modularity. A verification or analysis tool is modular if it can analyze the modules of a software system independently of each other and deduce the correctness of the whole system from the correctness of its components. Modularity allows a tool to analyze program libraries and improves scalability.

Automation. A verification or analysis tool has a high degree of automation if it requires little or no user interaction. Typical forms of user interaction include providing the specification to be checked by the tool, assisting the tool through program annotations, and constructing proofs manually. A high degree of automation is necessary to make the application of formal methods-based tools economically feasible.

Efficiency. A verification or analysis tool is efficient if it can analyze large programs in a relatively short amount of time and space. In general, the number of states and executions of a program grows exponentially in the size of the program (for instance, the number of variables, branches, and threads). Therefore, tools must be highly efficient in order to handle practical programs.

Deductive Verification

Overview

Tools for deductive verification construct a formal proof that demonstrates that a given program satisfies its specification. Common ways of constructing the correctness proof are (1) to use a suitable calculus such as the weakest precondition calculus to compute verification conditions – logical formulas whose validity entails the correctness of the program – and then prove their validity in a theorem prover, or (2) to use symbolic execution to compute symbolic states for each path through the program and then use a theorem prover to check that the symbolic states satisfy the specification. Both approaches employ a formal semantics of the programming language. The specification to be verified typically includes implicit properties (such as deadlock freedom) as well as properties explicitly specified by the user (for instance through pre- and postconditions).

Deductive verifiers for concurrent programs apply various verification methodologies, which are illustrated by the Java example below. Monitor invariants (see entry ▶ [Monitors, Axiomatic Verification of](#)) allow one to express properties of the monitor variables (here, the fields in class `Account`) that hold when the monitor is not currently locked by any thread. For instance, one could express that the transaction count is a nonnegative number. Rely-guarantee reasoning [14] allows one to reason about the possible interference of other threads. For instance, one could prove that no thread ever decreases the transaction count. Deadlock freedom can be proved by establishing a partial order on locks and proving that each thread acquires locks in ascending order (see entry on ▶ [Deadlocks](#)). For instance, one could specify that the order on the locks associated with `Account` objects is given by the less-than order on the accounts' numbers. The check that locks are acquired in ascending order would fail for the example because the locks of `this` and `to` are acquired regardless of the order. Therefore, the concurrent execution of `x.transfer(y, a)` and `y.transfer(x, b)` might deadlock.

```
class Account {
    int number;
    int balance;
    int transactionCount;
```

```
void transfer(Account to, int amount) {
    if(this == to) return;
    acquire this;
    acquire to;
    balance = balance - amount;
    to.balance = to.balance + amount;
    transactionCount = transactionCount + 1;
    to.transactionCount = to.transactionCount + 1;
    release to;
    release this;
}

// constructors and other methods omitted
```

The absence of data races can be proved using a permission system that maintains an access permission for each shared variable. The permission gets created when the variable comes into existence; it can be transferred among threads and between threads and monitors, but not duplicated. Each shared variable access gives rise to a proof obligation that the current thread possesses the permission for that variable. Since access permissions cannot be duplicated, this scheme prevents data races. In the example above, one could store the permissions for `balance` and `transactionCount` in the monitor of their object. By acquiring the monitors for `this` and `to`, the current thread obtains those permissions and, therefore, is allowed to access the fields. When the monitors are released, the permissions are transferred back to the monitors. Such a permission system is for instance applied by concurrent separation logic [19].

An alternative technique for proving the absence of data races is through object ownership [12]. Ownership schemes associate zero or one owner with each object. An owner can be another object or a thread. A thread becomes the owner of an object by creating it or by locking its monitor. Each access to an object's field gives rise to a proof obligation that the object is (directly or transitively) owned by the current thread. Since an object has at most one owner, this scheme prevents data races.

Besides preventing data races, both permissions and ownership guarantee that the value of a variable does not change while a thread holds its permission or owns the object it belongs to. Therefore, they also give an atomicity guarantee, which allows verifiers to apply sequential reasoning techniques in order to prove additional program properties.

Discussion

Program verifiers are sound unless there is a flaw in the underlying logic or the implementation of the verifier.

In principle, program verification is complete if the underlying logic is complete with respect to the semantics of the programming language. However, program verifiers typically enforce some kind of verification methodology as described above. These methodologies simplify the verification of certain programs, but fail for others. For instance, a tool that requires lock ordering for deadlock prevention might not be able to handle programs that prevent deadlocks by other strategies. Another source of incompleteness are the limitations of theorem provers. Since the validity of verification conditions is in general undecidable, program verifiers based on automatic provers such as SMT solvers report spurious errors when the prover cannot confirm the validity of a verification condition.

A number of program verifiers support modular reasoning. For instance, a permission system removes the necessity to inspect the whole program in order to detect data races. Nevertheless, modular verification is still challenging for certain program properties such as global invariants and liveness properties.

Deductive program verifiers are typically not fully automatic. Users have to provide the specification the program is verified against. Even if the property to be proved is the absence of a simple error such as data races, users typically have to annotate the code with auxiliary assertions such as loop invariants. Moreover, interactive verifiers require users to guide the proof search.

The efficiency of automatic verifiers (those verifiers where the only user interaction is by writing annotations) depends on the number and complexity of the generated verification conditions as well as on the performance of the underlying automatic theorem prover. The former aspect is positively influenced by applying a modular verification methodology, the latter benefits from the enormous progress in the area of automatic theorem proving.

In summary, since program verifiers are sound and since modular verifiers scale well, they are well suited for software projects with the highest quality requirements, especially safety-critical software. However, the overhead of writing specifications as well as limitations of existing verification methodologies and automatic

theorem provers have so far prevented program verification from being applied routinely in mainstream software development.

Examples

Most verifiers for concurrent programs are in the stage of research prototypes. Microsoft's VCC is an automatic verifier for concurrent, low-level C code. It has been used to verify the virtualization layer Hyper-V. VCC applies a verification methodology based on ownership [7]. Permission systems are used by verifiers based on separation logic such as VeriFast for C programs [13], SmallfootRG [4], and Heap-Hop [24], as well as by Chalice [15]. Both Heap-Hop and Chalice support shared variable concurrency and message passing. Lock-free data structures have been verified using the interactive verifier KIV [22].

State Space Exploration

Overview

Software model checkers consider all possible states that may occur during the execution of a program. They check properties of individual states or sequences of states (traces) through an exhaustive search for a counterexample. This search is either performed by enumerating all possible states of a program execution (explicit state model checking) or by representing states through formulas in propositional logic (symbolic model checking). In both approaches, programs are regarded as transition systems whose transitions are described by a formal semantics of the programming language. The specifications to be checked are given as formulas in propositional logic for individual states (assertions) or as formulas in a temporal logic (typically LTL or CTL) for traces. The use of temporal logic allows model checkers in particular to check liveness properties such as “every request will eventually be handled.” Liveness properties are important for the correctness of all parallel programs, but especially for those based on message passing (such as MPI programs) because they often apply sophisticated protocols. Other errors such as deadlocks can be detected without giving an explicit specification. For instance for the account example above, a model checker detects that for some input values and thread interleavings, method transfer does not reach a valid terminal

state. The inputs and interleavings are then reported as a counterexample that can be inspected and replayed by the user.

The main limitation of software model checking is the so-called state space explosion problem. The state space of a program execution grows exponentially in the number of variables and the number of threads. Therefore, even small programs have a very large state space and require elaborate reduction techniques to be efficiently checkable. Partial order reduction reduces the number of relevant interleavings by identifying operations that are independent of actions of other threads (for instance, local variable access).

Abstraction is used to simplify the transition system before checking it. It is common that many aspects of a program execution are not relevant for a given property to be checked. For instance, the values of amount and balance in the `transfer` example are not relevant for the existence of a deadlock. Therefore, they can be abstracted away, which reduces the state space significantly. Yet another approach to reduce the state space is to limit the search to program executions with a small number of data objects, threads, or thread preemptions. Such limits compromise soundness, but practical experience shows that many concurrency errors may be detected with a small number of threads and preemptions. For instance, detecting the deadlock in method `transfer` requires only two `Account` objects, two threads, and one preemption.

Discussion

For finite transition systems (i.e., programs with a finite number of states such as programs with an upper bound on the number of threads, the number of dynamically allocated data objects, and the recursion depth, in particular, terminating programs), model checking is sound since all possible states and traces can be checked. However, some model checkers explore only a subset of the possible states of a program execution based on heuristics that are likely to detect errors; this approach trades efficiency for soundness.

Model checking for finite transition systems is in principle complete, although abstraction may lead to spurious errors. Counterexample-guided abstraction refinement [6] is a technique to recover completeness by using the counterexample traces of spurious errors to

iteratively refine the abstraction. In contrast to deductive verification, model checking is not limited by the expressiveness of a verification methodology. Model checkers are thus capable of analyzing arbitrary programs, including for instance optimistic concurrency, benevolent data races, and interlocked operations. In practice, software model checking can be inconclusive because the state space is too large, causing the model checker to abort.

Although there is work on compositional model checking, most model checkers are not modular because it is difficult to summarize temporal properties at module boundaries.

Model checking, including abstraction, is fully automatic. Users need to provide only the property to be checked. When the checking is not feasible with the available resources, users also need to manually simplify the program or provide upper limits on the number of objects, threads, etc.

Due to the large state space of programs (in particular of parallel programs and programs that manipulate large data structures) and the non-modularity of the approach, model checking is typically too slow to be applied routinely during software development (in contrast to type checking and similar static analyses). However, for control-intensive programs with rather small data structures such as device drivers or embedded software, model checking is an efficient and very effective verification technique.

Examples

Even though most software model checkers focus on sequential programs, there are a number of tools available that check concurrency errors. JavaPathFinder [25] is an explicit state model checker for concurrent Java programs that has been applied in industry and academia. It detects data races and deadlocks as well as violations of user-written assertions and LTL properties.

MAGIC [5] checks whether a labeled transition system is a safe abstraction of a C procedure. The C procedure may invoke other procedures which are themselves specified in terms of state machines, which enables compositional checking. MAGIC uses counterexample-guided abstraction refinement to reduce the state space of the system.

BLAST [11] finds data races in C programs. It combines counterexample-guided abstraction refinement and assume-guarantee reasoning to infer a suitable model for thread contexts, which results in a low rate of false positives.

The Zing tool [2] checks for data races, deadlocks, API usage rules, and other safety properties. Its distinctive features are the use of procedure summaries to make the model checking compositional and the use of Lipton's theory of reduction [16] to prune irrelevant thread interleavings.

CHESS [17] is a tool for systematically enumerating thread interleavings in order to find errors such as data races, deadlocks, and livelocks in Win32 DLLs and managed.NET code. The analysis is complete, that is, every error found by CHESS is possible in an execution of the program. CHESS uses preemption bounding, that is, limits the number of thread preemptions per program execution to reduce the state space. Modulo this preemption bound, CHESS is sound; all remaining errors require more preemptions than the bound. Soundness is achieved by capturing all sources of non-determinism, including memory model effects.

Model checkers for message-passing concurrency include for instance MPI-Spin [20], which check Promela models of MPI programs, and ISP [26], which operates directly on the MPI/C source code. Both tools detect deadlocks and assertion violations; MPI-Spin also checks liveness properties.

Static Program Analysis

Overview

Static analyzers compute static approximations of the possible behaviors of a program and then check properties of these approximations. Common forms of static analysis include, among others, data flow analysis and type systems. Both techniques are typically described formally as sets of inference rules that allow the analyzer to infer properties of execution states, for instance, the set of possible values of a variable. When annotations are given by the programmer, these rules are also used to check the annotations. Both data flow analysis and type systems have been applied extensively to detect concurrency errors.

Static data flow analyses typically apply the lockset algorithm to detect races. They compute the set of locks each thread holds when accessing any given variable. If for each variable the locksets of all threads are not disjoint then there is mutual exclusion on the variable accesses (see entry on Race Detection Techniques for details). In the example above, the static analysis would render the field accesses safe if it can show that for all accesses to `x.balance` and `x.transactionCount`, the executing thread holds at least the lock associated with the object `x`.

Static analyses detect atomicity violations using Lipton's theory [16]. Via a classification of operations into right and left movers, an analysis can show that a given code block is atomic, that is, any execution of the block is equivalent to an execution without interference from other threads. For this purpose, the analysis must show that variable accesses are both left and right movers, which amounts to showing the absence of data races. In the example, the conditional statement does not access any shared variable and is, thus, a both-mover. The `acquire` statements are right movers, the `release` statements are left movers, and the field accesses are both-movers provided that there are no data races. Consequently, the method is atomic.

Deadlocks can be detected by computing a static lock-order graph and checking this graph to be acyclic. A deadlock analysis would complain about the `transfer` example if it cannot rule out that two threads execute `transfer` concurrently with reversed arguments.

Most data flow analyses infer the information needed to check for concurrency errors. This also involves the computation of a whole range of additional program properties, which are required for these checks. For instance, the analyses require alias information in order to decide whether two expressions refer to the same object at run time. A may-alias analysis is for instance used for sound deadlock checking (to check whether two threads *potentially* compete for the same lock), whereas a must-alias analysis is required for sound race checking (to check whether two locksets *definitely* overlap). Another common auxiliary analysis is thread-escape analysis which distinguishes thread-local variables from shared variables; this is for instance useful to suppress warnings when accesses to thread-local variables are not guarded by any lock.

Discussion

Static analyses are in principle sound. However, many existing tools sacrifice soundness in favor of efficiency. For instance, several data race analyses omit a must-alias analysis, which is necessarily flow-sensitive, and, therefore, cannot check soundly whether two locksets overlap.

Static analyses are by nature incomplete since they over-approximate the possible executions of a program. Another source of incompleteness is that static analyses – much like deductive verification – check whether programs comply with a given methodology, such as lock-based synchronization or static lock ordering. Programs that do not comply might lead to false positives.

Whether or not a static analysis is modular depends mostly on the existence of program annotations. Most data flow analyses are whole-program analyses, but there exist a number of analyses that compute procedure summaries to enable modular checking. By contrast, type systems typically require annotations, which are then checked modularly.

Aside from annotations that may be required from programmers, static analyses are fully automatic. However, they often produce a large number of false positives, which need to be inspected manually or filtered aggressively (which may compromise soundness).

Static analyses are extremely efficient. Many static analyzers have been applied to programs consisting of hundreds of thousands or even millions of lines of code. This scale is orders of magnitudes larger than for deductive verification and model checking.

In summary, static analysis tools typically favor efficiency over soundness and completeness. This choice makes them ideal for finding errors in large applications, whereas deductive verification and model checking are more appropriate when strong correctness guarantees are needed.

Examples

Warlock [21], RacerX [8], and Relay [27] use the lock-set algorithm to detect data races in C programs. RacerX also computes a static lock-order graph to detect deadlocks. It uses various heuristics to improve the analysis results, for instance, to identify benign races. Relay is a modular analysis that limits the sources of unsoundness to four very specific sources, one of them being the syntactic filtering of warnings to reduce

the number of false positives. RacerX and Relay have been applied to millions of lines of code such as the Linux kernel.

Chord [18] is a context-sensitive, flow-insensitive race checker for Java that supports three common synchronization idioms: lexically scoped lock-based synchronization, fork/join, and wait/notify. Since Chord does not perform a must-alias analysis, it is not sound. Chord has been applied to hundreds of thousands of lines of code.

rccjava [9] uses a type system to check for data races in Java programs. The annotations required from the programmer include declarations of thread-local variables and of the locks that guard accesses to a shared variable. The type system has been extended to atomicity checking [10]. rccJava scales to hundreds of thousands of lines of code.

Bibliographic Notes and Further Reading

This entry focuses entirely on tools that detect concurrency errors present in programs. Two related areas are (1) tools that prevent concurrency errors during the construction of the program and (2) tools that detect concurrency errors in other artifacts.

Tools of the first kind support correctness by construction. Programs are typically constructed through a stepwise refinement of some high-level specification to executable code. Since the code is derived systematically from a formal specification, errors including concurrency errors are prevented. Interested readers may start from Abrial's book [1].

Tools of the second kind do not operate on programs but on other representations of software and hardware. Races and deadlocks may occur for instance also in workflow graphs; they can be detected by the

approaches described here, but also through Petri-net and graph algorithms [23]. Similarly, hardware can be verified not to contain concurrency errors such as deadlock [3], an area in which model checking has been applied with great success.

Fortran 90 and Its Successors

MICHAEL METCALF
Berlin, Germany

Definition

Fortran is a high-level programming language that is widely used in scientific programming in the physical sciences, engineering, and mathematics. The first version was developed by John Backus at IBM in the 1950s. Following an initial, rapid spread in its use, the language was standardized, first in 1966 and, after many intermediate standards, most recently in 2010. The language is a procedural, imperative, compiled language with a syntax well suited to a direct representation of mathematical formulae. Individual procedures may either be grouped into modules or compiled separately, allowing the convenient construction of very large programs and of subroutine libraries. Fortran contains features for array processing, abstract and polymorphic data types, and dynamic data structures. Compilers typically generate very efficient object code, allowing an optimal use of computing resources. Modern language provide extensive facilities for object-oriented and parallel programming. Earlier versions have relied on auxiliary standards to facilitate parallel programming.

Discussion

The Development of Fortran

Historical Fortran

Backus, at the end of 1953, began the development of the Fortran programming language (the name being an acronym derived from FORmula TRANslator), with the objective of producing a compiler that would generate efficient object code. The first version, known as FORTRAN I, contained early forms of constructs that have survived to the present day: simple and subscripted variables, the assignment statement, a DO-loop, mixed-mode arithmetic, and input/output (I/O) specifications. Many novel compiling techniques had to be developed.

Based on the experience with FORTRAN I, it was decided to introduce a new version, FORTRAN II, in 1958. The crucial differences between the two were the

introduction of subprograms, with their associated concept of shared data areas, and separate compilation.

In 1962, FORTRAN IV was released. It contained type statements, the logical IF statement, and the possibility to pass procedure names as arguments. In 1966, a standard for FORTRAN, based on FORTRAN IV, was published. This was the first programming language to achieve recognition as an American and subsequently international standard, and is now known as FORTRAN 66.

The permissiveness of the standards led to a proliferation of dialects and a new revision was published in 1978, becoming known as FORTRAN 77. It was adopted by the International Standards Organization (ISO) shortly afterwards. The new standard brought with it many new features, for instance the IF...THEN...ELSE construct, a character data type, and enhanced I/O facilities. Although only slowly adopted, this standard eventually gave Fortran a new lease of life that allowed it to maintain its position as the most widely used scientific programming language.

Modern Fortran

Fortran 90

Fortran's strength had always been in the area of numerical, scientific, engineering, and technical applications. In order that it be brought properly up to date, an American subcommittee, working as a development body for the ISO committee ISO/IEC JTC1/SC22/WG5 (or simply WG5), prepared a further standard, now known as Fortran 90. It was developed in the heyday of the supercomputer, when large-scale computations using vectorized codes were being carried out on machines like the Cray 1 and CDC Cyber 205, and the experience gained in this area was brought into the standardization process by representatives of computer hardware and software vendors, users, and academia. Thus, one of the main features of Fortran 90 was the array language, built on whole array operations and assignments, array sections, intrinsic procedures for arrays, and dynamic storage. It was designed with optimization in mind. Another was the notion of abstract data types, built on modules and module procedures, derived data types (structures), operator overloading and generic interfaces, together with pointers. Also important were new facilities for

numerical computation including a set of numeric inquiry functions, the parameterization of the intrinsic types, new control constructs (SELECT CASE and new forms of DO), internal and recursive procedures, optional and keyword arguments, improved I/O facilities, and new intrinsic procedures. The resulting language was a far more powerful tool than its predecessor and a safer and more reliable one too. Subsequent experience showed that Fortran 90 compilers detected errors far more frequently than previously, resulting in a faster development cycle. The array syntax in particular allowed compact code to be written, in itself an aid to safe programming. Fortran 90 was published by ISO in 1991.

Fortran 95

Following the publication of Fortran 90, the Fortran standards committees continued to operate, and decided on a strategy whereby a minor revision of Fortran 90 would be prepared, establishing a principle of having major and minor revisions alternating. At the same time, the High-Performance Fortran Forum (HPFF) was founded.

The HPFF was set up in an effort to define a set of extensions to Fortran such that it would be possible to write portable, single-threaded code when using parallel computers for handling problems involving large sets of data that can be represented by regular grids, allowing efficient implementations on SIMD (Single-Instruction-Multiple-Data) architectures. This version of Fortran was to be known as High Performance Fortran (HPF), and it was quickly decided, given its array features, that Fortran 90 should be its base language. Thus, the final form of HPF was of a superset of Fortran 90, the main extensions being in the form of directives. However, HPF included some new syntax too and, in order to avoid the development of divergent dialects of Fortran, it was agreed to include some of this new syntax into Fortran 95. Apart from this syntax, only a small number of other pressing but minor changes were made, and Fortran 95 was adopted as a formal standard in 1997. It is currently the most widely used version of Fortran.

Auxiliary Standards

With few exceptions, no Fortran standard up to and including Fortran 2003 included any feature intended

directly to facilitate parallel programming. Rather, this has had to be achieved through the intermediary of ad hoc industry standards, in particular HPF, MPI, OpenMP, and Posix Threads.

The HPF directives, already introduced, take the form of Fortran 90 comment lines that are recognized as directives only by an HPF processor. An example is

```
!HPF$ ALIGN WITH b :: a1, a2, a3
```

to align three conformable arrays with a fourth, thus ensuring locality of reference. Further directives allow, for instance, aligned arrays to be distributed over a set of processors.

MPI is a library specification for message passing. OpenMP supports multi-platform, shared-memory parallel programming and consists of a set of compiler directives, library routines, and environment variables that determine run-time behavior. Posix Threads is again a library specification, for multithreading.

In any event, outside Japan, HPF met with little success, whereas the use of MPI and OpenMP has become widespread.

Fortran 2003

The following language standard, Fortran 2003, was published in 2004. Its main features were: the handling of floating-point exceptions, based on the IEEE model of floating-point arithmetic; allowing allocatable arrays as structure components, dummy arguments, and function results; interoperability with C; parameterized data types; object-orientation via constructors/destructors, inheritance, and polymorphism; derived type I/O; asynchronous I/O; and procedure variables. Although all this all represented a major upgrade, especially given the introduction of object-oriented programming, there was no new development specifically related to parallel programming.

Fortran 2008

Notwithstanding the fact that Fortran 2003-conformant compilers had been very slow to appear, the standardization committees thought fit to proceed with yet another standard, Fortran 2008. In contrast to the previous one, its single most important new feature is directly related to parallel processing – the addition of coarray handling facilities. Further, the DO CONCURRENT form of loop control and the CONTIGUOUS attribute

are introduced. These are further described below. Other major new features include: sub-modules, enhanced access to data objects, enhancements to I/O and to execution control, and more intrinsic procedures, in particular for bit processing. Fortran 2008 was published in 2010.

Selected Fortran Features

Given that all the actively supported Fortran compilers on the market offer at least the whole of Fortran 95, that version is the one used as the basis of the descriptions in this section, except where otherwise stated. Only those features are described that are relevant to vectorization or parallelization. Under Fortran 95, achieving effective parallelization requires the exploitation of a combination of efficient Fortran serial execution on individual processors with, say, MPI, controlling the communication between processors.

The DO Constructs

Many iterative calculations can be carried out in the form of a DO construct. A simplified but sufficient nested form is illustrated by:

```
outer: DO
inner:   DO i = j, k, m ! from j to
           ! k in steps of m
           ! (m is optional)
           :
           IF (...) CYCLE ! take
           ! next iteration of
           ! construct 'inner'
           :
           IF (...) EXIT outer ! exit
           ! the construct 'outer'
         END DO inner
      END DO outer
```

(The Fortran language is case insensitive; however, to enhance the clarity of the code examples, Fortran keywords are distinguished by being written in upper case.) As shown, the constructs may be optionally named so that any EXIT or CYCLE statement may specify which loop is intended.

Potential data dependencies between the iterations of a DO construct can inhibit optimization, including vectorization. To alleviate this problem, Fortran 2008 introduces the DO CONCURRENT form of the DO construct, as in

```
DO CONCURRENT (i = 1:m)
  a(k + i) = a(k + i) + scale * a(n + i)
END DO
```

that asserts that there is no overlap between the range of values accessed (on the right-hand side of the assignment) and the range of values altered (on the left-hand side). The individual iterations are thus independent.

Array Handling

Array Variables

Arrays are variables in their own right; typically they are specified using the DIMENSION attribute. Every array is characterized by its type, rank (dimensionality), and shape (defined by the extents of each dimension). The lower bound of each dimension is by default 1, but arbitrary bounds can be explicitly specified. The DIMENSION keyword is optional; if omitted, the array shape must be specified after the array-variable name. The examples

```
REAL :: x(100)
INTEGER, DIMENSION(0:1000, -100:100) :: plane
```

declare two arrays: x is rank-1 and plane is rank-2. Fortran arrays are stored with elements in column-major order. Elements of arrays are referenced using subscripts, for example,

```
x(n) x(i*j)
```

Array elements are scalar. The subscripts may be any scalar integer expression.

A section is a part of an array variable, referenced using subscript ranges, and is itself an array:

x(i:j)	! rank one
plane(i:j, k:l:m)	! rank two
x(plane(7, k:l))	! vector subscript zero
x(5:4)	! zero length

Array-valued constants and variables (array constructors) are available, enclosed in (/ ... /) or, in Fortran 2003, in square brackets, []:

```
(/ 1, 2, 3, 4, 5 /)
(/ ( / 1, 2, 3 /), i = 1, 10) /
(/ (i, i = 1, limit, 2) /)
[ (0, i = 1, 1000) ]
[ (0.01*i, i = 1, 100) ]
```

They may make use of an implied-DO loop notation, as shown, and can be freely used in expressions and assignments.

A derived data type may contain array components. Given

```
TYPE point
    REAL, DIMENSION(3) :: vertex
END TYPE point
TYPE(point), DIMENSION(10) :: points
TYPE(point), DIMENSION(10, 10):: &
    points_array
```

`points(2)` is a scalar (a structure) and `points(2)%vertex` is an array component of a scalar. A reference like `points_array(n, 2)` is an element (a scalar) of type `point`. However, `points_array(n, 2)%vertex(2)` is an array of type `real`, and `points_array(n, 2)%vertex(2)` is a scalar element of it. An array element always has a subscript or subscripts qualifying at least the last name. Arrays of arrays are not allowed.

The general form of subscripts for an array section is

`[lower] : [upper] [:stride]`

where `[]` indicates an optional item. Examples for an array `x(10, 100)` are

```
x(i, 1:n)          ! part of one row
x(1:m, j)          ! part of one column
x(i, :)            ! whole row i
x(i, 1::3)          ! every third
                   ! element of row i
x(i, 100:1:-1)     ! row i in reverse
                   ! order
x((/1, 7, 3/), 10) ! vector
                   ! subscript
x(:, 1:7)          ! rank-2 section
```

A given value in an array can be referenced both as an element and as a section:

```
x(1, 1)      ! scalar (rank zero)
x(1:1, 1)    ! array section (rank one)
```

depending on the circumstances or requirements.

Operations and Assignments

As long as they are of the same shape (conformable), scalar operations and assignments are extended to arrays on an element-by-element basis. For example, given declarations of

```
REAL, DIMENSION(10, 20) :: x, y, z
REAL, DIMENSION(5)      :: a, b
```

it can be written:

```
x = y           ! whole array
z = x/y         ! assignment
                ! whole array
                ! division and
                ! assignment
z = 10.0        ! whole array
                ! assignment of
                ! scalar value
b = a + 1.3    ! whole
                ! array addition
                ! to scalar value
b = 7/a + x(1:5, 5) ! array
                    ! division, and
                    ! addition to
                    ! section
z(1:8, 5:10) = x(2:9, 5:10) + &
               z(1:8, 15:20)
                    ! array section
                    ! addition
                    ! and assignment
a(2:5) = a(1:4) ! overlapping
                  ! section
                  ! assignment
```

An array of zero size is a legitimate object, and is handled without the need for special coding.

Elemental Procedures

In an assignment like

```
y = SQRT(x)
```

an intrinsic function, `SQRT`, returns an array-valued result for an array-valued argument. It is an elemental procedure.

Elemental procedures may be called with scalar or array actual arguments. The procedure is applied to array arguments as though there were a reference for each element. In the case of a function, the shape of the result is the shape of the array arguments.

Most intrinsic functions are elemental and Fortran 95 extended this feature to non-intrinsic procedures. It is a further aid to optimization on parallel processors. An elemental procedure requires the `ELEMENTAL` attribute and must be pure (i.e., have no side effects, see below).

Array-Valued Functions and Arguments

Users can write functions that are array valued; they require an explicit interface and are usually placed in a module. This example shows such a module function, accessed by a main program:

```
MODULE show
CONTAINS
  FUNCTION func(s, t)
    REAL, DIMENSION(:) :: s, t
    ! An assumed-shape
    ! array, see below
    REAL, DIMENSION(SIZE(s)) :: func
    func = s * t**2
  END FUNCTION func
END MODULE show

PROGRAM example
USE show
REAL, DIMENSION(3)
  :: x = (/ 1., 2., 3./),           &
        y = (/ 3., 2., 1. /), s
  s = func(x, y)
  PRINT *, s
END PROGRAM example
```

In order to allow for optimization, especially on parallel and vector machines, the order of expression evaluation in executable statements is not specified. However, some potential optimizations might be lost if it is not certain that an array is in contiguous storage; for instance, if the array is an assumed-shape dummy argument array or a pointer array. In Fortran 2008, it is open to a programmer to assert that an array is contiguous by adding the CONTIGUOUS attribute to its specification, as in

```
REAL, CONTIGUOUS, DIMENSION(:, :) :: x
```

The many intrinsic functions that accept array-valued arguments should be regarded as an integral part of the array language. A brief summary of their categories appears in [Table 1](#).

Assumed-Shaped Arrays

Given an actual argument in a procedure reference, as in:

```
REAL, DIMENSION(0:10, 0:20) :: x
:
CALL calc(x)
```

Fortran 90 and Its Successors. Table 1 Classes of intrinsic procedures, with examples

Class of intrinsic array function	Examples
Numeric	abs, modulo
Mathematical	acos, log
Floating-point manipulation	exponent, scale
Vector and matrix multiply	dot_product, matmul
Array reduction	maxval, sum
Array inquiry	allocated, size
Array manipulation	cshift, eoshift
Array location	maxloc, minloc
Array construction	merge, pack
Array reshape	reshape

the corresponding dummy argument specification must define the type and rank of the array, but it may omit the shape. Thus in

```
SUBROUTINE calc(d)
REAL, DIMENSION(:, :) :: d
```

it is as if d were dimensioned (11, 21). The shape, not the bounds, is passed, meaning that the default lower bound is 1 and the default upper bound is the corresponding extent. However, any lower bound can be specified and the array maps accordingly. Assumed-shape arrays allow great flexibility in array argument passing.

Automatic Arrays

Automatic arrays are useful for defining local, temporary work space in procedures, as in

```
SUBROUTINE exchange(x, y)
  REAL, DIMENSION(:)          :: x, y
  REAL, DIMENSION(SIZE(x))   :: work
  work = x
  x = y
  y = work
END SUBROUTINE exchange
```

Here, the array work is created on entering the procedure and destroyed on leaving. The actual storage is typically maintained on a stack.

Allocatable Arrays

Fortran provides dynamic allocation of storage, commonly implemented using a heap storage mechanism.

An example, for establishing a work array for a whole program, is

```
MODULE global
  INTEGER :: n
  REAL, DIMENSION(:, :, ), ALLOCATABLE :: &
    work
END MODULE global
PROGRAM analysis
  USE global
  READ (*, *) n
  ALLOCATE(work(n, 2*n), STAT=status)
  :
  DEALLOCATE (work)
```

The work array can be propagated throughout the whole program via a USE statement in each program unit. An explicit lower bound may be specified and several entities may be allocated in one statement. Deallocation of arrays is automatic when they go out of scope.

Masked Assignment

Often, there is a need to mask an assignment. This can be done using either a WHERE statement:

```
WHERE (x /= 0.0) x = 1.0/x
```

an example that avoids division by zero by replacing only non-zero values by their reciprocals, or a WHERE construct:

```
WHERE (x /= 0.0)
  x = 1.0/x
  y = 0.0 ! all arrays assumed
        conformable
ELSEWHERE
  x = HUGE(0.)
  y = 1.0 - y
END WHERE
```

The ELSEWHERE statement may also have a mask clause, but at most one ELSEWHERE statement can be without a mask, and that must be the final one; WHERE constructs may be nested within one another.

The FORALL Statement and Construct

When a DO construct is executed, each successive iteration is performed in order and one after the other – an impediment to optimization on a parallel processor. To help in this situation, Fortran 95 introduced the

FORALL statement and construct, which can be considered as an array assignment expressed with the help of indices. An example is

```
FORALL(i = 1:n) x(i, i) = s(i)
```

where the individual assignments may be carried out in any order, and even simultaneously. In

```
FORALL(i=1:n, j=1:n, y(i,j)/=0.)
  x(j,i) = 1.0/y(i,j)
```

the assignment is subject also to a masking condition.

The FORALL construct allows several assignment statements to be executed in order, as in

```
FORALL(i = 2:n-1, j = 2:n-1)
  x(i,j) = x(i,j-1) + x(i,j+1)
  + x(i-1,j) + x(i+1,j)
  y(i,j) = x(i,j)
END FORALL
```

Assignment in a FORALL is like an array assignment: it is as if all the expressions were evaluated in any order, held in temporary storage, then all the assignments performed in any order. The first statement in a construct must fully complete before the second can begin. Procedures referenced within a FORALL must be pure (see below).

In general, the FORALL has been poorly implemented and the DO CONCURRENT is seen as a better alternative: using DO CONCURRENT requires the programmer to ensure that the iterations are independent, whereas, with FORALL, the compiler is expected to determine whether a temporary copy is needed, which is often unrealistic.

Pure Procedures

This is another Fortran 95 feature expressly for parallel computing, ensuring that execution of a procedure referenced from within a FORALL statement or construct (or, in Fortran 2008, from within a DO CONCURRENT construct) cannot have any side effects (whereby the result of one reference could cause a change to the result of another). Any such side effects in a function could impede optimization on a parallel processor – the order of execution of the assignments could affect the results. To control this situation, a PURE keyword may be added to the SUBROUTINE or FUNCTION statement – an assertion that the procedure: alters no global variable;

performs no input/output operations; has no saved variables; and, in the case of functions, alters no argument. These constraints are designed such that they can be verified by a compiler.

All the intrinsic functions are pure.

The FORALL statement and construct and the PURE keyword were adopted from HPF.

Coarrays (Fortran 2008 Only)

The objective of coarrays is to distribute over some number of processors not only *data*, as in an SIMD model, but also *work*, using the SPMD (Single-Program-Multiple-Data) model. The syntax required to implement this facility has been designed to make the smallest possible impact on the appearance of a program and to require a programmer to learn just a modest set of new rules.

Data distribution is achieved by specifying the relationship among memory images using an elegant new syntax similar to conventional Fortran. Any object *not* declared using this syntax exists independently in all the images and can be accessed only from within its own image. Objects specified *with* the syntax have the additional property that they can be accessed directly from any other image. Thus, the statement

```
REAL, DIMENSION(1024)[*] :: a, b
```

specifies two coarrays, a and b, that have the same size (1024) in each image. Execution by an image of the statement

```
a(:) = b(:, [j])
```

causes the array b from image j to be copied into its own array a, where square brackets are the notation used to access an object on another image. On a shared-memory machine, an implementation of a coarray might be as an array of a higher dimension. On a distributed-memory machine with one physical processor per image, a coarray is likely to be stored at the same address in each physical processor.

Work is distributed according to the concept of *images*, which are copies of the program that each have a separate set of data objects and a separate flow of control. The number of images is normally chosen on the command line, and its fixed value is available at execution time via an inquiry function, NUM_IMAGES. The images execute asynchronously and the execution

path in each may differ, possibly under the control of an image index to which the programmer has access (via the THIS_IMAGE function). When synchronization between two images is required, use can be made of a set of intrinsic synchronization procedures, such as SYNCH_ALL or LOCK. Thus, it is possible in particular to avoid race conditions whereby one image alters a value still required by another, or one image requires an altered value that is not yet available from another. Handling this is the responsibility of the programmer. Between synchronization points, an image has no access to the fresh state of any other image. Flushing of temporary memory, caches, or registers is normally handled implicitly by the synchronization mechanisms themselves. In this way, a compiler can safely take advantage of all code optimizations on all processors between synchronization points without compromising data integrity.

Where it might be necessary to limit execution of a code section to just one image at a time, a critical section may be defined using a CRITICAL ... END CRITICAL construct.

The codimensions of a coarray are specified in a similar way to the specifications of assumed-size arrays, and coarray sub-objects may be referenced in a similar way to sub-objects of normal arrays.

The following example shows how coarrays might be used to read values in one image and distribute them to all the others:

```
REAL :: val[*]
...
IF (THIS_IMAGE() == 1) THEN
  ! Only image 1 executes this construct
  READ(*, *) val
  DO image = 2, NUM_IMAGES()
    val[image] = val
  END DO
END IF
CALL SYNC_ALL()
  ! Execution on all images
  ! pauses here until all
  ! images reach this point
```

Coarrays can be used in most of the ways that normal arrays can. The most notable restrictions are that they cannot be automatic arrays, cannot be used for a function result, cannot have the POINTER attribute, and cannot appear in a pure or elemental procedure.

Bibliographic Notes and Further Reading

The development of Fortran 90 was very contentious and the entire issue of the journal [2] is devoted to its various aspects.

Fortran 2003, is defined in the ISO publication [3]. Fortran 2008 was published in 2010 as [4]. Fortran 95 and Fortran 2003 are informally but completely described in [1] and [5] and, with the latest additions contained in Fortran 2008, in [6].

Coarrays have evolved from a programming model initially intended for the Cray-T3D. They were extended to Fortran 90 by Numrich and Steidel [7] and subsequently defined for Fortran 95 by Numrich and Reid [8]. Their formal definition is in the Fortran 2008 standard [4] and they are described informally also in [6].

Definition

Fortress is a programming language designed to support parallel computing for scientific applications at scales ranging from multicore desktops and laptops to petascale supercomputers. Its generality and features for user extension also make it a useful framework for experimental design of domain-specific languages. The project originated at Sun Microsystems Laboratories in 2003 as part of their work on the DARPA HPCS (High Productivity Computing Systems) program [6] and became an open-source project in 2007.

Discussion

Design Principles

Fortress provides the programmer with a single global address space, an automatically managed heap, and automatically managed thread parallelism. Programs can also spawn threads explicitly.

The three major design principles for Fortress are:

- **Mathematical syntax:** Fortress syntax is inspired by mathematical tradition, using the full Unicode character set and two-dimensional notation where relevant. The goal is to simplify the desk-checking of code against what working scientists and mathematicians tend to write in their notebooks or on their whiteboards.
- **Parallelism by default:** Rather than grafting parallel features onto a sequential language design, Fortress

uses parallelism wherever possible and reasonable. The design intentionally makes sequential idioms a little more verbose than parallel idioms, and intentionally makes side effects a little more verbose than “pure” (side effect free) code.

- **A growable language [7]:** As few features as possible are built into the compiler, and as many language design decisions as possible are expressed at the source-code level. In many ways, Fortress is a framework for constructing domain-specific languages, and while the first such language is aimed at scientific programmers, the intent is that radically different design choices can also be supported.

Fortress is a strongly typed language. The type system is object oriented, with parameterized polymorphic types but also with type inference so that programmers frequently need not declare the types of bound variables explicitly. The objects enjoy multiple inheritance of code but not of data fields. A Fortress *trait* is much like an interface in the Java™ programming language but can contain concrete implementations of methods that can be inherited. A Fortress *object* can declare data fields and in other respects is also much like a Java class, but a Fortress object can extend (and therefore inherit from) only traits, not other objects. Methods may be overloaded; overload resolution is performed by multimethod dispatch using the dynamic types of *all* arguments. (In contrast, the Java programming language uses the dynamic type of the invocation target “before the dot” but the static types of the arguments in parentheses.)

Fortress supports and favors the use of pure, functional object-oriented programming, but also supports side effects, including assignment to variables and to fields of objects that have been declared mutable. Atomic blocks are used to manage the synchronization of side effects.

Fortress also favors divide-and-conquer approaches to parallelism (as opposed to, say, pipelining); *generators* split aggregate data structures and numeric ranges into portions that can be processed in parallel, and *reducers* combine or aggregate the results for further processing. Generators and reducers are classified according to their algebraic properties, such as associativity and commutativity; this classification is expressed through,

and enforced by, specific traits defined by a standard library, enabling a generator to choose from a variety of implementation strategies.

Salient Features

Syntax

Fortress syntax is designed to resemble standard mathematical notation as much as possible while integrating programming-language notions of variable binding, assignment, and control structures. All mathematical operator symbols in the Unicode character set [8], such as $\odot \oplus \otimes \leq \geq \cap \cup \sqcap \sqcup \subseteq \subseteq \prec \succ \sum \prod$, may be defined and overloaded as user-defined infix, prefix, and postfix operators; a large number of bracketing symbols such as $\{ \} \langle \rangle \lceil \rceil \lfloor \rfloor \ll \gg$ are likewise available for library or user (re-)definition. Relational operators may be chained, as in $1 \leq n \leq 10$; the compiler treats it as if it had been written $(1 \leq n) \wedge (n \leq 10)$ but arranges to evaluate the expression n just once. Simple juxtaposition is itself a binary operator that can be defined and overloaded by Fortress source code; the standard library defines juxtaposition to perform function application (as in $f(x,y)$ or $print x$), numerical multiplication (as in $3n$ and $5x^2y$), and string concatenation (as in “My name is” $myName$ “.”).

Unicode characters may be used directly or represented in ASCII through a Wiki-inspired syntax that is reasonably readable in itself. Fortress also provides concise syntax to mimic mathematical notation: semicolons and parentheses may often be omitted, and curly braces $\{ \}$ denote sets (rather than blocks of statements). The notation is whitespace sensitive but not indentation sensitive. Fortress is expression oriented, and it favors the use of immutable bindings over mutable variables, requiring a slightly more verbose syntax for declaration of mutable variables and for assignment.

The left-hand side of Fig. 1 shows a sample Fortress function that performs a matrix/vector “conjugate gradient” calculation (based on the NAS “CG” conjugate gradient benchmark for parallel algorithms) [4]. The function *conjGrad* takes a matrix and a vector, performs a number of calculations, and returns two values: a result vector and a measure of the numerical error. The right-hand side of Fig. 1 presents the original

<pre> conjGrad[E extends Number, nat N, V extends Vector[E,N], M extends Matrix[E,N,N]] (A : M, x : V) : (V,E) = do z : V := 0 r : V := x ρ : E := r·r p : V := r for j ← seq(1 # 25) do q = A p α = ρ/(p·q) z += α p ρ₀ = ρ r -= α q ρ := r·r β = ρ/ρ₀ p := r + β p end (z, \ x - A z\) end </pre>	$ \begin{aligned} z &= 0 \\ r &= x \\ \rho &= r^T r \\ p &= r \\ \text{DO } i &= 1, 25 \\ q &= A p \\ \alpha &= \rho / (p^T q) \\ z &= z + \alpha p \\ \rho_0 &= \rho \\ r &= r - \alpha q \\ \rho &= r^T r \\ \beta &= \rho / \rho_0 \\ p &= r + \beta p \\ \text{ENDDO} \\ \text{compute residual norm explicitly:} \\ \ r\ &= \ x - A z\ \end{aligned} $
--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Fortress (Sun HPCS Language). Fig. 1 Sample Fortress code for a conjugate gradient calculation (left) and the original NAS CG pseudocode specification (right)

specification of the conjugate gradient calculation to show how the Fortress program resembles the problem specification. The principal differences are that the Fortress code provides type declarations – including a generic (type-parametric) function header – and distinguishes between binding and assignment of variables (within the loop body, q and α and ρ_0 are read-only variables that are locally bound using $=$ syntax, whereas z and r and ρ and p are mutable variables that are updated by the assignment operator $:=$ and the compound assignment operators $+=$ and $-=$).

Fortress is designed to grow over time to accommodate the changing needs of its users via a syntactic abstraction mechanism [3] that, in effect, allows source-code declarations to augment the language grammar by specifying rewriting rules for new language constructs. Parsing of new constructs is done alongside parsing of primitive constructs, allowing programmers to detect syntax errors in use sites of new constructs early. Programs in domain-specific languages can be embedded in Fortress programs and parsed as part of their host programs. Moreover, the definition of many constructs

that are traditionally defined as core language primitives (such as `for` loops) can be moved into Fortress' own libraries, thereby reducing the size of the core language.

Type System

Fortress has a rich type system designed to give programmers the expressive power they need to write libraries that provide features often built into other languages. The Fortress type system is a trait-based, object-oriented system that supports parametrically polymorphic named types (also known as *generic traits*) organized as a multiple-inheritance hierarchy. Fortress code is statically type-checked: it is a static (“compile-time”) error if the type of an expression is not a subtype of the type required by its context.

Objects may be declared to extend traits, from which they can inherit method declarations and definitions. If an object inherits an abstract method declaration, then it has the obligation to provide (or inherit) a concrete implementation of that method. A trait may also extend one or more other traits. Extension creates a subtype relationship; if type A extends type B , then every

object belonging to type A (that is, every *instance* of A) necessarily also belongs to type B .

In addition to subtyping, Fortress allows the declaration of *exclusion* and *comprises* relationships among types. If type A excludes type B , then no value can be an instance of both A and B . If a type T comprises a set of types $\{U_1, U_2, \dots, U_n\}$, then every instance of T is an instance of some U_i (possibly more than one). This allows a more flexible description of important relationships among types than simply the ability to declare that a class is *final*.

Types, values, and expressions Fortress provides several kinds of types, including *trait types*, *tuple types*, *arrow types*. At the top of the type hierarchy is the type *Any*, which comprises three types, *Object*, *Tuple*, and $()$ (pronounced “void”); at the bottom of the hierarchy is the type *BottomType*. Every expression in Fortress has a *static type*. Every value in Fortress is either an *object*, a *tuple*, or the value $()$, and has a (*run-time*) *tag*, or *ilk*, which is a “leaf” in the type hierarchy: the only strict subtype of a value’s tag is *BottomType*. Fortress guarantees that when an expression is evaluated, the *ilk* of the resulting value is a subtype of the type of the expression.

Traits Like an interface in the Java programming language, a *trait* is named program construct that declares a set of *methods*, and which may *extend* one or more other traits, inheriting their methods. However, unlike Java interfaces, whose methods are always abstract (i.e., they do not provide bodies), the methods of Fortress traits may be either *abstract* or *concrete* (having bodies). Like functions, methods may be *overloaded*, and a call to such a method is resolved using the run-time tags of its arguments.

Objects Objects form the leaves of the trait hierarchy: no trait may extend an object trait type. Thus object declarations are analogous to `final` classes in the Java programming language. In addition to methods, *objects* may have *fields*, in which state may be stored.

Numbers and booleans and characters are all objects. This does not imply that they are always heap-allocated. Objects declared with the `value` keyword have no object identity, must have only immutable fields, and may be freely copied by the implementation.

Tuples A tuple is written as a comma-separated series of expressions within parentheses, for example, $(a, 3, b + 7)$; they are convenient for passing multiple arguments and for returning multiple results. Tuples are first-class values but are not objects. Tuple types are covariant: if type A extends type B , and C extends D , and E extends F , then the tuple type (A, C, E) extends the tuple type (B, D, F) . The type of a variable, of a field, or of array elements may be a tuple type. Tuples of variables may appear on the left-hand side of binding and assignment constructs.

Functions and Methods Functions are also first-class values, and furthermore, they are objects. However, their types are not traits, but *arrow types*, constructed from other types using the arrow combinator \rightarrow . A function that is declared to return an instance of type B whenever it is passed an instance of type A as an argument is an instance of the arrow type $A \rightarrow B$. Because a function can be overloaded, having multiple definitions with different parameter types, it can be an instance of several different arrow types (Fig. 2). Because arrow types are covariant in their return types and contravariant in their parameter types, every arrow type is a subtype of $\text{BottomType} \rightarrow \text{Any}$ and a supertype of $\text{Any} \rightarrow \text{BottomType}$.

Fortress provides two kinds of methods that may be declared in objects and traits: *dotted methods*, which are similar to methods in other object-oriented languages and are invoked using the syntax `target.methodName(arguments)`, and *functional methods*, which are overloadings of global function names and therefore are invoked using the syntax `methodName(arguments)`, but one of the arguments is treated as the `target` just as for a dotted method (Fig. 3).

Ignoring the possibility of automatic coercion, a function declaration is applicable to a call to that function if its parameter type is a supertype of (possibly equal to) the run-time tag of the argument, and it is more specific than another declaration if its parameter type is a strict subtype of the parameter type of the other. (If a declaration of a function or method takes more than one argument, then its “parameter type” (singular) is considered to be a tuple type.)

The Java programming language allows any set of overloaded method declarations, resolves overloading based on the static types of the arguments and the

```
(* The function pad is an instance of the arrow type String → String and also of the arrow type  $\mathbb{Z}32 \rightarrow \mathbb{Z}64$ ,  
neither of which is a subtype of the other. *)  
pad(x: String) : String = " " x  
pad(y:  $\mathbb{Z}32$ ) :  $\mathbb{Z}64$  = y  
(* Arrow types can include the types of exceptions that can be thrown. The function pad' in  
an instance of the arrow type String → String throws EmptyString and also of the arrow type  
 $\mathbb{Z}32 \rightarrow \mathbb{Z}64$  throws ZeroNumber. *)  
pad'(x: String) : String throws EmptyString =  
  if x = "" then throw EmptyString else " " x " " end  
pad'(y:  $\mathbb{Z}32$ ) :  $\mathbb{Z}64$  throws ZeroNumber =  
  if y = 0 then throw ZeroNumber else y end
```

Fortress (Sun HPCS Language). Fig. 2 Two examples of a function that belongs to more than one arrow type

```
(* This example object has one field, v, and four method definitions. The method add is a conventional  
"dotted method"; the method name maximum is overloaded with three functional method definitions.  
The parameter self indicates that a method is a functional method that is invoked using functional  
rather than dot syntax. *)  
  
object Example(v:  $\mathbb{Z}32$ )  
  add(n:  $\mathbb{Z}32$ ) = n + v                                ④ Dotted method (no self parameter)  
  maximum(self, n:  $\mathbb{Z}32$ ) =  
    if n > v then n else v end  
  maximum(n:  $\mathbb{Z}32$ , self) =  
    maximum(self, n)  
  maximum(self, other: Example) =  
    maximum(self, other.v)  
end  
  
do  
  o = Example(5)  
  p = Example(6)  
  ④ Examples of method invocation  
  println o.add(7)          ④ Prints "12"  
  println p.add(7)          ④ Prints "13"  
  println maximum(o, 3)      ④ Prints "5"  
  println maximum(7, o)      ④ Prints "7"  
  println maximum(o, p)      ④ Prints "6"  
end
```

Fortress (Sun HPCS Language). Fig. 3 Example definition of a dynamically parameterized object

dynamic type of the target, and requires this resolution be unambiguous for calls that actually appear in the program (i.e., ambiguity is separately checked at every call site). In contrast, when a call to an overloaded Fortress function or method is executed, the most specific applicable declaration is selected based on the tags of the arguments passed to the function; that is, Fortress performs full multimethod dynamic dispatch on the target and all arguments. Furthermore, Fortress imposes rules on the set of overloaded declarations so that dispatch is always unambiguous (i.e., ambiguity is checked for each set of declarations and no separate check is needed at each call site). In particular, any pair of declarations of overloaded functions or method must satisfy one of three conditions:

Subtype rule: The parameter type of one declaration is a strict subtype of the parameter type of the other, and the return type of the first declaration is a subtype of (possibly the same as) the return type of the second declaration.

Exclusion rule: The parameter types of the two declarations exclude each other.

Meet rule: The parameter types of the two declarations are incomparable (there is neither a subtype nor an exclusion relationship between them) and there is another declaration of that function whose parameter type “covers” the intersection of the parameter types of the two incomparable declarations.

If all pairs of declarations satisfy one of these conditions, there can be no ambiguity for any particular call to that function or method: in the first case, one declaration is more specific than the other; in the second case, there is no call to which both declarations are applicable; and in the third case, whenever both declarations are applicable, there is another declaration that is more specific than both that is also applicable, so neither of the two incomparable declarations can be the most specific applicable declaration. These rules are how the design of Fortress solves the problem of multiple inheritance of methods.

Access to fields of objects is abstract: the field access syntax `x.fieldName` actually invokes a `getter` method that takes no arguments but returns a value. Declaring a field by default provides a trivial `getter` method that simply fetches the contents of the field, but this method can be suppressed or displaced by

an explicit `getter` declaration. Similarly, the assignment operator `:=` actually invokes a `setter` method, and the declaration of a mutable field by default provides a trivial `setter` method. In this manner, the behavior of field access and assignment is completely programmable.

Parametric polymorphism (or Generic types and functions) Fortress supports *generic traits* (and objects), as well as generic functions (and methods). All these entities can have static parameters of various kinds: type parameters (for which any type can serve as an actual argument), `nat` and `int` and `bool` parameters (for which static arithmetic and Boolean expressions can serve as actual arguments), `unit` and `dim` parameters (for which declared physical dimensions and units can serve as actual arguments), and `opr` parameters (for which operator symbols can serve as actual arguments).

Type parameters may be given one or more bounds, thereby requiring that they be instantiated only with subtypes of all the bounds. If no bound is given, it is implicitly assumed to be bound by `Object`. Note that `Object` is not the root of the Fortress type hierarchy; a type parameter that may be instantiated with a tuple type, for example, must be given an explicit bound (Fig. 4). This unusual default for the bounds of type parameters helps to reduce confusion when functions and methods are overloaded with different numbers of parameters.

The Java programming language has a system of generic types that *erases* type parameter information at run time. In contrast, Fortress types are *not* erased, and it is possible to perform the equivalent of an `instanceof` check to distinguish a list of strings from a list of booleans. Thus, there is no significant disparity between the static type system and the run-time tags associated with Fortress values: tags are simply a special class of types corresponding to leaves in the type hierarchy.

In addition to standard parametric polymorphism, Fortress provides `where` clauses, in which *hidden* type variables can be declared and used within a trait (or object) or function declaration; they are called “hidden” because they are not static parameters of the trait or function – rather, they are universally quantified within their declared bounds.

```
(* The trait LinkedList can contain elements of type T. Because the declared bound on the type T is Any, the
actual element type may be a tuple type. Because of the comprises clause, only instances of the object
types Cons[T] and Empty can be instances of LinkedList[T]. *)
```

```
trait LinkedList[T extends Any] comprises { Cons[T], Empty } end
```

```
(* A Cons instance has two fields, first and rest. This object declaration implicitly declares a constructor
function called Cons that takes two arguments and creates a new instance with its two fields initialized to
the given arguments. *)
```

```
object Cons[T extends Any](first : T, rest : List[T]) extends LinkedList[T] end
```

```
@ The single object Empty belongs to all LinkedList types.
```

```
object Empty extends LinkedList[T] where { T extends Any } end
```

Fortress (Sun HPCS Language). Fig. 4 Example definitions of a statically parameterized trait and two objects that implement it

Having to write out all static type arguments and complete type signatures for all functions and methods, especially local “helper” functions, can be tedious, and often results in code that is difficult to read and maintain. To mitigate these problems, Fortress (like ML and Haskell) has a type-inference mechanism that allows many types and static parameters to be elided in practice.

Coercion A trait T may contain one or more *coercion* declarations; such a declaration specifies a computation that, when given any instance of another type U , will return a corresponding instance of type T . Such declarations should be used with care, only in situations where it is desirable that *every* instance of type U also be regarded as, in effect, an instance of type T in every computational context whatsoever. Typically this is used to convert among specialized numerical representations, and in particular to convert numeric literals to other numeric types. (Fortress is unusual in that the type of a literal such as 43 is not any of the standard computational integer types such as \mathbb{Z} or $\mathbb{Z}32$ or $\mathbb{Z}64$, but a special numeric-literal trait.)

Coercion comes into play during multimethod dispatch: if there is *no* applicable function or method declaration for a given call, then the net is cast wider by considering declarations that would be applicable if the arguments were automatically coerced to some other type; if there is a unique most specific applicable

declaration in this larger set, then that is the one that will be invoked. To help prevent surprises, coercions in Fortress are *not* transitive.

Parallelism

Many constructs in the Fortress language give rise to multiple implicit *tasks* to execute subexpressions, such as the components of a tuple, blocks of the do-also construct, function arguments, operands of binary operators, and the target and arguments of a method call (Fig. 5). This is *fork-join* parallelism: all tasks for a construct execute to completion before execution of the construct itself can complete. Tasks are implicitly scheduled and provide no fairness guarantees; while tasks *may* execute concurrently, a Fortress compiler or run-time may choose to schedule tasks for sequential execution instead. This allows flexible allocation of hardware resources.

Comprehensions, reduction expressions, and for loops are all syntactic sugar for uses of generators and reducers. A *generator* is an object capable of supplying some number of separate values to a reducer through one or more library-defined protocols; a *reducer* is an object that can accept values from a generator and produce a combined or aggregated result.

For example, the nested for loop in Fig. 6 contains two generator expressions $0 : 9$ and $(i + 1) : 9$ representing parallel counted ranges; the loop desugars into a nested pair of calls to their respective *loop* methods.

(* Five examples of situations in which expressions such as $f(x)$ and $g(y)$ and $h(z)$ may be executed in parallel as concurrent tasks.
*)

$(a, b, c) = (f(x), g(y), h(z))$	⊗ Elements of a tuple
do	⊗ Separate blocks of a do -also construct
$f(x)$	
also do	
$g(y)$	
also do	
$h(z)$	
end	
$p(f(x), g(y), h(z))$	⊗ Arguments of a function call
$f(x) + g(y)$	⊗ Operands of a binary operator
$f(x).m(g(y), h(z))$	⊗ Target and arguments of a method call

Fortress (Sun HPCS Language). Fig. 5 Implicit parallelism in Fortress

The actual parallelism is provided by using implicit tasks in the implementation of the *loop* method, generally using a divide-and-conquer coding style. Most Fortress data structures are generators and support structure-respecting parallel traversal. It is a library convention that generators are implicitly parallel by default; the *seq(self)* method conventionally constructs a sequential version of a generator. Definitions of BIG operators typically define the behavior of reductions (Fig. 7) and comprehensions (Fig. 8) in terms of an underlying monoid.

Note that while generators run computations in parallel, there is still a well-defined spatial order to the results produced by a generator (Fig. 9).

Fortress also provides explicit parallelism using the spawn construct (Fig. 10). Spawns threads are scheduled fairly with respect to one another, and implicit tasks of separately spawned threads are scheduled fairly with respect to one another.

The programmer is responsible for wrapping concurrent accesses to shared data in an atomic block. The semantics of an atomic block is that either all the reads and writes to memory happen simultaneously, or none of them do; in effect, all the memory reads and memory writes of an atomic block appear to all other tasks to occur as a single atomic memory transaction. Such transactions are in fact *strongly atomic* (transactional and non-transactional accesses can coexist).

Implicit parallelism may be exploited inside of a transaction. Inner transactions may be retried independently of the outer transaction (“closed nesting”). Contention may be managed by the run-time system, or at the Fortress language level using the *tryAtomic* construct.

The current implementation of Fortress uses an automatic dynamic load-balancing algorithm (based on work done at MIT as part of the Cilk project) that uses work-stealing to move pending tasks from one processor to another.

Programming in the Large

Fortress supports a number of features for programming in the large.

Components and APIs Fortress source code is encapsulated in *components*, which contain definitions of program elements. Each component imports a collection of *APIs* (Application Programming Interfaces) that declare the program elements used by that component. Each component also exports a collection of APIs. If a component *C* exports an API *A*, then *C* must include a definition for every element declared in *A*. Components can be linked together into larger components. If a component *C* exports an API *A* that is imported by a component *D*, and *C* and *D* are linked, then references in *D* to the declarations in *A* are resolved to the corresponding definitions in *C*.

```

(* This for loop controls two index variables in nested fashion. The : operator, given two integers,
produces a CountedRange object that can serve as a generator of integer index values. *)  

for i ← 0 : 9, j ← (i + 1) : 9 do  

  ai,j := 3i - 2j  

end  

(* The for loop is desugared into nested calls to higher-order methods that take functions as arguments.  

These functions bind the index variables. The fn syntax is analogous to Lisp's lambda expression syntax  

for anonymous functions. *)  

(0 : 9).loop(fn (i) =>  

  ((i + 1) : 9).loop(fn (j) =>  

    do ai,j := 3i - 2j end))  

(* The loop method of the CountedRange generator object uses a recursive divide-and-conquer strategy that  

exploits implicit task parallelism (do-also) to permit concurrent execution of loop iterations. *)  

object CountedRange(lo: Z32, hi: Z32) extends Generator[Z32]  

  ...  

  loop(body: Z32 →()): () =  

    if lo = hi then body(lo)  

    elif lo < hi then  

      mid = ⌊ (lo + hi) / 2 ⌋  

      do  

        CountedRange(lo, mid).loop(body)  

      also do  

        CountedRange(mid + 1, hi).loop(body)  

      end  

    end  

  ...  

  seq(self) = ...  

end

```

Fortress (Sun HPCS Language). Fig. 6 Implementation of for loops through desugaring

Contracts Fortress functions and methods can be annotated with *contracts* that declare preconditions and post-conditions (Fig. 11).

Test code, properties, and automated unit testing Fortress includes support for defining tests inline in programs alongside the data and functionality they test. Similar to tests are *property declarations*, which document conditions that a program is expected to obey. The parameters in a property declaration denote the types of values over which the property is expected to hold.

When test data is provided with a property, the property is checked against all values in the test data when the program tests are run.

One use of the design-by-contract features is to document and enforce algebraic relationships that are necessary for correct parallel execution of generators and reducers (Fig. 12).

Innovations

- Fortress introduced `comprises` and `excludes` clauses that allow the type checker to deduce that two types are disjoint; this matters for certain kinds

- ⊗ Summation is one kind of reduction expression.

$$\sum_{\substack{i \leftarrow 0 : 9 \\ j \leftarrow (i+1) : 9}} a_{i,j}$$

- ⊗ The summation is desugared into nested calls to higher-order methods.

```
 $\sum((0 : 9).nest(\text{fn } (i) \Rightarrow ((i + 1) : 9).map(\text{fn } (j) \Rightarrow a_{i,j})))$ 
```

- (*) The unary \sum operator takes a generator and gives its *reduce* method an object that implements the standard reduction protocol using addition. The *reduce* method, like the *loop* method, provides implicit parallelism. This \sum operator is generic; it can be used with any data type T that implements the Additive trait, meaning that type T implements a binary $+$ operator and can supply an identity value named *zero*. *)

```
opr  $\sum[[T \text{ extends Additive}[T]]](g : \text{Generator}[T]) : T =$   
 $g.\text{reduce}(\text{SumReduction}[T])$ 
```

```
object SumReduction[[T extends Additive[T]]] extends Reduction[T, T]  
  empty() : T = zero          ⊗ Additive[T] means type T has a zero value  
  join(a : T, b : T) : T = a + b    ⊗ that is the identity for the + operator on type T.  
  singleton(a : T) : T = a        ⊗ The sum of one number is the number itself.
```

end

Fortress (Sun HPCS Language). Fig. 7 Implementation of reduction operations through desugaring

- ⊗ List comprehension $\langle \dots | \dots \rangle$ is one kind of comprehension expression.

- ⊗ It produces an ordered list of values.

$$\langle a_{i,j} \mid i \leftarrow 0 : 9, j \leftarrow (i+1) : 9 \rangle$$

- (*) Other kinds of comprehension brackets construct arrays, sets, or multisets. They are desugared in much the same manner as reduction expressions. *)

- (*) The meaning of a comprehension is defined by library code in the same way as for a reduction operator. *)

```
opr BIG  $\langle [T] g : \text{Generator}[T] \rangle : \text{List}[T] =$   
 $g.\text{reduce}(\text{ListReduction}[T])$ 
```

- (*) List aggregation is essentially reduction of singleton lists using the list concatenation operator $\|$. The library definitions of the $\|$ operator and the (noncomprehension) list constructors $\langle \rangle$ and $\langle x \rangle$ are not shown here. *)

```
object ListReduction[T] extends Reduction[T, List[T]]  
  empty() : List[T] =  $\langle \rangle$           ⊗ Produce an empty list.  
  join(a : List[T], b : List[T]) : List[T] = a  $\|$  b    ⊗ Concatenate two lists.  
  singleton(a : T) : List[T] =  $\langle a \rangle$         ⊗ Produce a singleton list.
```

end

Fortress (Sun HPCS Language). Fig. 8 Implementation of comprehension expressions through desugaring

of code optimization. Such declarations can also improve code maintainability.

- Lexical syntax is inspired in part by Wiki notation: the visual appearance of “rendered” code depends

(* The squares of the nine values 1, 2, 3, 4, 5, 6, 7, 8, 9 may be computed concurrently or in any temporal order, but the *logical* or *spatial* order of the results within ordered list will always be {1, 4, 9, 16, 25, 36, 49, 64, 81}. *)

$\langle k^2 \mid k \leftarrow 1 : 9 \rangle$

Fortress (Sun HPCS Language). Fig. 9 The distinction between logical order and temporal order

on whether an identifier is lowercase, uppercase, or mixed case, and whether underscore characters are used in particular ways. Many single-character operators and brackets can be represented by multicharacter ASCII sequences, but there is no single “escape” character (such as backslash) that introduces such sequences. As a rule, if an operator has a standard name in \TeX or \LaTeX , then that same name converted to uppercase, omitting the backslash, is a Fortress name for that operator. See Fig. 13. Text in comments uses a markup syntax based on Wiki Creole 1.0 [9]. See Fig. 14.

- Most programming languages handle operator precedence by imposing a total order on operators (sometimes by mapping them to specific integer values). Fortress uses only precedence rules that would

do

- ⊗ The `spawn` construct forks a fair concurrent thread
- ⊗ and immediately returns a handle object for the thread.

$firstThread = \text{spawn } f(x)$
 $secondThread = \text{spawn } g(y)$

- ⊗ Other computations here will run concurrently with
- ⊗ the spawned threads. The `val` method waits for a
- ⊗ spawned thread to complete and then produces whatever
- ⊗ value or exception the thread may have produced.

$firstThread.val + secondThread.val$
end

Fortress (Sun HPCS Language). Fig. 10 Explicit spawning of fair concurrent threads

(* This definition of `factorial` has a contract that requires the argument to be nonnegative. The contract also guarantees that the result will be nonnegative. *)

$\text{factorial}(n) \text{ requires } \{ n \geq 0 \} \text{ ensures } \{ outcome \geq 0 \} =$
 $\quad \text{if } n = 0 \text{ then } 1 \text{ else } n \text{factorial}(n - 1) \text{ end}$

(* This test-only code (indicated by the keyword `test`) calls the `factorial` function for all values from 0 to 100, and checks that the result for each is not less than the argument. *)

$\text{test factorialNotLessThanInput } [x \leftarrow 0 : 100] = (x \leq \text{factorial}(x))$

(* This property declaration requires that the result of `factorial` be not less than the argument for *every* argument of type \mathbb{Z} . Test data for spot-checking a property may be provided separately. *)

$\text{property factorialNeverLessThanInput} = \forall (x : \mathbb{Z}) (x \leq \text{factorial}(x))$

Fortress (Sun HPCS Language). Fig. 11 Examples of contracts, test code, and declared properties

(* This trait imposes upon any trait T that extends $\text{BinaryOperator}[\![T, \odot]\!]$ the requirement to provide a concrete implementation of the specified binary operator \odot . Note that both T and \odot are parameter names, for which an actual type and actual operator are substituted by an invocation such as $\text{BinaryOperator}[\![\mathbb{Q}, +]\!]$ or $\text{BinaryOperator}[\![\mathbb{Z}32, \text{MAX}]\!]$. *)

```
trait BinaryOperator[\!T, opr \odot\!] comprises T
  opr \odot(self, other : T) : T
end
```

⊕ An associative operator is a binary operator with the associative property.

```
trait Associative[\!T, opr \odot\!] comprises T
  extends { \text{BinaryOperator}[\!T, \odot\!], \text{EquivalenceRelation}[\!T, =\!] }
  property \forall(A; T, b: T, c: T)((a \odot b) \odot c) = (a \odot (b \odot c))
end
```

⊖ A monoid is a type with an operator that is associative and has an identity.

```
trait Monoid[\!T, opr \odot\!] comprises T
  extends { \text{Associative}[\!T, \odot\!], \text{HasIdentity}[\!T, \odot\!] }
end
```

Fortress (Sun HPCS Language). Fig. 12 Use of declared properties to enforce algebraic relationships

be familiar from high-school or college mathematics courses. A consequence is that operator precedence in Fortress is not transitive (Fig. 15).

- The “meet rule” eliminates the need for arbitrary “tie-break” or “ordering” rules found in other multiple-inheritance type systems.
- Fortress addresses the “self-type problem” common to many type systems with inheritance by using generic traits that each have a static parameter that is a type that must extend the generic trait; the `comprises` clause is used to enforce this requirement. The parameter name then serves as a self-type adequate to solve the “binary method problem.”
- The Fortress libraries use the self-type idiom to encode and enforce (through use of design-by-contract features) a hierarchy of algebraic properties of data types and operators ranging from commutativity and associativity all the way up to partial and total orders, monoids and groups, and Boolean algebras. Type-checking ensures that, for example, a comparison operator given to a `sort` method actually implements a correct ordering criterion; overloaded method dispatch allows the `sort` method to use different algorithms depending on whether the order is partial or total.

- Fortress supports units and dimensions with a relatively small amount of built-in mechanism. All the Fortress compiler knows is that units and dimensions may be declared (Fig. 16), that they form a free Abelian group under multiplication, that these abstract values may be used as static arguments to generic types, and that such a generic type may optionally be declared to *absorb* units. That you can multiply apples and oranges, that apples may be added only to apples, and whether you can exclusive-or apples and apples, are all at the discretion of the library programmer. Dimensioned types can ensure that data is correctly scaled (Fig. 17).
- The Maybe type (instances are either `Just x` or `Nothing`), borrowed from Haskell, can be used as a generator of at most one item. A syntactic convenience allows it to be used in an `if` statement so as to bind a variable to the item in just the `then` clause (Fig. 18).
- The Java programming language allows a method of the superclass to be called using the *super* keyword. A language with multiple inheritance requires a more general feature. Using a type assumption expression `x asif T` as an argument causes method dispatch to use the specified static

opr OPLUS(self, other: Boolean): Boolean
```

and it is rendered as follows:

(* Compute the logical exclusive OR of two Boolean values.

Arguments

self a first Boolean value

other a second Boolean value

Returns

The exclusive OR of the two arguments. This is *true* if **either** argument is *true*, but not if **both** arguments are *true*.

		<i>other</i>	
		false	true
\oplus	false	false	true
	true	true	false

*)

opr \oplus (*self,other*: Boolean): Boolean

Fortress (Sun HPCS Language). Fig. 14 Example of rendering Wiki-style markup in Fortress comments

type *T* for the argument expression *x* during method lookup. This general mechanism solves the multiple supertype problem as a special case (Fig. 19).

- Fortress provides an object-oriented implicit coercion feature. It differs from a conventional method such as *toString* in that it is declared in the type converted *to* rather than the type converted *from*, and

$a + b > c + d$	⊗ Correct: + has higher precedence than >
$p > q \wedge r > s$	⊗ Correct: > has higher precedence than \wedge
$w + x \wedge y + z$	⊗ Incorrect: no defined precedence between + and \wedge
$(w + x) \wedge (y + z)$	⊗ Correct: parentheses specify desired grouping
$w + (x \wedge y) + z$	⊗ Correct: parentheses specify desired grouping

Fortress (Sun HPCS Language). Fig. 15 Operator precedence in Fortress is not transitive

⊗ Declarations of several physical dimensions and their default units

```
dim Mass default kilogram
dim Length default meter
dim Time default second
dim ElectricCurrent default ampere
```

⊗ Declarations of derived physical dimensions

```
dim Velocity = Length/Time
dim Acceleration = Length/Time2
dim Force = Mass·Acceleration
dim Energy = Force·Length
```

⊗ Declarations of basic units and their abbreviations

```
unit kilogram kg : Mass
unit meter m : Length
unit second s : Time
unit ampere A : ElectricCurrent
```

⊗ Declarations of derived units

```
unit newton n : Force = meter·kilogram/second2
unit joule J : Energy = newton meter
```

⊗ Declarations of derived units that require scaling factors

```
unit gram g : Mass = 10-3 kilogram
unit kilometer km : Length = 103 meter
unit centimeter cm : Length = 10-2 meter
unit nanosecond ns : Time = 10-9 second

unit inch inches in : Length = 2.54 cm
unit foot feet ft : Length = 12 inches
```

Fortress (Sun HPCS Language). Fig. 16 Example declarations of physical dimensions and units

in that it is invoked implicitly by method dispatch if necessary. Among method overladings, one that requires no coercion to be applicable is always considered more specific than one that requires one or more coercions. Coercion declarations may also

be marked as *widening*; automatic rewriting rules on parts of the expression tree that include widening coercions provide the effect of “widest need evaluation” [5], but in a manner that is fully under user (or library) control.

- Declarations in terms of dimensions implicitly use default units.

$$\text{kineticEnergy}(m : \mathbb{R} \text{ Mass}, v : \mathbb{R} \text{ Velocity}) : \mathbb{R} \text{ Energy} = \frac{m v^2}{2}$$

- Alternatively, declarations may specify units explicitly.

$$\text{kineticEnergy}(m : \mathbb{R} \text{ kg}, v : \mathbb{R} \text{ m/s}) : \mathbb{R} \text{ J} = \frac{m v^2}{2}$$

do

mySpeed = 3.7 feet per second

- The function *kineticEnergy* requires a speed measured in meters per second, so *mySpeed* by itself is not a valid argument.
- The *in* operator multiplies by the necessary scale factor, which in this case is $12 \times 2.54 \times 10^{-2}$. The scale factor is determined automatically from the declarations of the units.

kineticEnergy(30 kg, *mySpeed* in m/sec)

end

Fortress (Sun HPCS Language). Fig. 17 Examples of the use of declared physical dimensions and units

- Assume the *position* method returns a value of type *Maybe*[\mathbb{Z}_{64}].

if p \leftarrow *myString.position*('=') *then*

myString[0 : p] • Here *p* is bound to a value of type \mathbb{Z}_{64} .

else

myString

end

Fortress (Sun HPCS Language). Fig. 18 Use of a generator expression in an *if* statement

- Fortress uses *where* clauses to bind additional type parameters and to constrain relationships among static type parameters. In particular, the constraint may be a subtype relationship. This general mechanism suffices to express covariance and contravariance (Fig. 20), which are important type relationships that require more specialized mechanisms in other languages.
- MPI allows a program to inquire how many hardware processors there are, but little else about the execution environment. High Performance Fortran provides alignment and distribution directives that describe how arrays should be laid out across multiple processors, but the processors must be organized as a flat Cartesian grid, and the class of distributions (such as block, cyclic, and block-cyclic) is fixed.

Fortress defines a *hierarchical* data structure (the *region*) that can describe hardware resources (both processors and memory) and relative communication costs, and can be queried by a running program. A Fortress *distribution* maps the parts of an aggregate data structure to one or more regions. The class of distributions is open ended and library programmers can define new distributions.

Influences from Other Programming Languages

Aspects of the Fortress type system, including inheritance and overloaded multimethod dispatch, were influenced by the ML, Haskell, Java, NextGen, Scala, CLOS, Smalltalk, and Cecil programming languages, among others. Inspirations for the use of mathematical syntax and a character set beyond ASCII include

```

trait FloorWax
  advertise(self) = print "Great shine!"
end

trait DessertTopping
  advertise(self) = print "Great taste!"
end

trait Shimmer extends { FloorWax, DessertTopping }
  advertise(self) = do
    @ Type assumption controls which “super-method” to call.
    advertise(self asif FloorWax)
    advertise(self asif DessertTopping)
  end
end

```

Fortress (Sun HPCS Language). Fig. 19 Example use of `asif` expressions

@ List is covariant in its type parameter T .

```

trait List[T] extends List[U] where { T extends U }
  ...
end

```

@ OutputStream is contravariant in its type parameter E .

```

trait OutputStream[E] extends OutputStream[G] where { G extends E }
  ...
end

```

APL, MADCAP, MIRFAC, the Klerer-May System, and COLASL. The idea of having “publication” (beautifully rendered) textual form as well as one or more “implementation” forms goes back to Algol 60. Notions of data encapsulation, comprehensions, generators, and reducers can be traced to CLU, Alphard, KRC, Miranda, and Haskell. In the area of functional programming, higher-order functions, and divide-and-conquer parallelism, many languages had an influence, but especially Lisp, Haskell, and APL. The approach to data distribution was strongly influenced by experience with High Performance Fortran and its predecessors.

Future Directions

The current Fortress compiler targets the Java Virtual Machine (JVM) and uses a custom class loader to instantiate generic types as they are needed. The JVM provides good multiplatform native code generation, threads, and garbage collection, and hosts libraries implementing both work-stealing and transactions. The Fortress type system is embedded into the Java type system where it is convenient, but tuple types and arrow types are handled specially. Fortress value types are eligible for compilation into an unboxed (primitive) representation. Fortress traits compile to Java interfaces, and Fortress objects compile to Java final classes.

A straightforward analysis of traits comprising object singletons can demonstrate finiteness, which permits the general application of unboxing to new types.

A specialized virtual machine (VM) and run-time system may someday be desirable, but at this time the benefits of targeting the JVM far outweigh the overhead.

The design of regions and distributions for managing the mapping of data and threads to hardware resources has been worked out on paper, but has not yet been implemented.

The original design of Fortress includes a form of where clause that conditionally gates such type relationships as extension, comprising, and exclusion. For example, one might define an generic aggregate data structure $A[E]$ with a multiplication operator that is defined in terms of multiplication for the element type E , and one might well wish to declare that the multiplication of aggregates is commutative if and only if multiplication of the elements is commutative. This may be achieved by declaring

```
trait A[E] extends { Commutative[A[E], ×]
  where { E extends Commutative[E, ×] } }
```

The implications of such conditional type relationships for the implementation of a practical type checker are still a subject of research.

An object-oriented pattern-matching facility for easily binding multiple variables to the fields of an object, similar to the pattern-matching facilities in Haskell and Scala but with more provisions for user extensibility, has been sketched out but only recently implemented.

National Institute of Informatics, Tokyo,
Japan

Synonyms

Fujitsu vector processors; Fujitsu VPP systems; SIMD (single instruction, multiple data) machines

Definition

Fujitsu Vector Machines are the series of supercomputers developed by Fujitsu from 1976 to 1999. They are based on the pipeline architecture, and VPP systems have also incorporated a high degree of parallelism with distributed memory in the system architecture, utilizing the full crossbar network for non-blocking system interconnect.

Discussion

FACOM 230-75 Array Processor Unit (APU)

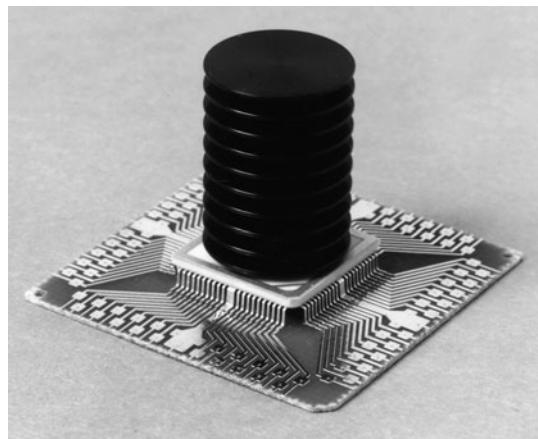

The first vector machine in Japan was FACOM 230-75 Array Processing Unit (APU) which was installed at the National Aerospace Laboratory (later became the Japanese Aerospace Exploration Agency (JAXA) in October 2003) in 1977 [1].

This system was organized as an asymmetric multi-processor system which consists of the mainframe computer FACOM 230-75 and the Array Processor Unit. The clock was 90 ns, and the peak performance of APU is 22 Mflop/s for addition/subtraction and 11 Mflop/s for multiplication. This system was a pipeline-based array processor with 256 data registers (scalar) and one vector register with 1,792 word (36 bits/word) for vector operations. The capacity of the main memory was 1 M words with 32-way interleave. AP-Fortran, an extended Fortran language, was developed for the 230-75 APU to allow parallelism description.

FACOM VP100/200 Series

The vector processor FACOM VP100 and FACOM VP200 [2–5] were announced in July 1982. The major goals of the VP100/200 Series were to achieve a very high performance, ease-of-use, and a good affinity with general-purpose computing environment with the FACOM M-Series mainframe computers. The state-of-the-art semiconductor technology was incorporated in the system; the ECL LSI with a gate delay time of 350 ps (Fig. 1) and 400 and 1,300 gates per chip, and high-speed RAM with an access time of 5.5 ns for vector registers. As for the memory technology, the main memory unit with high capacity and high data transfer capability was realized by using the 64 Kbit SRAM with access time of 55 ns.

Figure 2 illustrates the architecture of VP100/200 Series system. It consists of the scalar unit, vector unit,

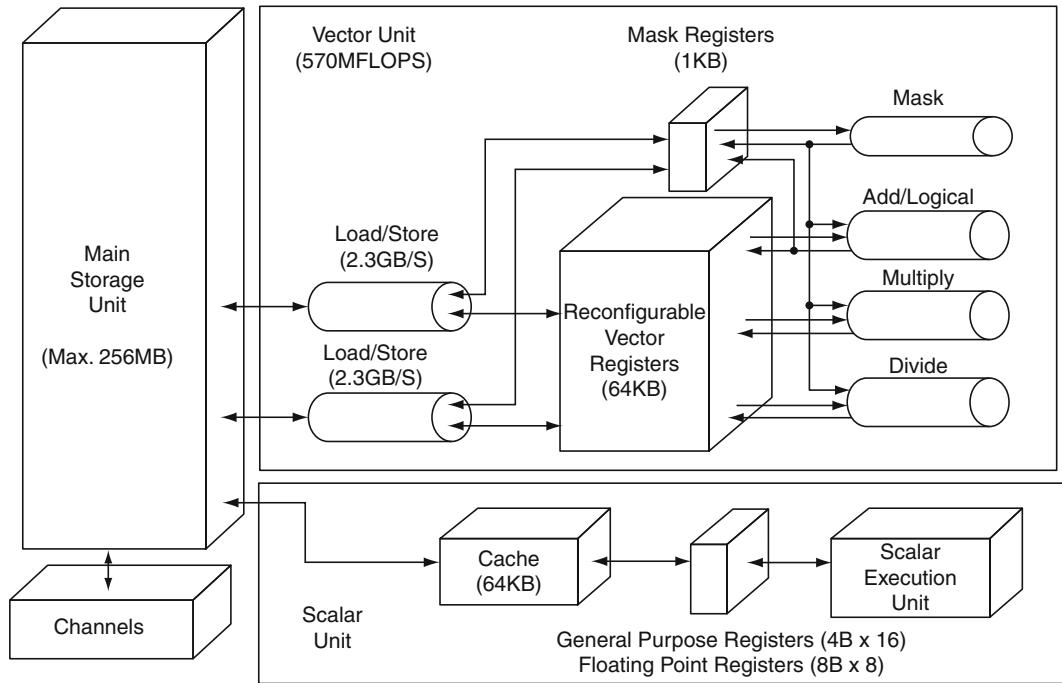

Fujitsu Vector Computers. Fig. 1 VP200 LSI packaging technology. (Photo Credit: Fujitsu Limited)

and main storage unit. The scalar unit fetches and decodes all the instructions and executes the scalar instructions. The vector unit consists of six functional pipeline units, vector registers, and mask registers. The functional pipes are add/logical pipe, multiply pipe, divide pipe, mask pipe, and two load/store ports, which are also pipelined. The first three pipes are for arithmetic operations. The load/store pipes support the contiguous access, strided access, and the indirect addressing (gather/scatter) for flexible vector operations. The mask pipes are used to handle the conditional branches within loops. One of the most unique features of the VP100/200 Series is the dynamically reconfigurable vector registers. The total capacity of the vector registers for VP200 is 8 K words (64 bits), but they can take such configurations as 32 (vector length) × 256 (number of vector registers), $64 \times 128, 128 \times 64, \dots, 1024 \times 8$.

The major features of the VP100/200 Series are summarized in Table 1. Figure 3 shows the cabinet of the VP200 system.

The first delivery of the VP-Series system took place in January 1984, that is, VP-100 at the Institute for Plasma Physics in Nagoya. Later, the high-end model FACOM VP-400, with improved performance, was added, and a processing performance exceeding 1Gflop/s was achieved. Also, the market was expanded by adding lower-end models: the FACOM VP30 and FACOM VP 50.

The VP-Series E Models, enhanced versions of the VP 100/200 Series, were announced in July 1987.

There were five models : VP 30E, VP 50E, VP 100E, VP 200E, and VP 400E. These E models achieved performance which is 1.5 times more powerful than that of the previous VP 100/200 Series machines by installing high-speed vector memory and an additional arithmetic pipeline for the fused multiply-add operations.

FUJITSU VP2000 Series

The VP2000 Series [6–8] was announced in December 1988 as the successor to Fujitsu's VP-E Series supercomputers. Figure 4 illustrates the architecture of VP2000 Series systems. It carries most of the VP100/200 architectural features with various enhancements in the vector unit, such as two sets of fused multiply-add pipelines, doubled mask pipelines, and faster division circuit. The most notable feature of the VP2000 Series is that it can be configured with one or two scalar units

sharing one vector unit. This feature, called Dual Scalar Processors (DSP), may be regarded as two-threaded system. The objective of DSP is to utilize the vector unit more efficiently when the vectorization ratio of users' application programs is not very high [7].

The key features of VP2000 Series system are summarized in Table 2.

Numerical Wind Tunnel and VPP500-Series

Numerical Wind Tunnel

The National Aerospace Laboratory (NAL) of Japan developed the Numerical Wind Tunnel (NWT) [9] parallel supercomputer system jointly with Fujitsu. The system architecture was a distributed memory vector-parallel computer, in which vector supercomputers

Fujitsu Vector Computers. Fig. 5 NWT system. (Photo Credit: JAXA)

were connected with the non-blocking crossbar network. The NWT's final specifications were 166 processing elements, each with 1.7 Gflop/s of processing power to give a peak performance of 280 Gflop/s with 44.5 GB of the total main memory.

The NWT's processing element consisted of a CPU and memory. The CPU is a vector supercomputer by itself, comprising three types of LSIs: GaAs, ECL, and BiCMOS, 121 in total. It is one of the very few commercially successful GaAs-based system. The primary cooling method was water cooling, but the forced air-cooling method was also used for the memory units.

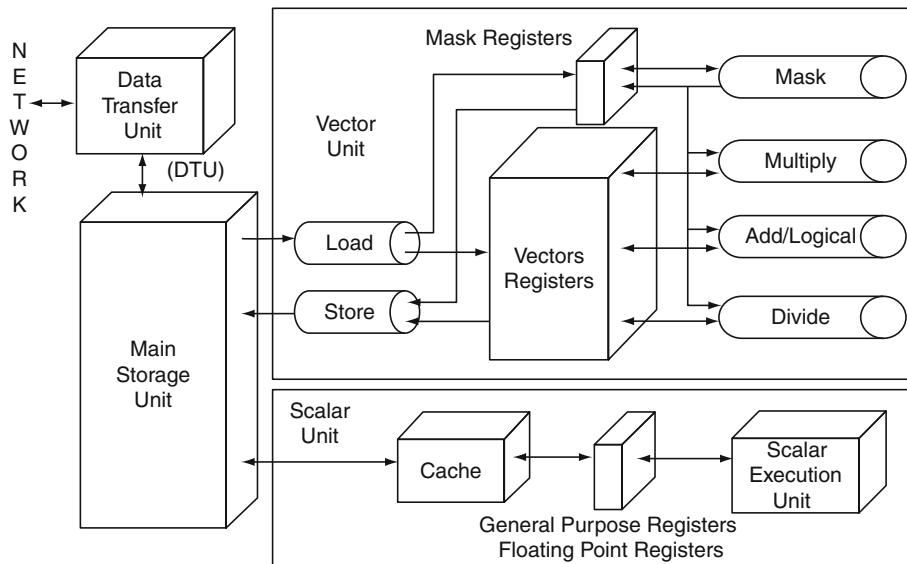

Figure 5 shows the NWT as installed at NAL. The NWT, which went into operation in January 1993, was rated as the most powerful supercomputer site in the world in the TOP500 list from 1993 to 1995. It should be noted that the NWT was the technology precursor to the VPP500, which will be described in more detail in the next section.

FUJITSU VPP500

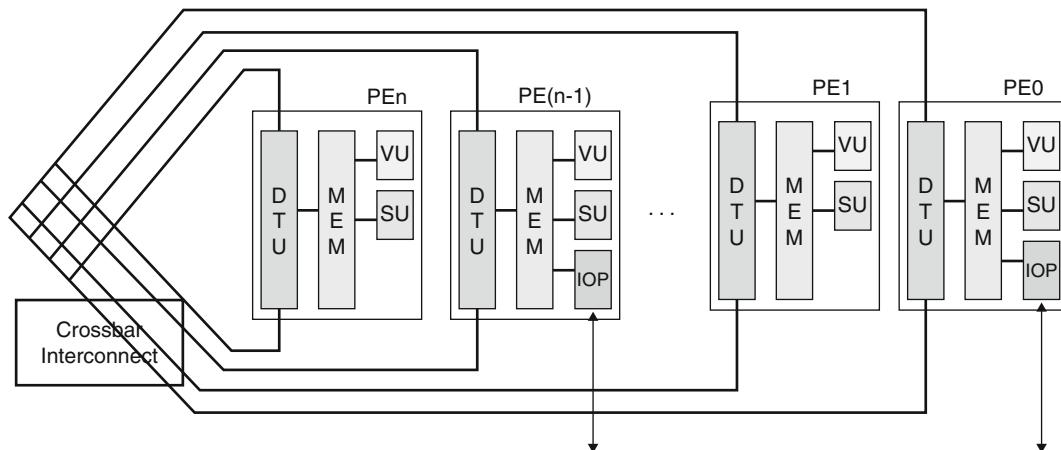

The VPP500 was Fujitsu's third generation supercomputer system [8, 10–14]. As stated in the previous section, it was a commercial version of NWT. Fujitsu announced the VPP500 in September 1992 as the world's most powerful supercomputer at that point in

time with a speed of 355 Gflop/s. Fujitsu has developed processor elements (PEs), each being capable of vector processing and also can operate in highly parallel fashion to obtain this performance. The maximum configuration was with 222 processing elements to reach 355 Gflop/s.

As shown in Fig. 6, each processing element consisted of a scalar unit, a vector unit, a main storage unit, and a Data Transfer Unit (DTU), built with Gallium Arsenide LSI's, Bipolar LSI's and BiCMOS LSI's, and ultrahigh-density circuit boards, and was able to deliver a maximum vector performance of 1.6 Gflop/s. The scalar unit is VLIW architecture and may execute up to four operations in parallel. In order to achieve very high system performance, PEs were connected with a high-speed crossbar network which allows non-blocking data transfer. The data transfer rate was 400 MB/s from one PE to another. Since a PE can simultaneously send and receive data, the aggregate data transfer rate per PE was 800 MB/s. Figure 7 illustrates the system configuration of VPP500, based around the crossbar network. In order to fully utilize the powerful capability of the interconnecting network, the Data Transfer Unit (DTU) was incorporated, which allows the mapping between the local and the global addresses, a very fast synchronization across PEs, and actual data transfer with proprietary message passing protocol. Various

Fujitsu Vector Computers. Fig. 6 VPP500 architectural block diagram

Fujitsu Vector Computers. Fig. 7 VPP500 system configuration

data transfer modes were supported by the DTU. They were: contiguous, constant-strided, sub-array, and indirect addressing (random gather/scatter).

Figure 8 shows the inside of one cabinet of VPP500, which contains 12 PEs. Plumbing for water cooling is also visible in this photo.

The specifications of the VPP500 system and the follow-on products are summarized in Table 3.

the distributed memory units of VPP500. The ability to define the array data in Fortran programs, distributed across multiple processing elements as a single global space, greatly simplified the porting and tuning of existing codes to VPP500 VPP Fortran may be regarded as an early implementation of PGAS (Partitioned Global Address Space). More details are described in [13].

New Parallel Language

Fujitsu developed a new parallel language, called VPP Fortran, which can define a single name space across

VPP300/VPP700/VPP5000 Series

After a great success with VPP500, Fujitsu developed the CMOS versions of the vector-parallel system. The

Fujitsu Vector Computers. Fig. 8 VPP500 cabinet. (Photo Credit: Fujitsu Limited)

Fujitsu VPP300 Series and VX Series (the single CPU model), which used CMOS (Complementary metal

oxide semiconductor) technology, were introduced in February 1995, the Fujitsu VPP700 Series in March 1996, and the VPP5000 Series in April 1999. All VPP Series supercomputers after the VPP300 Series used the CMOS technology. Packaging technology of VPP5000 is shown in Fig. 9.

The VPP5000 was the successor to the former VPP700/VPP700E systems (with E for extended, i.e., the clock cycle 6.6 instead of 7 ns). The clock cycle has been halved, and the vector pipes are able to deliver fused multiply-add results. With a multiplicity of 16 for these vector pipes, 32 floating-point results per clock cycle can be generated. In this way, a fourfold increase in speed per processor can be attained with respect to the VPP700E.

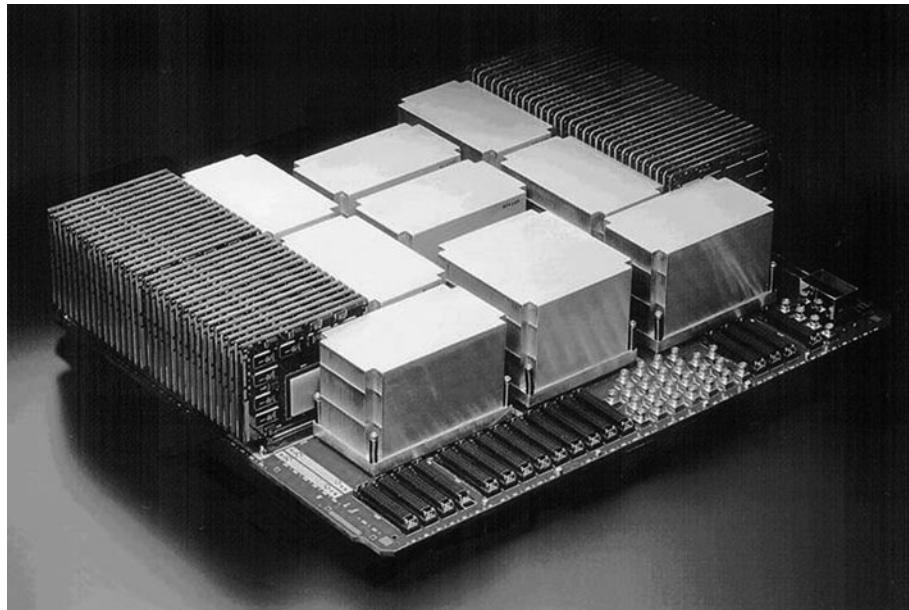

The architecture of the VPP5000 nodes is almost identical to that of the VPP700, but one of the major enhancements is in the performance of noncontiguous memory access by incorporating more address matching circuits.

Conclusion

While the vector processing with very sophisticated hardware pipelines together with highly interleaved memory subsystem was the dominant supercomputer architecture in the 1980s and 1990s, the wave of highly (or massively) parallel scalar systems have been gaining

Fujitsu Vector Computers. Table 3 VPP Series specifications (typical models)

Models	VPP500	VPP700E	VPP5000
Announcement	September, 1992	February, 1995	April, 1999
Ckt. technology	GaAs/ECL/Bipolar	CMOS(.35μ)	CMOS(.22μ)
Level of integration	100 K Tx's (GaAs)	8 M Tx's/chip	33 M Tx's/chip
Delay time/gate	60 ps	40 ps	24 ps
Cooling method	Liquid (water)	Forced air	Forced air
Clock frequency	100 MHz	154 MHz	303 MHz
Max. perf./PE	1.6 Gflop/s	2.4 Gflop/s	9.6 Gflop/s
Mem. capacity/PE	1GB	2 GB	2–16 GB
Memory technology	4 Mbit SRAM	16 Mbit SDRAM	128 Mbit SDRAM, 16 Mbit SSRAM
I/O capability/PE	400 MB × 2	615 MB × 2	3.2 GB × 2
Max. configuration	222 PEs	512 PEs	512 PEs
Max. system perf.	355 Gflop/s	1.2 Tflop/s	4.8 Tflop/s
CPU architecture	32 bit	32 bit	64 bit

Fujitsu Vector Computers. Fig. 9 VPP5000 PE/Memory board. (Photo Credit: Fujitsu Limited)

more popularities in this century. The major reasons may be stated as;

1. Pipelining has become the common techniques even in the scalar microprocessor design.
2. Larger market opportunities have arisen with the advent of high volume produced the powerful scalar microprocessors.
3. The highly interleaved memory structure in the vector architecture has become a more expensive implementation as compared with the cache-based approach in the scalar architecture, for the purpose of coping with the widening speed gap between CPU and memory.
4. More and more application programs have been tailored toward scalar architecture.

Thus, Fujitsu decided to change direction from vector architecture to highly parallel scalar Symmetric Multi-processor (SMP) and its constellations. The VPP5000 system was Fujitsu's last vector product.

But it should also be pointed out that the recent trends in SIMD instructions in the general purpose microprocessors and the popularity of GPGPU (General Purpose Graphic Processing Unit) could be regarded as "the return of vectors," in the sense that the

programming models and compiler technology developed for the vector architecture continue to be vital technologies in the new approaches.

Functional Languages

PHILIP TRINDER¹, HANS-WOLFGANG LOIDL¹,
KEVIN HAMMOND²

¹Heriot-Watt University, Edinburgh, UK

²University of St. Andrews, St. Andrews, UK

Definition

Parallel functional languages are parallel variants of functional languages, that is, languages that treat computation as the evaluation of mathematical functions and avoid state and mutable data. Functional languages are founded on the lambda calculus. The majority of parallel functional languages add a small number of high-level parallel coordination constructs to some functional language, although some introduce parallelism without changing the language.

Discussion

Introduction

The potential of functional languages for parallelism has been recognized for over 30 years, for example [44]. The key advantage of functional languages is that they mainly, or solely, contain stateless computations. Subject to data dependencies between the computations, the evaluation of stateless computations can be arbitrarily reordered or interleaved while preserving the sequential semantics.

Parallel programs must not only specify the *computation*, that is, a correct and efficient algorithm, it must also specify the *coordination*, for example, how the program is partitioned, or how parts of the program are placed on processors. As functional languages provide high level constructs for specifying computation, for example, higher-order functions and sophisticated type systems, they typically provide correspondingly high level coordination sublanguages. A wide range of parallel paradigms and constructs have been used,

for example, data-parallelism [5], and skeleton-based parallelism [37].

As with computation, the great advantage of high-level coordination is that it frees the programmer from specifying low-level coordination details. Where low-level coordination constructs encourage programmers to construct static, simple, or regular coordination, higher-level constructs encourage more dynamic and irregular coordination. The challenges of high-level coordination are that automatic coordination management complicates the operational semantics, makes the performance of programs opaque, requires a sophisticated language implementation, and is frequently less effective than hand-crafted coordination. Despite these challenges many new nonfunctional parallel programming languages also support high-level coordination, and examples include Fortress [1], Chapel [10] or X10 [11] that also support high-level coordination.

Coordination may be managed statically by the compiler as in PSML [31], dynamically by the runtime system as in GpH [41], or by both as in Eden [28]. Whichever mechanism is chosen, the implementation of sophisticated automatic coordination management is arduous, and there have been many more parallel language designs than well-engineered implementations.

The combination of a high-level computation and coordination language requires specialized parallel development tools and methodologies, as discussed below.

Strict and Non-strict Parallel Functional Languages

Most programming languages strictly evaluate the arguments to a function before evaluating the function. However, as purely functional languages have significant freedom of evaluation order, some use non-strict or *lazy* evaluation. Here the arguments to a function are evaluated only if and when they are demanded by the function body. In consequence more programs terminate, it is easy to program with infinite structures, and programming concerns are separated [23].

Like most languages, many parallel functional languages are strict, for example, NESL [5] or Manticore [19]. However there are many parallel variants of lazy

languages like Haskell [34] and Clean [32]. At first glance this is surprising as lazy evaluation is sequential and performs minimum work, but non-strict languages have a number of advantages for parallelism [42]. They can be easily married to many different coordination languages as the execution order of expressions is immaterial; they naturally support highly dynamic coordination where evaluation is performed and data communicated on demand; their implementations already have many of the mechanisms required for parallel execution. Laziness also exists in the language implementations, for example, distributing work and data on demand [41].

Paradigms

Parallel functional languages have adopted a range of paradigms. For the main parallel paradigms this section outlines the correspondence with the functional paradigm, and describes a representative language. Some languages support more than one paradigm, for example, Manticore [19] combines data and task parallelism, and Eden [28] combines semi-explicit and skeleton parallelism.

Skeleton-Based Languages

Algorithmic Skeletons [14, 37] are a popular parallel coordination construct, and as higher-order functions fit naturally in the functional model. Often these higher order functions work over compound data structures like lists or vectors and consequently the resulting parallel code often resembles data parallel code as discussed in section.

Example skeleton-based functional languages include SCL [15], P3L [3], Eden [28], PSML [31], and HDC. HDC [21] is a strictly evaluated subset of the Haskell language with skeleton-based coordination. HDC programs are compiled using a set of skeletons for common higher-order functions, like fold and map, and several forms of divide-and-conquer. The language supports two divide-and-conquer skeletons and a parallel map, and the system relies on the use of these higher-order functions to generate parallel code.

Data Parallel Languages

Data parallel languages [33] focus on the efficient implementation of the parallel evaluation of every element

in a collection. Functional languages fit well with the data parallel paradigm as they provide powerful operations on collection types, and in particular lists. Indeed, all of the languages discussed here use some parallel extension of list comprehensions and implicitly parallel higher order functions such as `map`. Compared to other approaches to parallelism, the data parallel approach makes it easier to develop good cost models, although, it is notoriously difficult to develop cost models for languages with a non-strict semantics.

Example data parallel functional languages include NESL [5] and Data Parallel Haskell [30]. NESL is a strict, strongly typed, language with implicit parallelism and implicit thread interaction. It has been implemented on a range of parallel architectures, including several vector computers. A wide range of algorithms have been parallelized in NESL, including a Delaunay algorithm for triangulation [8], several algorithms for the n-body problem [7], and several graph algorithms.

Semi-explicit Languages

Semi-explicit parallel languages provide a few high-level constructs for controlling key coordination aspects, while automatically managing most coordination aspects statically or dynamically. Historically, annotations were commonly used for semi-explicit coordination, but more recent languages provide compositional language constructs. As a result, the distinction between semi-explicit coordination and coordination languages is now rather blurred, but the key difference in the approach is that semi-explicit languages aim for *minimal* explicit coordination and minimal change to language semantics.

Example semi-explicit parallel functional languages include Eden [28] and GpH [40]. GpH is a small extension of Haskell with a parallel (`par`) composition primitive. `par` returns its second argument and indicates that the first argument *may* be executed in parallel. In this model the programmer only has to expose expressions in the program that can usefully be evaluated in parallel. The runtime-system manages the details of the parallel execution such as thread creation, communication, etc. Experience in implementing large programs in GpH shows that the unstructured use of `par` and `seq` operators often leads to

obscure programs. This problem is overcome by *evaluation strategies*: lazy, polymorphic, higher-order functions controlling the evaluation degree and the parallelism of a Haskell expression. They provide a clean separation between coordination and computation. The driving philosophy behind evaluation strategies is that it should be possible to understand the computation specified by a function without considering its coordination.

Coordination Languages

Parallel coordination languages [26] are separate from the computation language and thereby provide a clean distinction between coordination and computation. Historically, Linda [12] and PCN [18] have been the most influential coordination languages, and often a coordination language can be combined with many different computation languages, typically Fortran or C. Other systems such as SCL [15] and P3L [3] focus on a skeleton approach for introducing parallelism and employ sophisticated compilation technology to achieve good resource management.

Example coordination languages using functional computation languages include Haskell-Linda [35] and Caliban [25, 39]. Caliban has constructs for explicit partitioning of the computation into threads, and for assigning threads to (abstract) processors in a static process network. Communication between processors works on streams, that is, eagerly evaluated lists, similar to Eden.

Dataflow Languages

Historically a number of functional languages adopted the dataflow paradigm and some, like SISAL [9], achieved very impressive performance.

Example dataflow functional languages include SISAL [9], pHluid system [17]. SISAL [9] is a first-order, strict functional language with implicit parallelism and implicit thread interaction. Its implementation is based on a dataflow model and it has been ported to a range of parallel architectures. Comparisons of SISAL code with parallel Fortran code show that its performance is competitive with Fortran, without adding the additional complexity of explicit coordination [27].

Explicit Languages

In contrast to the high-level coordination found in the majority of parallel functional languages, a number of languages support low-level explicit coordination. For example, there are several bindings for explicit message passing libraries, such as PVM [36] and MPI [29] for languages like Haskell and OCaml [6, 43].

These languages use an open system model of explicit parallelism with explicit thread interaction. Since the coordination language is basically a stateful (imperative) language, stateful code is required at the coordination level. Although the high availability and portability of these systems are appealing, the language models suffer from the rigid separation between the stateful and purely functional levels.

Other functional languages support explicit coordination, for example, ERLANG [2]. ERLANG is probably the most commercially successful functional language, and was developed in the telecommunications industry for constructing distributed, real-time fault tolerant systems. ERLANG is strict, impure, weakly typed, and relatively simple: omitting features such as currying and higher order functions. However the language has a number of extremely useful features, including the OTP libraries, hot loading of new code into running applications, explicit time manipulation to support soft real-time systems, message authentication, and sophisticated fault tolerance.

Tools and Methodologies

Development methodologies for parallel functional programs exploit the amenability of the languages to derivation and analysis. For example, a programmer can reason about costs during program design using abstract cost models like BMF-PRAM [38]. Guided by the cost information the program design can relatively easily be transformed to reduce resource consumption before implementation, for example, [16]. Similarly, automated static resource analysis can provide information to improve coordination, for example, predicted task execution time can improve scheduling.

Parallel functional languages favour high-level and often dynamic coordination in contrast to detailed static

coordination. As a consequence the parallel behaviour of programs is often far from obvious, and hence hard to tune. Hence suites of profiling and visualization tools are very important for many parallel functional languages, for example [4, 24, 39].

Implicit parallelism, often promised in the context of functional languages, offers the enticing vision of parallel execution without changes to the program. In reality, however, the program must be designed with parallelism in mind to avoid unnecessary sequentiality. In theory, program analyses such as granularity, sharing, and usage analysis can be used to automatically generate parallelism. In practice, however, almost all current systems rely on some level of programmer control.

Current development methodologies, like [40], have several interesting features. The combination of languages with high-level coordination and good profiling tools facilitates the prototyping of alternative parallelisations. Obtaining good coordination at an early stage of parallel software development avoids expensive redesigns. In later development stages, detailed control over small but crucial parts of the program may be required, and profiling tools can help locate expensive parallel computations. During performance tuning the high level of abstraction may obscure key low-level features that could be usefully controlled by the programmer.

Parallel Functional Languages Today

Parallel functional languages are used in a range of domains including numeric, symbolic, and data intensive [22]. Commercially Erlang has been enormously successful for developing substantial telecoms and banking applications [2] and parallel Haskell for providing standardized parallel computational algebra systems.

The high-level coordination and computation constructs in parallel functional languages have been very influential. For example, algorithmic skeletons appear in MPI [29] and are the interface for cloud parallel search engines like Google MapReduce. Similarly, stateless threads or comprehensions occur in modern parallel languages like Fortress [1], Chapel [10], or X10 [11]. Moreover the dominance of multicore and emergence

of many-core architectures has focused attention on the importance of stateless computation.

Some trends are as follows. As clock speeds plateau but register width increases, data parallelism becomes attractive for functional, and other, parallel languages. In the functional community there are often multiple parallelizations of a single base language, for example, GpH and Eden are both Haskell variants, moreover, a single compiler often supports more than one parallel version, for example, the Glasgow Haskell Compiler has four experimental multicore implementations [20].

Definition

The programming language construct “future E” indicates that the evaluation of the expression “E” may proceed in parallel with the evaluation of the rest of the program. It is typically implemented by immediately returning a *future object* that is a proxy for the eventual value of “E.” Attempts to access the value of an undetermined future object block until that value is determined.

Discussion

Introduction

The construct “future E” permits the run-time system to evaluate the expression “E” in parallel with the rest of the program. To initiate parallel evaluation, the run-time system forks a parallel task that evaluates “E,” and also creates an object known as a *future object* that will eventually contain the result of that computation of “E.” The future object is initially *undetermined*, and becomes

determined or *resolved* once the parallel task evaluates “E” and updates (or resolves/fulfills/binds) the future object to contain the result of that computation.

Parallel evaluation arises because the future object is immediately returned as the result of evaluating “future E,” without waiting for the future object to become determined. Thus, the continuation (or enclosing context) of “future E” executes in parallel with the evaluation of “E” by the forked task.

The result of performing a primitive operation on a future object depends on whether that operation is considered strict or not. Some program operations, such as assignments, initializing a data structure, passing an argument to a procedure, returning a result from a procedure, are *non-strict*. These operations can manipulate (determined or undetermined) future objects in an entirely transparent fashion, and do not need to know the underlying value of that future object.

In contrast, *strict* program operations, such as addition, need to know the value of their arguments, and so cannot be directly applied to future objects. Instead, the arguments to these operations must first be converted to a regular (non-future) value, by *forcing* or *touching* that argument.

Forcing a future object that has been determined extracts its underlying value (which may in turn be a future and so the force operation must operate recursively). Forcing an undetermined future object blocks until that future is determined, and so force operations introduce synchronization between parallel tasks.

Implicit Versus Explicit Futures

A central design choice in a language with futures is whether forcing operations should be explicit in the source code, or whether they should be performed implicitly by strict operations, such as addition, that need to know the values of their argument. Explicit futures can be implemented as a library that introduces an additional data type. For example, the polymorphic type Future<T> could denote a future object containing values of type T. However, explicit futures require explicit forcing operations that are tedious and error-prone for programs that use futures heavily.

In contrast, implicit futures require language support since futures objects should be indistinguishable from their final resolved value. Implicit futures do

introduce additional overheads, since every strict primitive operation must now check whether its operands are futures.

As an optimization, a static analysis can be used to translate from a language with implicit futures into one with explicit futures. Essentially, the translation introduces explicit touch operations on those primitive operations that, according to a static analysis, may be applied to futures. In the context of the Gambit compiler, this optimization reduces the overhead of implicit futures from roughly 90% to less than 10% [3]. As an orthogonal optimization, a copying garbage collector could replace a determined future object by its underlying value, saving space and reducing the cost of subsequent touch operations.

Task Scheduling

Future annotations are often used to introduce parallel evaluation into recursive, divide-and-conquer style computations such as quicksort. In this situation, there may be exponentially more tasks than processors, and consequently task scheduling has a significant impact on overall performance. A naïve choice of round-robin scheduling would interleave the executions of all available tasks and result in an essentially *breadth-first* exploration of the computation tree, which may require exponentially more memory than an equivalent sequential execution.

Unfair scheduling policies significantly reduce this memory overhead, by better matching the number of concurrently active tasks to the number of processors. In the Multilisp implementation of this technique [1], each task has two possible states: *active* and *pending*, and each processor maintains a LIFO queue of pending tasks. When evaluating “future E,” the newly forked task evaluating “E” is marked active, while the parent task is moved to the pending queue. In the absence of idle processors, the parent task remains in the pending queue until the task evaluating “E” terminates, resulting in the same evaluation order (and memory footprint) as sequential execution, and the pending task queue functions much like the control stack of a sequential execution.

The benefit of the pending task queue is that if another processor becomes idle, it can *steal* and start evaluating one of these pending tasks. In this manner, the number of active tasks in the system is roughly

dynamically balanced with the number of available processors. Each processor typically has just one active task. Once that task terminates, it removes and makes active the next task in its pending queue. If the processor's pending task queue becomes empty, it tries to *steal* and activate a pending task from one of the other processors in the system.

An active task may block by trying to force an undetermined future object. In this situation, the task is typically put on a waiting list associated with that future. Once the future is later determined, all tasks on the waiting list are marked as pending, and will become active once an idle processor is available.

Lazy Task Creation

Lazy task creation [2, 5] provides a mechanism for reducing task creation overhead. Under this mechanism, the evaluation of “future E” does not immediately create a new task. Instead, the expression “E” is evaluated as normal, except that the control stack is marked to identify that the continuation of this future expression is implicitly a pending task.

Later, an idle processor can inspect this control stack to find this implicit pending task, create the appropriate future object, and start executing this pending task. The control stack is also modified so that after the evaluation of “E” terminates, its value is used to resolve that future object.

In the common case, however, the evaluation of “E” will terminate without the implicit pending task having been stolen by a different processor. In this situation, the result of “E” will be returned directly to the context of “future E” which still resides on the control stack, with little additional overhead and without any need to create a new task or future object.

Futures in Purely Functional Languages

Programs in purely functional languages offer numerous opportunities for executing program components in parallel. For example, the evaluation of a function application could spawn a parallel task for the evaluation of each argument expression. Applying such a strategy indiscriminately, however, leads to many parallel tasks whose overhead outweighs any benefits of parallel execution.

Futures provide a simple method for taming the implicit parallelism of purely functional programs. A programmer who believes that the parallel evaluation of some expression outweighs the overhead of creating a separate task may annotate the expression with the keyword “future.” In a purely functional language, these future annotations are *transparent* in that they have no effect on the final values computed by the program, and only influence the amount of parallelism exposed during the program’s computation. Consequently, purely functional programs with future are *deterministic*, just like their sequential counterparts.

F

Futures in Mostly Functional Languages

Futures have been used effectively in “mostly functional” languages such as Multilisp [1] and Scheme [2], where most computation is performed in a functional style and assignment statements are limited to situations where they provide increased expressiveness. In this setting, futures are *not transparent*, as they introduce parallelism that may change the order in which assignments are performed. To preserve determinism, the programmer needs to ensure there are no race conditions between parallel computations, possibly by introducing additional forcing operations that block until a particular task has terminated and all of its side effects have been performed.

Mostly functional languages include a side effect-free subset with substantial expressive power, and so the future construct is still effective for exposing parallelism within functional sub-computations written in these languages.

Deterministic Futures in Imperative Languages

Futures have been combined with transactional memory techniques to guarantee determinism even in the presence of side effects. Essentially, each task is considered to be a transaction, and these transactions must commit in a fixed, as-if-sequential order. Each transaction tracks its read and write sets. If one transaction accesses data that another transaction is mutating, then the later transaction is rolled back and restarted [8].

Futures in Distributed Systems

Future objects have been used in distributed systems to hide the latency associated with a remote procedure call (RPC). Instead of waiting for a message send and a matching response from a remote machine, an RPC can immediately return a future object as a proxy for the eventual result of that call. Note that this future could be returned even before the first RPC message is sent over the network. Consequently, if one machine performs multiple RPCs to the same remote machine, then these calls can all be batched into a single message; this technique is referred to as *promise pipelining*.

Thread-Specific Futures, Resolvable Futures, and I-vars

The programming language construct “future E” described above does not expose the ability to resolve the future to an arbitrary value; it can only be resolved to the result of evaluating the expression “E.”

An *I-var* is analogous to a future object in that it functions as a proxy for a value that may not yet be determined. The key difference is that an I-var does not have an explicit associated thread that is computing its value (as in the case for future objects). Instead, any thread can update or *resolve* the I-var. Thus, an I-var is essentially a single entry, one-shot queue. Attempts to access an I-var before it is determined block, as with future objects.

Somewhat confusingly, the terms “future” and “promise” are sometimes used to mean an I-var object that also exposes this *resolve* operation. The terms “thread-specific future” and “resolvable future” help disambiguate these distinct meanings.

Futures and Lazy Evaluation

Futures are closely related to lazy evaluation, in that both immediately return a placeholder for the result of a pending computation. A major difference is that future expressions typically must be evaluated before program termination, but lazy expressions need not be evaluated before program termination. This semantic difference means that preemptive evaluation of lazy expressions is considered speculative, whereas evaluation of future expressions is considered mandatory.

Sometimes, as in the language Alice ML, the term “lazy future” is used to denote a future whose expression

is evaluated lazily, that is, when the future object is first touched.

Futures and Exceptions

In the construct “future E,” an interesting design choice is how to handle any exceptions that are raised during the evaluation of “E,” since enclosing exception handlers from the context of “future E” may be no longer active. A more general version of this question is how the future construct should interact with call/cc (call-with-current-continuation). This question has been studied by a number of researchers (see, e.g., Moreau [10]), with the goal of providing determinism guarantees in the presence of these constructs.

Some languages take a more pragmatic choice, whereby if “E” raises an exception, then any attempt to touch the corresponding future object will also raise that exception.

Bibliographic Notes and Further Reading

Friedman and Wise introduced the term “promise” in 1976 [7]. Peter Hibbard described a form of explicit futures, called “eventual values,” in the context of Algol [6]. Baker and Hewitt [9] proposed implicit futures for the parallel evaluation of functional languages. Implicit futures were implemented in the Multilisp version of Scheme in the mid-1980s [1], and futures have since been adapted to a variety of other languages and compilers, including the Gambit Scheme compiler [2], Mul-T [5], Butterfly Lisp, Portable Standard Lisp, Act 1, Alice ML, Habanero Java, and many others.

Libraries supporting futures have been implemented for several languages, including (to name just a few of many examples) Java, C++0x, OCaml, python, Perl, and Ruby.

The single-assignment I-var structure originated in Id [12] and was included in subsequent languages such as parallel Haskell and Concurrent ML.

Genome sequencing

Definition

Genome assembly is the computational process of deciphering the sequence composition of the genetic material (DNA) within the cell of an organism, using numerous short sequences called *reads* derived from different portions of the target DNA as input. The term *genome* is a collective reference to all the DNA molecules in the cell of an organism. *Sequencing* generally refers to the experimental (wetlab) process of determining the sequence composition of biomolecules such as DNA, RNA, and protein. In the context of genome assembly, however, the term is more commonly used to refer to the experimental (wetlab) process of generating reads from the set of chromosomes that constitutes the genome of an organism. Genome *assembly* is the computational step that follows sequencing with the objective of reconstructing the genome from its reads.

Discussion

Introduction

Deoxyribonucleic acid (or DNA) is a double-stranded molecule which forms the genetic basis in most known organisms. The DNA along with other molecules, such as the ribonucleic acid (or RNA) and proteins, collectively constitute the subject of study in various

branches of biology such as molecular biology, genetics, genomics, proteomics, and systems biology. A DNA molecule is made up of two equal length strands with opposite directionality, with the ends labeled from 5' to 3' on one and 3' to 5' on the other. Each strand is a sequence of smaller molecules called *nucleotides*, and each nucleotide contains one of the four possible nitrogenous bases – adenine (a), cytosine (c), guanine (g), and thymine (t). Therefore for computational purposes, each strand can be represented in the form of a string over the alphabet {a, c, g, t}, expressed always in the direction from 5' to 3'. Furthermore, the base at a given position in one strand is related to the base at the corresponding position in the other strand by the following base-pairing rule (referred to as "base complementarity"): $a \leftrightarrow t, c \leftrightarrow g$. Therefore, the sequence of one strand can be directly deduced from the sequence of the other. For example, if one strand is 5' agaccaggtaac 3', then the other is 5' gtaactggct 3'.

The length of a genome is measured in the number of its base pairs ("bp"). Genomes range in length from being just a few million base pairs in microbes to several billions of base pairs in many eukaryotic organisms. However, all sequencing technologies available till date, since the invention of Sanger sequencing in late 1970s, have been limited to accurately sequencing DNA molecules no longer than ~1 Kbp. Consequently, scientists have had to deploy alternative sequencing strategies for extending the reach of technology to genome scale. The most popular strategy is the *whole genome shotgun* (or WGS) strategy, where multiple copies of a single long target genome are shredded randomly into numerous fragments of sequenceable length and the corresponding reads sequenced individually using any standard technology. Another popular albeit more expensive strategy is the hierarchical approach, where a library of smaller molecules called Bacterial Artificial Chromosomes (or BACs) is constructed. Each BAC is ~150 Kbp in length and they collectively provide a minimum tiling path over the entire length of the genome. Subsequently, the BACs are sequenced individually using the shotgun approach.

In both approaches, the information of the relative ordering among the sequenced reads is lost during sequencing either completely or almost completely. Therefore, the primary information that genome assemblers should rely upon is the end-to-end sequence

overlap preserved between reads that were sequenced from overlapping regions along the target genome. To increase the chance of overlap, the target genome is typically sequenced in a redundant fashion. This is referred to as *genome coverage*. A higher coverage typically tends to provide information for a more accurate assembly, although at increased costs of generation and analysis. The fact that reads could have originated from an arbitrary strand adds another dimension to the complexity of the reconstruction process. The process is further complicated by other factors such as errors introduced during read sequencing and the presence of genomic repeats that could ambiguously overlap detection and read placement. To partially aid the resolving of the genomic repeat regions, sequencing is sometimes performed in pairs from clonal insert libraries, where the genomic distance between the two reads of a pair can be estimated, typically in the 1–3 Kbp range. This technique is called *pair-end sequencing* and genome assemblers could take advantage of this information to resolve repeats that are smaller than the specified range.

Genome assembly is a classical computational problem in the field of bioinformatics and computational biology. More than two decades of research has yielded a number of approaches and algorithms and yet the problem continues to be actively pursued. This is because of several reasons. While there are different ways of formulating the genome assembly problem, all known formulations are NP-Hard. Therefore, researchers continue to work on developing improved, efficient approximation and heuristic algorithms. However, even the best serial algorithms take tens of thousands of CPU hours for eukaryotic genomes owing to their: large genomic sizes, which increase the number of reads to be analyzed; and high genomic repeat complexity, which adds substantial processing overheads. For instance, in the Celera's WGS version of the human genome assembly published in 2001, over 27 million reads representing 5.11x coverage over the genome were assembled in about 10,000 CPU h.

A paradigm shift in sequencing technologies has further aggravated the data-intensiveness of the problem and thereby the need for continued algorithmic development. Until the mid-2000s, the only available technology for use in genome assembly projects was Sanger sequencing, which produces reads of approximate length 1 Kbp each. Since then, a slew of

high-throughput sequencing technologies, collectively referred to as the *next-generation sequencing technologies*, have emerged, significantly revitalizing the sequencing community. Examples of next-generation technologies include Roche 454 Life Sciences system's pyrosequencing (read length ~400 bp), Illumina Genome Analyzer and HiSeq (read length ~35–125 bp); Life Technologies SOLiD (read length ~50 bp) and Helicos HeliScope (read length ~35 bp). While these instruments generate much shorter reads than Sanger, they do so at a much faster rate effectively producing several hundred millions of reads in a single experiment, and at significantly reduced costs (about 30–40 times cheaper). These attractive features are essentially democratizing the sequencing process and broadening community contribution to sequenced data. From a genome assembly perspective, a shorter read length could easily deteriorate the assembly quality because the reads are more likely to exhibit false or insufficient overlaps. To offset this shortcoming, sequencing is required at a much higher coverage (30x–200x) than for Sanger sequencing. The higher coverage has another desirable effect in that, because of its built-in redundancy, it could aid in a more reliable identification of real genomic variations and their differentiation from experimental artifacts. Detecting genomic variations such as single nucleotide polymorphisms (SNPs) is of prime importance in comparative and population genomics.

This combination of high coverage and short read lengths makes the short read genome assembly problem significantly more data-intensive than for Sanger reads. For instance, any project aiming to reconstruct a mammalian genome (e.g., human genome) *de novo* using any of the current next-generation technologies would have to contend with finding a way to assemble several billion short reads. This changing landscape in technology and application has led to the development of a new generation of short read assemblers. Although traditional developmental efforts have been targeting serial computers, the increasing data-intensiveness and the increasing complexity of genomes being sequenced have gradually pushed the community toward parallel processing, for what has now become an active branch within the area.

In what follows, an overview of the assembly problem, with its different formulations and algorithmic solutions is presented. This entry is not intended to be

a survey of tools for genome assembly. Rather, it will focus on the parallelism in the problem and related efforts in parallel algorithm development. In order to set the stage, the key ideas from the corresponding serial approach will also be presented as necessary. The bulk of the discussion will be on *de novo assembly*, which is typically the harder task of reconstructing a genome from its reads assuming no prior knowledge about the sequence of the genome except for its reads and as available, their pair-end sequencing information.

Algorithmic Formulations of Genome Assembly

The genome assembly problem: Let $R = \{r_1, r_2 \dots r_m\}$ denote a set of m reads sequenced from an unknown target genome G of length g . The problem of genome assembly is to reconstruct the sequence of genome G from R .

As a caveat, for nearly all input scenarios, the outcome expected is not a single assembled sequence but a *set of assembled sequences* for a couple of reasons. Typically, the genome of a species comprises of multiple chromosomes (e.g., 23 pairs in the human genome) and therefore each chromosome can be treated as an individual sequence target. Note that, however, the information about the source chromosome for a read is lost during a sequencing process such as WGS and it is left for the assembler to detect and sort these reads by chromosomes. Furthermore, any shotgun sequencing procedure tends to leave out “gaps” along the chromosomal DNA during sampling, and therefore it is possible to reconstruct the genome only for those sampled sections. It is expected that, through incorporation of pair-end information, at least a subset of these assembled products (called “contigs” in genome assembly parlance) can be partially ordered and oriented.

Notation and terminology: Let s denote a sequence over a fixed alphabet Σ . Unless otherwise specified, a DNA alphabet is assumed – i.e., $\Sigma = \{a, c, g, t\}$. Let $|s|$ denote the length of s ; and $s[i \dots j]$ denote the substring of s starting and ending at indices i and j respectively, with the convention that string indexing starts at 1. A *prefix* i (alternatively, *suffix* i) of s is $s[1 \dots i]$ (alternatively, $s[i \dots |s|]$). Let $n = \sum_{i=1}^m |r_i|$ and $\ell = \frac{n}{m}$. The sequencing coverage c is given by $\frac{g}{n}$. The terms *string* and *sequence* are used interchangeably. Let p denote the number of processors in a parallel computer.

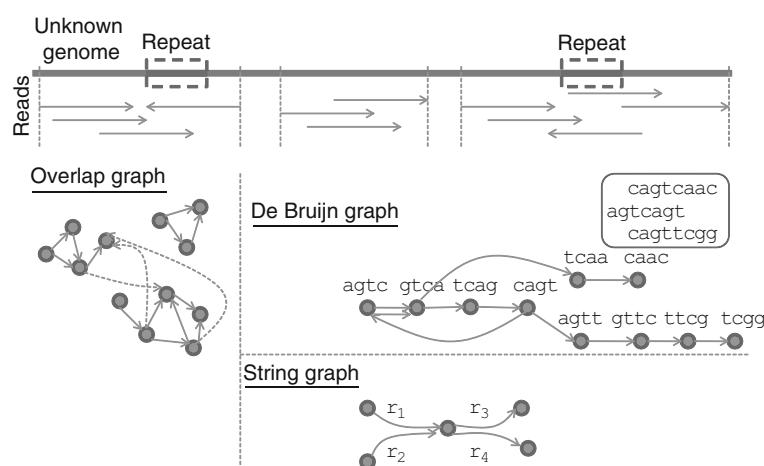

The most simplistic formulation of genome assembly is that of the *Shortest Superstring Problem* (SSP). A *superstring* is a string that contains each input read as a substring. The SSP formulation is NP-complete. Furthermore, its assumptions are not realistic in practice. Reads can contain sequencing errors and hence they need not always appear preserved as substrings in the genome; and genomes typically are longer than the shortest superstring due to presence of repeats and nearly identical genic regions (called paralogs).

Among the more realistic models for genome assembly, graph theoretic formulations have been in the forefront. In broad terms, there are three distinct ways to model the problem (refer to Fig. 1):

(1) *Overlap graph*: Construct graph $G(V, E)$ from R , where each read is represented by a unique vertex in V and an edge is drawn between (r_i, r_j) iff there is a significant suffix–prefix overlap between r_i and r_j . *Overlap* is typically defined using a pairwise sequence alignment model (e.g., semi-global alignment) and related metrics to assess the quality of an alignment. Given G , the genome assembly problem can be reduced to the problem of finding a Hamiltonian Path, if one exists, provided that there were no breaks (called sequencing gaps) along the genome during sequencing. If there

were gaps during sequencing, then one Hamiltonian Path is sought for every connected component in G (if it exists) and the genome can be recovered as an unordered set of pieces corresponding to the sequenced sections. This formulation using the overlap graph model has been shown to be NP-Hard.

- (2) *De Bruijn graph*: Let a k -mer denote a string of length k . Construct a De Bruijn graph, where the vertex set is the set of all k -mers contained inside the reads of R ; and a directed edge is drawn from vertices i to j , iff the $k - 1$ length suffix of the k -mer i is identical to the $k - 1$ length prefix of the k -mer j . Put another way, each edge in E represents a unique $k + 1$ -mer that is found in at least one of the reads in R . Given a De Bruijn graph G , genome assembly is the problem of finding a shortest Euler tour in which each read is represented by a sub-path in the tour. While finding an Euler tour is polynomially solvable, the optimization problem is still NP-Hard by reduction from SSP.
- (3) *String graph*: This model is a variant of the overlap graph in which the edges represent reads, and vertices represent branching of end-to-end overlaps of the adjoining reads. For example, if a read r_i overlaps with both r_j and r_k then it is represented by a vertex

Genome Assembly. Fig. 1 Illustration of the three different models for genome assembly. The top section of the figure shows a hypothetical unknown genome and the reads sequenced from it. The dotted box shows a repetitive region within the genome. In the overlap graph, solid lines indicate true overlaps and dotted lines show overlaps induced by the presence of the repeat. The De Bruijn graph shows the graph for an arbitrary section involving three reads. The string graph shows an example of a branching vertex with multiple possible entry and exit paths

which has an inbound edge corresponding to r_i and two outbound edges representing r_j and r_k . Furthermore, the graph is pruned off transitively inferable edges – e.g., if both r_i and r_j overlaps with r_k , whereas r_i also overlaps with r_j , then the overlap from r_j to r_k is inferable and is therefore removed. Given a string graph G , the assembly problem becomes one that is equivalent of finding a constrained least cost Chinese Postman tour of G . This formulation has also been shown to be NP-Hard.

All the three formulations incorporate features to handle sequencing errors. In the overlap graph model, the pairwise alignment formulation used to define edges automatically takes into account character substitutions, insertions, and deletions. In the other two models, an “error correction” procedure is run as a preprocessing step to mask off anomalous portions of the graph prior to performing the assembly tours.

Parallelization for the Overlap Graph Model

Algorithms that use the overlap graph model deploy a three-stage assembly approach of *overlap-layout-consensus*. In the first stage, the overlap graph is constructed by performing all-against-all pairwise comparison of the reads in R . As a result, a layout for the assembly is prepared using the pairwise overlaps and in the third stage, a multiple sequence alignment (MSA) of the reads is performed as dictated by the layout. Given the large number of reads generated in a typical sequencing project, the overlap computation phase dominates the run-time and hence is the primary target for parallelization and performance optimization.

A brute-force way of implementing this step will be to compare all $\binom{m}{2}$ possible pairs. This approach can also be parallelized easily, as individual alignment tasks can be distributed in a load-balanced fashion given the uniformity expected in the read lengths. However, an implementation may not be practically feasible for larger number of reads due to the quadratic increase in alignment workload. Each alignment task executed serially could take milliseconds of run-time. In fact, for the assembly problem, the nature of sampling done during sequencing guarantees that performing all-against-all comparisons is destined to be highly wasteful. This is because of the random shotgun approach to sequencing

which is expected to sample roughly equal number of reads covering each genomic base and it is typically only reads that originate from the same locus that tend to overlap with one another, with the exception of reads from repetitive regions of the genome.

A more scalable approach to detect pairwise overlaps is to first shortlist pairs of sequences based on the presence of sufficiently long exact matches (i.e., a filter built on a necessary-but-not-a-sufficient condition) and then compute pairwise comparisons only on them. Methods vary in the manner in which these “promising pairs” are shortlisted. One way of generating promising pairs is to use a string lookup table data structure that is built to record all k -mer occurrences within the reads in linear time. Sequence pairs that share one or more k -mers can be subsequently considered for alignment-based evaluation. While this approach supports a simple implementation, it poses a few notable limitations. The size complexity of the lookup table data structure contains an exponential term $O(|\Sigma|^k)$. This restricts the value of k in practice; for DNA alphabet, physical memory constraints demand that $k \leq 15$. Whereas, reads could share arbitrarily long matches, especially if the sequencing error rates are low. Another disadvantage of the lookup table is that it is only suited to detect pairs with fixed length matches. An exact match of an arbitrary length q will reveal itself as $q - k + 1$ smaller k -mer matches, thus increasing computation cost. Furthermore, the distribution of entries within the lookup table is highly data dependent and could scatter the same sequence pair in different locations of the lookup table, making it difficult for parallelization on distributed memory machines. Methods that use lookup tables simply use a high end shared memory machine for serial generation and storage, and focus on parallelizing only the pairwise sequence comparison step.

An alternative albeit more efficient way of enumerating promising pairs based on exact matches is to use a string indexing data structure such as suffix tree or suffix array that will allow detection of *variable* length matches. A match α between two reads r_i and r_j is called *left-maximal* (alternatively, *right-maximal*) if the characters preceding (alternatively, following) it in both strings, if any, are different. A match α between reads r_i and r_j is said to be a *maximal match* between the two reads if it is both left- and right-maximal. Pairs containing maximal matches of a minimum length cutoff, say

ψ , can be detected in optimal run-time and linear space using a suffix tree data structure. A generalized suffix tree of a set of strings is the compacted trie of all suffixes in the strings. The pair enumeration algorithm first builds a generalized suffix tree over all reads in R and then navigates the tree in a bottom-up order.

Parallel Generalized Suffix Tree Construction

For constructing a suffix tree, there are several linear time construction serial algorithms and optimal algorithms for the CRCW-PRAM model. However, optimal construction under the distributed memory machine model, where memory per processor is assumed to be too small to store the input sequences in R , is an open problem. Of the several approaches that have been studied, the following approach is notable as it has demonstrated linear scaling to thousands of processors on distributed memory supercomputers.

The major steps of the underlying algorithm are as follows. Each step is a parallel step. The steps marked as *comm* are communication-bound and the steps marked *comp* are computation-bound.

S1. (*comp*) Load R from I/O in a distributed fashion such that each processor receives $O\left(\frac{n}{p}\right)$ characters and no read is split across processor boundaries.

S2. (*comp*) Slide a window of length $k \leq \psi$ over the set of local reads and bucket sort locally all suffixes of reads based on their k length prefix. Note that for DNA alphabet, even a value as small as 10 for k is expected to create over a million buckets, sufficient to support parallel distribution. An alternative to local generation of buckets is to have a master-worker paradigm where the reads are scanned in small-sized batches and have a dedicated master distribute batches to workers in a load-balanced fashion.

S3. (*comm*) Parallel sort the buckets such that each processor receives approximately $\sim \frac{n}{p}$ suffixes and no bucket is split across processor boundaries. While the latter cannot be theoretically guaranteed, real-world genomic data sets typically distribute the suffixes uniformly across buckets thereby virtually ensuring that no bucket exceeds the $O\left(\frac{n}{p}\right)$ bound. If a bucket size becomes too big to fit in the local memory, then an alternative strategy can be deployed

whereby the prefix length for bucketing is iteratively extended until the size of the bucket fits in the local memory.

S4. (*comm, comp*) Each bucket in the output corresponds to a unique subtree in the generalized suffix tree rooted exactly k characters below the root. The subtree corresponding to each bucket is then locally constructed using a recursive bucket sort-based method that compares characters between suffixes. However, this step cannot be done strictly locally because it needs the sequences of reads whose suffixes are being compared. This can be achieved by building the local set of subtrees in small-sized batches and performing one round of communication using *Alltoallv()* to load the reads required to build each batch from other processors. In order to reduce the overhead due to read fetches, observe that the aggregate memory on a relatively small group of processors is typically sufficient to accommodate the read set for most inputs in practice. For example, even a set of 100 million reads each of length 1Kbp needs only of the order of 100 GB. Even assuming 1 GB per processor, this means the read set will fit within 100 processors. Higher number of processors is required only to speedup computation. One could take advantage of this observation by partitioning the processor space into subgroups of fixed, smaller size, determined by the input size, and then have the on-the-fly read fetches to seek data from processors from within each subgroup. This improved scheme could distribute the load of any potential hot spots and also the overall communication could be faster as the collective transportation primitive now operates on a smaller number of processors.

The above approach can be implemented to run in $O\left(\frac{n\ell}{p}\right)$ time and $O\left(\frac{n}{p}\right)$ space, where ℓ is the mean read length. The output of the algorithm is a distributed representation of the generalized suffix tree, with each processor storing roughly $\frac{n}{p}$ suffixes (or leaves in the tree).

The *cluster-then-assemble* Approach

A potential stumbling block in the overlap-layout-consensus approach is the large amount of memory required to store and retrieve the pairwise overlaps so that they can be used for generating an assembly layout. For genomes which have been sequenced at a uniform

coverage c , the expectation is that each base along the genome is covered by c reads on average, thereby implying $\binom{c}{2}$ overlapping read pairs for every genomic base. However, this theoretical linear expectation holds for only a fraction of the target genome, whereas factors such as genomic repeats and oversampled genic regions could increase the number of overlapping pairs arbitrarily beyond the expected level. An example case in point is the gene-enriched sequencing of the highly repetitive ~2.5 billion bp maize genome.

One way to overcome this scalability bottleneck is to use clustering as a preprocessing step to assembly. This approach, referred to as *cluster-then-assemble*, builds upon the assumption that any genome-scale sequencing effort is likely to undersample the genome, leaving out sequencing gaps along the genome length and thereby allowing the assemblers to reconstruct the genome in pieces – one piece for every contiguous stretch of the genome (aka “contig” or “genomic island”) that is fully sampled through sequencing. This assumption is not unrealistic as tens of thousands of sequencing gaps have always resulted in almost all eukaryotic genomes sequenced so far using the WGS approach. The cluster-then-assemble takes advantage of this assumption as follows: The set of m reads is first partitioned into groups using a single-linkage transitive closure clustering method, such that there exists a sequence of overlapping pairs connecting every read to every other read in the same cluster. Ideally, each cluster

should correspond to one genomic island, although the presence of genomic repeats could collapse reads belonging to different islands together. Once clustered, each cluster represents an independent subproblem for assembly, thereby breaking a large problem with m reads into numerous, disjoint subproblems of significantly reduced size small enough to fit in a serial computer. In practice, tens of thousands of clusters are generated making the approach highly suited for trivial parallelization after clustering.

The primary challenge is to implement the clustering step in parallel, in a time- and space-efficient manner. In graph-theoretic terms, the output produced by a transitive closure clustering is representative of connected components in the overlap graph, thereby allowing the problem to be reduced to one of connected component detection. However, generating the entire graph G prior to detection would contradict the purpose of clustering from a space complexity standpoint.

Figure 2 outlines an algorithm to perform sequence clustering. The algorithm can be described as follows: Initialize each read in a cluster of its own. In an iterative process, generate promising pairs based on maximal matches in a non-increasing order of their lengths using suffix trees (as explained in the previous section). Before assigning a promising pair for further alignment processing, a check is made to see whether the constituent reads are in the same cluster. If they are part of the same cluster already, then the pair is discarded; otherwise it

Algorithm 1 Read Clustering

```

Input: Read set  $R = \{r_1, r_2, \dots, r_m\}$ 
Output: A partition  $C = \{C_1, C_2, \dots, C_k\}$  of  $R$ ,  $1 \leq k \leq m$ 

1. Initialize Clusters:
    $C \leftarrow \{\{r_i\} \mid 1 \leq i \leq m\}$   $\Rightarrow (\text{master})$ 
2. FOR each pair  $(r_i, r_j)$  with a maximal match of length  $\geq \psi$ 
   generated in non-increasing order of maximal match length  $\Rightarrow (\text{worker})$ 
    $C_p \leftarrow \text{Find}(r_i)$   $\Rightarrow (\text{master})$ 
    $C_q \leftarrow \text{Find}(r_j)$   $\Rightarrow (\text{master})$ 
   IF  $C_p \neq C_q$  THEN  $\Rightarrow (\text{master})$ 
     overlap quality  $\leftarrow \text{Align}(r_i, r_j)$   $\Rightarrow (\text{worker})$ 
     IF overlap quality is significant THEN  $\Rightarrow (\text{master})$ 
        $\text{Union}(C_p, C_q)$   $\Rightarrow (\text{worker})$ 
3. Output  $C$   $\Rightarrow (\text{master})$ 
```

Genome Assembly. Fig. 2 Pseudocode for a read clustering algorithm suited for parallelization based on the master-worker model. The site of computation is shown in brackets. Operations on the set of clusters are performed using the Union-Find data structure

is aligned. If the alignment results show a satisfactory overlap (based on user-defined alignment parameters), then merge the clusters containing both reads into one larger cluster. The process is repeated until all promising pairs are exhausted or until no more merges are possible. Using the union–find data structure would ensure the *Find* and *Union* calls to run in amortized time proportional to the Inverse Ackerman function – a small constant for all practical inputs.

There are several advantages to this clustering strategy. Clustering can be achieved in at most $m - 1$ merging steps. Checking if a read pair is already clustered before alignment is aimed at reducing the number of pairs aligned. Generating promising pairs in a non-increasing order of their maximal match lengths is a heuristic that could help identify pairs that are more likely to succeed the alignment test sooner during execution. Furthermore, promising pairs are processed as they are generated, obviating the need to store them. This coupled with the use of the suffix tree data structure implies an $O(n)$ serial space complexity for the clustering algorithm.

The parallel algorithm can be implemented using a master–worker paradigm. A dedicated master processor can be responsible for initializing and maintaining the clusters and also for distributing alignment workload to the workers in a load-balanced fashion. The workers at first can generate a distributed representation of the generalized suffix tree in parallel (as explained in the previous section). Subsequently, they can generate promising pairs from their local portion of the tree and send them to the master. To reduce communication overheads, pairs can be sent in arbitrary-sized batches as demanded by the situation of the work queue buffer at the master. The master processor can check the pairs against the current set of clusters, filter out pairs that do not need alignment, and add only those pairs that need alignment to its work queue buffer. The pairs in the work queue buffer can be redistributed to workers in fixed size batches, to have the workers compute alignments and send back the results. Communication overheads can be masked by overlapping alignment computation with communication waits using non-blocking calls. The PaCE software suite implements the above parallel algorithm, and it has demonstrated linear scaling to thousands of processors on a distributed memory supercomputer.

Short Read Assembly

The landscape of genome assembly tools has significantly transformed itself over the last few years with the advent of next-generation sequencing technologies. A plethora of new-generation assemblers that collectively operate under the banner of “short read assemblers” is continuing to emerge. Broadly speaking, these tools can be grouped into two categories: (1) those that follow or extend from the classical overlap graph model; and (2) those that deploy either the De Bruijn graph or the string graph formulation. The former category includes programs such as Edena, Newbler, PE-Assembler, QSRA, SHARCGS, SSAKE, and VCAKE. The programs that fall under the latter category are largely inspired by two approaches – the De Bruijn graph formulation used in the EULER assembler; and the string graph formulation proposed by Myers. As of this writing, these programs include EULER-SR, ALLPATHS, Velvet, SOAPdenovo, ABySS, and YAGA. Either of these lists is likely to expand in the coming years, as new implementations of short read assemblers are continuing to emerge as are new technologies.

In principle, the techniques developed for assembling Sanger reads do not suit direct application for short read assembly due to a combination of factors that include shorter read length, higher sequencing coverage, an increased reliance on pair-end libraries, and idiosyncrasies in sequencing errors.

A shorter read length implies that the method has to be more sensitive to differences to avoid potential mis-assemblies. This also means providing a robust support for incorporating the knowledge available from pair-end libraries. In case of next-generation sequencing, pair-end libraries are typically available for different clone insert sizes, which translates to a need to implement multiple sets of distance constraints.

A high sequencing coverage introduces complexity at two levels. The number of short reads to assemble increases linearly with increased coverage, and this number can easily reach hundreds of millions even for modest-sized genomes because of shorter read length. For instance, a mid-size genome such as that of *Arabidopsis* (~115 Mbp) or fruit fly (~120 Mbp) sequenced at 100x coverage either using Illumina or SOLiD would generate a couple of hundred million reads. Secondly, the average number of overlapping read

pairs at every given genomic location is expected to grow quadratically ($\propto \binom{c}{2}$) with the coverage depth (c). This particularly affects the time and memory scalability of methods that use the overlap graph model not only because they operate at the level of pairwise read overlaps, but also because many tools assume that such overlaps can be stored and retrieved from local memory. Consequently, such methods take between 6–10 h and several gigabytes of memory even for assembling small bacterial genomes. From a parallelism perspective, a high coverage in sampling could also potentially mean fewer sequencing gaps, as the probability of a genomic base being captured by a read improves with coverage by the Lander–Waterman model. Therefore, divide-and-conquer-based techniques such as the cluster-then-assemble may not be as effective in breaking the initial problem size down.

Short read assemblers also have to deal with technology specific errors. The error rates associated with next-generation technologies are typically in the 1–5% range, and cannot be ignored as differentiating them from real differences could be key to capturing natural variations such as near identical paralogs.

In the current suite of tools specifically built for short read assembly, only a handful of tools support some degree of parallelism. These tools include PE-Assembler, ABySS, and YAGA. Others are serial tools that work on desktop computers and rely on high-memory nodes for larger inputs. Even the tools that support parallelism do so to varying degrees. PE-Assembler, which implements a variant of the overlap graph model, limits parallelism to node level and assumes that the number of parallel threads is small (< 10). It deploys a “seed-extend” strategy in which a subset of “reliable” reads are selected as seeds and other reads that overlap with each seed are incrementally added to extend and build into a consensus sequence in the 3' direction. Parallelism is supported by selecting multiple seeds and launching multiple threads that assume responsibility of extending these different reads in parallel. While the algorithm has the advantage of not having to build and manage large graphs, it performs a conservative extension primarily relying on pair-end data to collapse reads into contigs. From a parallelism perspective, the algorithm relies on shared memory access for managing the read set, which works well if the number of threads is very small. Furthermore, not

all steps in the method are parallel and some steps are disk-bound. Experimental results show that the parallel efficiency drops drastically beyond three threads.

ABySS and YAGA are two parallel methods that implement the De Bruijn graph model and work for distributed memory computers. The De Bruijn and string graph formulations are conceptually better suited for short read assembly. These formulations allow the algorithm to operate at a read or read's subunit (i.e., k -mer) level rather than the pairwise overlap level. Repetitive regions manifest themselves in the form of special graph patterns, and error correction mechanism could detect and reconcile anomalous graph substructures prior to performing assembly tours, thereby reducing the chance of misassemblies. The assembly itself manifests in the form of graph traversals. Constructing these graphs and traversing them to produce assembly tours (although not guaranteed to be optimal due to intractability of the problem) are problems with efficient heuristic solutions on a serial computer. The methods ABySS and YAGA provide two different approaches to implement the different stages in parallel using De Bruijn graphs. While these methods differ in their underlying algorithmic details and in the degree offered for parallelism, the structural layout of their algorithms is similar consisting of these four major steps: (1) parallel graph construction; (2) error correction; (3) incorporation of distance constraints due to pair-end reads; and (4) assembly tour and output.

In what follows, approaches to parallelize each of these major steps are outlined, with the bulk of exposition closely mirroring the algorithm in YAGA because its algorithm more rigorously addresses parallelization for all the steps, and takes advantage of techniques that are more standard and well understood among distributed memory processing codes (e.g., sorting, list ranking). By contrast, parallelization is described only for the initial phase of graph construction in ABySS. Therefore, where appropriate, variations in the ABySS algorithmic approach will be highlighted in the text. Other than differences in their parallelization strategies, the two methods also differ particularly in the type of De Bruijn graph they construct (directed vs. bidirected) and their ability to handle multiple read lengths. Such details are omitted in an attempt to keep the text focused on the parallel aspects of the problem. An interested reader can refer to the individual papers for details

pertaining to the nuances of the assembly procedure and the output quality of these assemblies.

Parallel De Bruijn Graph Construction and Compaction

Given m reads in set R , the goal is to construct in parallel a distributed representation of the corresponding De Bruijn graph built out of k -mers, for a user-specified value of k . Note that, once a De Bruijn graph representation is generated, it can be transformed into a corresponding string graph representation by compressing paths whose label when concatenated spells out the characters in a read, and by accordingly introducing branch nodes that capture overlap continuation between adjoining reads. This can be done in a successive stage of graph compaction, a minor variant of which is described in the later part of this section. The computing model assumed is p processors (or equivalently, processes), each with access to a local RAM, and connected through a network interconnect and with access to a shared file system where the input is made available.

To construct the De Bruijn graph, the reads in R are initially partitioned and loaded in a distributed manner such that each processor receives $O\left(\frac{n}{p}\right)$ input characters. Let R_i refer to the subset of reads in processor p_i . Through a linear scan of the reads in R_i , each p_i enumerates the set of k -mers present in R_i . However, instead of storing each such k -mer as a vertex of the De Bruijn graph, the processor equivalently generates and stores the corresponding edges connecting those vertices in the graph. In other words, there is a bijection between the set of edges and the set of distinct $k + 1$ -mers in R_i . In this edge-centric representation, the vertex information connecting each edge is implicit and the count of reads containing a given $k + 1$ -mer is stored internally at that edge. Note that after this generation process, the same edge could be potentially generated at multiple processor locations. To detect and merge such duplicates, the algorithm simply performs a *parallel sort* of the edges using the $k + 1$ -mers as the key. Therefore, in one sorting step, a distributed representation of the De Bruijn graph is constructed. Standard parallel sort routines such as sample sort can be used here to ensure even redistribution of the edges across processors due to sorting.

An alternative to this edge-centric representation is a vertex-centric representation, which is followed in ABySS and in an earlier version of YAGA. Here, the k -mer set corresponding to each R_i is generated by the corresponding p_i . The vertices adjacent to a given vertex could be generated remotely by one or more processors. Therefore, this approach necessitates processors to communicate with one another in order to check the validity of all edges that could be theoretically drawn from its local set of vertices. While the number of such edge validation queries is bounded by 8 per vertex ($\{a, c, g, t\}$ on either strand orientation), the method runs the risk of generating false edges, e.g., if a $k - 1$ -mer, say α , occurs in exactly two places along the genome as aac and gat , then the vertex-centric approach will erroneously generate edges for aat and gac , which are $k + 1$ -mers nonexistent in the input. Besides this risk, care must be taken to guarantee an even redistribution of vertices among processors by the end of the construction process. For instance, a static allocation scheme in which a hash function is used to map each k -mer to a destination processor, as it is done in ABySS, runs the risk of producing unbalanced distribution as the k -mer concentration within reads is input dependent.

Graph compaction: Once a distributed edge-centric representation of the De Bruijn graph is generated, the next step is to simplify it by identifying maximal segments of simple paths (or “chains”) and compact each of them into a single longer edge. Edges that belong to a given chain could be distributed and therefore this problem of removing chains becomes a two-step process: First, to detect the edges (or equivalently, the vertices) which are part of chains and then perform compaction on the individual chains. To mark the vertices that are part of some chain, assume without loss of generality that each edge is stored twice as $< u, v >$ and $< v, u >$. *Sorting* the edges in parallel by their first vertex it would bring all edges incident on a vertex together on some processor. Only those vertices that have a degree of two can be part of chains and such vertices can be easily marked with a special label. In the next step, the problem of compacting the vertices along each chain can be treated as a variant of *segmented parallel list ranking*. A distributed version of the list ranking algorithm can be used to calculate the relative distances of each marked vertex from the start and end of its respective chain. The same procedure can also be used to determine the

vertex identifiers of those two boundary vertices for each marked vertex. Compaction then follows through the operations of concatenating the edge labels along the chain at one of the terminal edges, removing all internal edges, and aggregating an average $k + 1$ -mer frequency of the constituent edges along the chain. All of these operators are binary associative to allow being implemented using calls to a segmented parallel prefix routine. The output of this step is a distributed representation of the compacted graph.

Error Correction and Variation Detection

In the De Bruijn graph representation, errors due to sequencing manifest themselves as different subgraph motifs which could be detected and pruned. For ease of exposition, let us informally call an edge in the compacted De Bruijn graph as being “strongly supported” (alternatively, “weakly supported”) if its average $k + 1$ -mer frequency is relatively high (alternatively, low). Examples of motifs are follows: (1) *Tips* are weakly supported dead ends in the graph created due to a base miscall occurring in a read at one of its end positions. Because of compaction such tips occur as single edges branching out of a strongly supported path, and can be easily removed; (2) *Bubbles* are detours that provide alternative paths between two terminal vertices. Due to compaction, these detours will also be single edges. There are two types of bubbles – weakly supported bubbles are manifestations of single base miscall occurring internal to a read and need to be removed; whereas, bubbles that originate from the same vertex and are supported roughly to the same degree could be the result of natural variations such as near identical paralogs (i.e., copies of the same gene occurring at different genomic loci). Such bubbles need to be retained. (3) *Spurious links* connect two otherwise disparate paths in the graph. Weakly supported links are manifestations of erroneous $k + 1$ -mers that happen to match the $k + 1$ -mer present at a valid genomic locus, and they can be severed by examining the supports of the other two paths.

The first pass of error correction on the compacted graph could reveal new instances of motifs that can be pruned through iterative passes subsequently until no new instances are observed.

Incorporation of Distance Constraints Using Pair-End Information

The goal of this step is to map the information provided by read pairs that are linked by the pair-end library onto the compacted and error corrected De Bruijn graph. Once mapped, this information can be used to guide the assembly tour of the graph consistent (to the extent possible) with the distance constraints imposed by the pair-end information. To appreciate the value added by this step to the assembly procedure, recall that the pair-end information consists of a list of read pairs of the form $\langle r_i, r_j \rangle$ that have originated from the same clonal insert during sequencing. In genomic distance parlance, this implies that the number of bases separating the two reads is bounded by a minimum and maximum. Also recall that an assembly from a De Bruijn graph corresponds to a tour of the graph (possibly multiple tours if there were gaps in the original sequencing). Now consider a scenario where a path in the De Bruijn graph branches into multiple separate subpaths. A correct assembly tour would have to decide which of those branches reflect the sequence of characters along the unknown genome. It should be easy to see how pair-end information can be used to resolve such situations.

To incorporate the information provided in the form of read pairs by such pair-end libraries, the YAGA algorithm uses a *cluster summarization* procedure, which can be outlined as follows: First, the list of read pairs provided as input by the pair-end information is delineated into a corresponding list of constituent $k + 1$ -mer pairs. Note that two $k + 1$ -mers from two reads of a pair can map to two different edges on the distributed graph. Furthermore, different positions along the same edge could be paired with positions emanating from different edges. To this effect, the algorithm attempts to compute a grouping of edge pairs based on their best alignment with the imposed distance constraints. To achieve this, an observed distance interval is computed between every edge pair on the graph linked by a read pair, and then overlapping intervals that capture roughly the same distances along the same orientation are incrementally clustered using a greedy heuristic. This last step is achieved using a two-phase clustering step that primarily relies on several rounds of *parallel sorting* tuples containing edge pair and interval distance information. The formal details pertaining to this algorithmic step has been omitted here for brevity.

Completing the Assembly Tour

An important offshoot of the above summarization procedure is that redundant distance information captured by edge pairs in the same cluster can be removed, thereby allowing significant compression in the level of information needed to store relative to the original graph. This compression, in most practical cases, would allow for the overall tour to be performed sequentially on a single node. The serial assembly touring procedure begins by using edges that have significantly longer edge labels than the original read length as “seeds,” and then by extending them in both directions as guided by the pair-end summarization traversal constraints.

The YAGA assembler has demonstrated scaling on 512 IBM BlueGene/L processors and performs assembly of over a billion synthetically generated reads in under 2 h. The run-time is dominated by the pair-end cluster summarization phase. As of this writing, performance-related information is not available for ABySS.

Future Trends

Genome sequencing and assembly is an actively pursued, constantly evolving branch of bioinformatics. Technological advancements in high-throughput sequencing have fueled algorithmic innovation and along with a compelling need to harness new computing paradigms. With the adoption of ever faster, cheaper, and massively parallel sequencing machines, this application domain is becoming increasingly data- and compute-intensive. Consequently, parallel processing is destined to play a critical role in genomic discovery.

Numerous large-scale sequencing projects including the 2001 assembly of the human genome to the most recent 2009 assembly of the maize genome have benefited from the use of parallel processing, although in different ad hoc ways. Heterogeneous clusters comprising of a mixture of a few high-end shared memory machines along with numerous compute nodes have been used to “farm” out tasks and accelerate the overlap computation phase in particular. This is justified because nearly all of these large-scale projects used the more traditional Sanger sequencing. A few special-purpose projects such as the 2005 maize gene-enriched sequencing used more strongly coupled parallel codes such as PaCE. However, with an aggressive adoption of next-generation sequencing for genome sequencing

and more complex genomes in the pipeline for sequencing (e.g., wheat, pine, metagenomic communities), this scenario is about to change, and more strongly coupled parallel codes are expected to become part of the mainstream computing in genome assembly.

In addition to *de novo* sequencing, next-generation sequencing is also increasingly being used in *genome resequencing* projects, where the goal is to assemble a genome of a particular variant strain (or subspecies) of an already sequenced genome. The type of computation that originates is significantly different from that of *de novo* assembly. For resequencing, the reads generated from a new strain are compared against a fully assembled sequence of a reference strain. This process, sometimes called *read mapping*, only requires comparison of reads against a much larger reference. Approaches that capitalize on advanced string data structures such as suffix trees are likely to play an active role in these algorithms. Also, as this branch of science becomes more data-intensive, reaching the petascale range, different parallel paradigms such as MapReduce need to be explored, in addition to distributed memory and shared memory models. The developments in genome sequencing can be carried over to other related applications that also involve large-scale sequence analysis, e.g., in transcriptomics, metagenomics, and proteomics.

Fine-grain parallelism in the area of string matching and sequence alignment has been an active pursued topic over the last decade and there are numerous hardware accelerators for performing sequence alignment on various platforms including General Purpose Graphical Processing Units, Cell Broadband Engine, Field-Programmable Gate Arrays, and Multicores. These advances are yet to take their place in mainstream sequencing projects.

Genome sequencing is at the cusp of revolutionary possibilities. With a rapidly advancing technology base, the possibility of realizing landmark goals such as personalized medicine and “\$1,000 genome” do not look distant or far-fetched. The well-advertised \$10 million Archon Genomics X PRIZE will be awarded to the first team that sequences 100 human genomes in 10 days, at a recurring cost of no more than \$10,000 per genome. In 2010, the cost for sequencing a human genome plummeted below \$10,000 using technologies from Illumina and SOLiD. Going past these next-generation technologies, however, companies such as

Pacific Biosciences are now releasing a third-generation (“gen-3”) sequencer that uses an impressive approach called single-molecule sequencing (or “SMS”) [9], and have proclaimed grand goals such as sequencing a human genome in 15 min for less than \$100 by 2014. These are exciting times for genomics, and the field is likely to continue serving as a rich reservoir for new problems that pose interesting compute- and data-intensive challenges which can be addressed only through a comprehensive embrace of parallel computing.

Bibliographic Notes and Further Reading

Even though DNA sequencing technologies have been available since the late 1970s, it was not until the 1990s that they were applied at a genome scale. The first genome to be fully sequenced and assembled was the ~1.8 Mbp bacterial genome of *H. influenzae* in 1995 [8]. The sequencing of the more complex, ~3 billion bp long human genome followed [27]. Several other notable large-scale sequencing initiatives followed in the new millennium including that of chimpanzee, rice, and maize (to cite a few examples). All of these used either the WGS strategy or hierarchical strategy coupled with Sanger sequencing, and their assemblies were performed using programs that followed the overlap–layout–consensus model. The National Center for Biotechnology Information (NCBI) (<http://www.ncbi.nlm.nih.gov>) maintains a comprehensive database of all sequenced genomes. More than a dozen programs exist to perform genome assembly under the overlap–layout–consensus model. Notable examples include PCAP [12], Phrap (<http://www.phrap.org/>), Arachne [2], Celera [22], and TIGR assembler [26]. For a detailed review of fragment assembly algorithms, refer to [7, 24]. The parallel algorithm that uses the cluster-then-assemble approach along with the suffix tree data structure for assembly was implemented in a program called PaCE and was first described in [16] in the context of clustering Expressed Sequence Tag data and then later adapted for genome assembly [17]. Experiments

conducted as part of the maize genome sequencing consortium demonstrated scaling of this method to over a million reads generated from gene-enriched fractions of the maize genome on a 1,024 node BlueGene/L supercomputer [17]. The parallel suffix tree construction algorithm described in this entry was first described in [16] and a variant of this method was later presented in [11]. An optimal algorithm to detect maximal matching pairs of reads in parallel using the suffix tree data structure is presented in [16].

The NP-completeness of the Shortest Superstring Problem (SSP) was shown by Gallant et al. [10]. The De Bruijn graph formulation for genome assembly was first introduced by Idury and Waterman [13] in the context of a sequencing technique called sequencing-by-hybridization, and later extended to WGS based approaches in the EULER program by Pevzner et al. [23]. The string graph formulation was developed by Myers [21]. The proof of NP-Hardness for the overlap–layout–consensus is due to Kececioglu and Myers [18]. The proofs of NP-Hardness for the De Bruijn and string graphs models of genome assembly are due to Medvedev et al. [20].

Since the later part of 2000s, various next-generation sequencing technologies such as Roche 454 (<http://www.genome-sequencing.com/>), SOLiD (<http://www.appliedbiosystems.com/>), Illumina (<http://www.illumina.com/>), and HeliScope (<http://www.helicosbio.com/>) have emerged along side serial assemblers. A “third” generation of machines that promise a brand new way of sequencing (by single-molecule sequencing) are also on their way (e.g., Pacific Biosciences (<http://www.pacificbiosciences.com/>)). Consequently, the development of short read assemblers continue to be in hot pursuit. Edena, Newbler (<http://www.454.com>), PE-Assembler [1], QSRA [3], SHARCGS [6], SSAKE [28], and VCAKE [15] are all examples of programs that operate using the overlap graph model. EULER-SR [5], ALLPATHS [4], Velvet [29], SOAPdenovo [19], ABySS [25], and YAGA [14] are programs that use the De Bruijn graph formulation. Of these tools, PE-Assembler, ABySS, and YAGA are parallel implementations, although to varying degrees as described in the main text.

Glasgow Parallel Haskell (GpH)

KEVIN HAMMOND

University of St. Andrews, St. Andrews, UK

Synonyms

GpH (Glasgow Parallel Haskell)

Definition

Glasgow Parallel Haskell (GpH) is a simple parallel dialect of the purely functional programming language, Haskell. It uses a *semi-explicit* model of parallelism, where possible parallel threads are marked by the programmer, and a sophisticated runtime system then

decides on the timing of thread creation, allocation to processing elements, migration. There have been several implementations of GpH, covering platforms ranging from single multicore machines through to computational grids or clouds. The best known of these is the GUM implementation that targets both shared-memory and distributed-memory systems using a sophisticated virtual shared-memory abstraction built over a common message-passing layer, but there is a new implementation, GHC-SMP, which directly exploits shared-memory systems, and which targets multicore architectures.

Discussion

Purely Functional Languages and Parallelism

Because of the absence of side effects in purely functional languages, it is relatively straightforward to identify computations that can be run in parallel: any sub-expression can be evaluated by a dedicated parallel task. For example in the following very simple function definition, each of the two arguments to the addition operation can be evaluated in parallel.

```
f x = fibonacci x + factorial x
```

This property was already realized by the mid-1980s, when there was a surge of interest both in parallel evaluation in general, and in the novel architectural designs that it was believed could overcome the sequential “von-Neumann bottleneck.” In fact, the main issue in a purely functional language is not extracting enough parallelism – it is not unusual for even a short-running program to produce many tens of thousands of parallel threads – but is rather one of identifying sufficiently large-grained parallel tasks. If this is not done, then thread creation and communication overheads quickly eliminate any benefit that can be obtained from parallel execution. This is especially important on conventional processor architectures, which historically provided little, if anything, in the way of hardware support for parallel execution. The response of some parallel functional language designers has therefore been to provide very explicit parallelism mechanisms. While this usually avoids the problem of excessive parallelism, it places a significant burden on the programmer, who must understand the details of parallel execution as well as

the application domain, and it can lead to code that is specialized to a specific parallel architecture, or class of architectures. It also violates a key design principle for most functional languages, which is to provide as much isolation as possible from the underlying implementation. GpH is therefore designed to allow programmers to provide information about parallel execution while delegating issues of placement, communication, etc. to the runtime system.

History and Development of GpH

Glasgow Parallel Haskell (GpH) was first defined in 1990. GpH was designed to be a simple parallel extension to the then-new nonstrict, purely functional language Haskell [10], adding only two constructs to sequential Haskell: *par* and *seq*. Unlike most earlier *lazy* functional languages, Haskell was always intended to be parallelizable. The use of the term “non-strict” rather than *lazy* reflects this: while *lazy* evaluation is inherently sequential, since it fixes a specific evaluation order for sub-expressions, under Haskell’s non-strict evaluation model, any number of sub-expressions can be evaluated in parallel provided that they are needed by the result of the program.

The original GpH implementation targeted the GRIP novel parallel architecture, using direct calls to low-level GRIP communications primitives. GRIP was a shared-memory machine, using custom microcoded “intelligent memory units” to share global program data between off-the-shelf processing elements (Motorola 68020 processors, each with a private 4 MB memory), developed in an Alvey research project which ran from 1985 to 1988. Initially, GpH built on the prototype **Haskell** compiler developed by Hammond and Peyton Jones in 1989. It was subsequently ported to the Glasgow Haskell Compiler, GHC [9], that was developed at Glasgow University from 1991 onward, and which is now the de-facto standard compiler for Haskell (since the focus of the maintenance effort was moved to Microsoft Research in 1998, GHC has also become known as the Glorious Haskell Compiler). In 1994, the communications library was redesigned to give what became the highly portable GUM implementation [15]. This allowed a single parallel implementation to target both commercial shared-memory systems and the then-emerging class of cost-effective loosely coupled networks of workstations. Initially, GUM targeted

system-specific communication libraries, but it was subsequently ported to PVM. There are now UDP, PVM, MPI, and MPICH-G2 instances of GUM, as well as system-specific implementations, and the same GUM implementation runs on multicore machines, shared-memory systems, workstation clusters, computational grids, and is being ported to large-scale high-performance systems, such as the 22,656-core HECToR system at the Edinburgh Parallel Computer Centre. Key parts of the GUM implementation have also been used to implement the *Eden* [5] parallel dialect of Haskell, and GpH is being incorporated into the latest mainstream version of GHC.

Although the two parallelism primitives that GpH uses are very simple, it became clear that they could be packaged using higher-order functions to give much higher-level parallel abstractions, such as parallel pipelines, data-parallelism, etc. This led ultimately to the development of *evaluation strategies* [14]: high-level parallel structures that are built from the basic *par* and *seq* primitives using standard higher-order functions. Because they are built from simple components and standard language technology, evaluation strategies are highly flexible: they can be easily composed or nested; the parallelism structure can change dynamically; and the applications programmer can define new strategies on an as-needed basis, while still using standard strategies.

The GpH Model of Parallelism

GpH is unusual in using only two parallelism primitives: *par* and *seq*. The design of the *par* primitive dates back to the late 1980s [8], where it was used in a parallel implementation of the Lazy ML (LML) compiler. The primitive, higher-order, function, *par* is used by the programmer to mark a sub-expression as being suitable for parallel evaluation. For example, a variant of the function *f* above can be parallelized using two instances of *par*.

```
f x =
  let r1 = fibonacci x;
  r2 = factorial x in
  let result = (r1, r2) in
    r1 `par` (r2 `par` result)
```

r1 and *r2* can now both be evaluated in parallel with the construction of the result pair (*r1*, *r2*). There is no need to specify any explicit communication, since

the results of each computation are shared through the variables *r1* and *r2*. The runtime system also decides on issues such as when a thread is created, where it is placed, how much data is communicated, etc. Very importantly, it can also decide *whether* a thread is created. The parallelism model is thus *semi-explicit*: the programmer marks possible sites of parallelism, but the runtime system takes responsibility for the underlying parallel control based on information about system load, etc. This approach therefore eliminates significant difficulties that are commonly experienced with more explicit parallel approaches, such as raw MPI. The programmer needs to make sure there is enough scope for parallelism, but does not need to worry about issues of deadlock, communication, throttling, load-balancing, etc. In the example above, it is likely that only one of *r1* or *r2* (or neither) will actually be evaluated in parallel, since the current thread will probably need both their values. Which of *r1* or *r2* is evaluated first by the original thread will, however, depend on the context in which it is called. It is therefore left unspecified to avoid unnecessary sequentialization.

Lazy Thread Creation

Several different versions of the *par* function have been described in the literature. The version used in GpH is asymmetric in that it marks its first argument as being suitable for possible execution (the expression is *sparked*), while continuing sequential execution of its second argument, which forms the result of the expression. For example, in *par s e*, the expression *s* will be sparked for possible parallel evaluation, and the value of *e* will be returned as the result of the current thread. Since the result expression is always evaluated by the spawning thread, and since there can be no side effects, it follows that it is completely safe to ignore any spark. That is, unlike many parallel systems, the creation of threads from sparks is entirely optional. This fact can be used to throttle the creation of threads from sparks in order to avoid swamping the parallel machine. This is a *lazy thread creation* approach (the term “*lazy task creation*” was coined later by Mohr et al. [7] to describe a similar mechanism in MultiLisp). A corollary is that, since sparks do not carry any execution state, they can be very lightweight. Generally, a single pointer is adequate to record a sparked expression in most implementations of GpH.

Sparks may be chosen for conversion to threads using a number of different strategies. One common approach is to use the oldest spark first. If the application is a divide-and-conquer program, this means that the spark representing the largest amount of work will be chosen. Alternatively, an approach may be used where the youngest (smallest) spark is executed locally and the oldest (largest) spark is offloaded for remote execution. This will improve locality, but may increase thread creation costs, since many of the locally created threads might otherwise be subsumed into their parent thread.

Parallel Graph Reduction

A second key issue that must be dealt with is that of thread synchronization. Efficient sequential non-strict functional language implementations generally use an evaluation technique called *graph reduction*, where a program builds a graph data structure representing the work that is needed to give the result of a program and gradually rewrites this using the functional rules defined in the program until the graph is sufficiently complete to yield the required result. This rewriting process is known as *reducing the graph to some normal form* (in fact *weak head normal form*). Each node in the graph represents an expression in the original program. Initially, this will be a single unevaluated expression corresponding to the result of the program (a “thunk”). As execution proceeds, thunks are evaluated, and each graph node is overwritten with its result. In this way, results are automatically shared between several consumers. Only graph nodes that actually contribute to the final result need to be rewritten. This means that unnecessary work can be avoided, a process that, in the sequential world, allows *lazy evaluation*.

The same mechanism naturally lends itself to parallel evaluation. Each shared node in the graph represents a possible synchronization point between two parallel threads. The first thread to evaluate a graph node will lock it. Any thread that evaluates the node in parallel with the thread that is evaluating it will then block when it attempts to read the value of the node. When the evaluating thread produces the result, the graph node will be updated and any blocked threads will be awoken. In this way, threads will automatically synchronize through the graph representing the computation, not

just at the root of each thread, but whenever they share any sub-expressions.

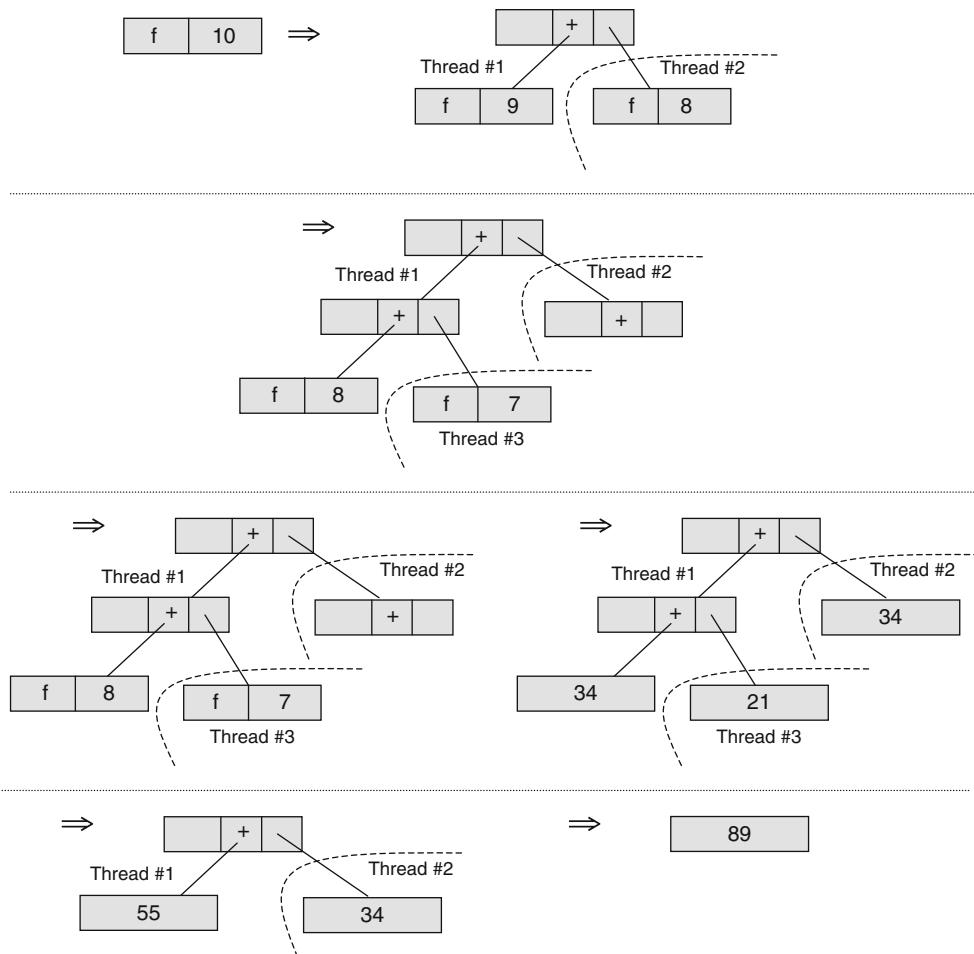

[Figure 1](#) shows a simple example of a divide-and-conquer parallel program, where the root of the computation, $f\ 9$, is rewritten using three threads: one for the main computation and two sub-threads, one to evaluate $f\ 8$ and one to evaluate $f\ 7$. These thunks are linked into the addition nodes in the main computation. Having evaluated the sparked thunks, the second and third threads update their root nodes with the corresponding result. Once the main thread has evaluated the remaining thunk (another call to $f\ 8$, which we have assumed is not shared with Thread #2), it will incorporate these results into its own result. The final stage of the computation is to rewrite the root of the graph (the result of the program) with the value 89.

Evaluate-and-Die

As a thread evaluates its program graph, it may encounter a node that has been sparked. There are three possible cases, depending on the evaluation status of the sparked node. If the thunk has already been evaluated, then its value can be used as normal. If the thunk has not yet been evaluated, then the thread will evaluate it as normal, first annotating it to indicate that it is under evaluation. Once a result is produced, the node will be overwritten with the result value, and any blocked threads will be reawakened. Finally, if the node is actually under evaluation, then the thread must be blocked until the result is produced and the node updated with this value. This is the *evaluate-and-die* execution model [8]. The advantage of this approach is that it automatically absorbs sparks into already executing threads, so increasing their granularity and avoiding thread creation overheads. If a spark refers to a thunk that has already been evaluated then it may be discarded without a thread ever being created.

The *seq* Primitive

While *par* is entirely adequate for identifying many forms of parallelism, Roe and Peyton Jones discovered [13] that by adding a sequential combining function, called *seq*, much tighter control could be obtained over parallel execution. This could be used both to reduce the need for detailed knowledge of the underlying parallel implementation and to encode more sophisticated patterns of parallel execution. For example, one

Glasgow Parallel Haskell (GpH). Fig. 1 Parallel graph reduction

of the *par* constructs in the example above can be replaced by a *seq* construct, as shown below.

```
f x =
  let r1 = fibonacci x;
  r2 = factorial x in
  let result = (r1, r2) in
  r1 `par` (r2 `seq` result)
  -- was r1 `par` r2 `par` result
```

The *seq* construct acts like ; in a conventional language such as C: it first evaluates its first argument (here *r2*), and then returns its second argument (here *result*). So in the example above, rather than creating two sparks as before, now only one is created. Previously, depending on the order in which threads were scheduled, either the parent thread would have blocked when it evaluated *r1* or *r2*, because these

were already under evaluation, or one or both of the sparked threads would have blocked, because they were being evaluated (or had been evaluated) by the parent thread. Now, however, the only possible synchronization is between the thread evaluating *r1* and the parent thread. Note that it is not possible to use either of the simpler forms of *par r1 (r1, r2)* or *par r2 (r1, r2)* to achieve the same effect, as might be expected. Because the implementation is free to evaluate the pair *(r1, r2)* in whichever order it prefers, there is a 50% probability that the spark will block on the parent thread.

This is not the only use of *seq*. For example, evaluation strategies (discussed below) also make heavy use of this primitive to give precise control over evaluation order. While not absolutely essential for parallel evaluation, it is thus very useful to provide a finer

degree of control than can be achieved using *seq* alone. However, there are two major costs to the use of *seq*. The first is that the strictness properties of the program may be changed – this means that some thunks may be evaluated that were previously not needed, and that the termination properties of the program may therefore be changed. The second is that parallel programs may become *speculative*.

Speculative Evaluation

As described above, in GpH it is safe to *spark* any sub-expression that is needed by the result of the parallel computation. However, nothing prevents the programmer from sparking a sub-expression that is not known to be needed. This therefore allows speculative evaluation. Although there was some early experimentation with mechanisms to control speculation, these were found to be very difficult to implement, and current implementations of GpH do not provide facilities to kill created threads, change priorities dynamically, etc., as is necessary to support safe speculation. For example,

```
spec x y = x `par` y
```

defines a new function *spec* that sparks *x* and continues execution of *y*. If *x* is not definitely needed by *y*, or is a completely independent expression, this will spark *x* speculatively. If a thread is created to evaluate *x*, it will terminate either when it has completed evaluation of *x*, or when the main program terminates, having produced its own result, or if it evaluates an undefined value. In the latter case, it may cause the entire program to fail. Moreover, it is theoretically possible to prevent any progress on the main computation by flooding the runtime system with useless speculative threads. For these reasons, any speculative evaluation has to be treated carefully: if the program is to terminate, speculative sub-expressions should terminate in finite time without an error, and there should not be too many speculative sparks.

Evaluation Strategies

As discussed above, it is possible to construct higher-level parallel abstractions from basic *seq/par* constructs using standard Haskell programming constructs. These parallel abstractions can be associated with computation functions using higher-order definitions. This is the *evaluation strategy* approach. The key idea of evaluation

strategies to separate what is to be evaluated from how it could be evaluated in parallel [14]. For example, a simple sequential ray tracing function could be defined as follows:

```
raytracer :: Int -> Int -> Scene ->
[Light] -> [[Vector]]
raytracer xlim ylim scene lights =
map traceline [0..ylim-1]
  where traceline y = [tracepixel scene
    lights x y | x <- [0..xlim-1]]
```

Given a visible image with maximum *x* and *y* dimensions of *xlim* and *ylim*, the *raytracer* function applies the *traceline* function to each line in the image (by mapping it across each value of *y* in the range *0..ylim-1*), and hence applies the *tracepixel* function to each pixel using the specified *scene* and lighting model. The *raytracer* function may be parallelized, for example, by adding the *parMap* strategy to parallelize each line as follows:

```
raytracer :: Int -> Int -> Scene ->
[Light] -> [[Vector]]
raytracer xlim ylim scene lights = map
  traceline [0..ylim-1] `using` parMap rnf
```

Here, *parMap* is a strategy that specifies that each element of its value argument should be evaluated in parallel. It is parameterized on another strategy that specifies what to do with each element. Here, *rnf* indicates that each element should be evaluated as far as possible (*rnf* stands for “reduce to normal form”). The *using* function simply applies its second argument (an evaluation strategy) to its first argument (a functional value), and returns the value. It can be easily defined using higher-order functions and the *seq* primitive as follows:

```
using :: a -> Strategy a -> a
x `using` s = s x `seq` x
```

So, when a strategy is applied to an expression by the *using* operation, the strategy is first applied to the value of the expression, and once this has completed, the value is returned. This allows the use of both parallel and sequential strategies.

In fact, any list strategy may be used to parallelize the *raytracer* function instead of *parMap*. For example, a task farm could be used, or the list could be divided into equally sized chunks as shown below.

```

raytracer :: Int -> Int -> Scene ->
[Light] -> [[Vector]]
raytracer xlim ylim scene lights = ...
`using' parListChunk chunkSize rnf

```

Evaluation strategies have proved to be very powerful and flexible, having been successfully applied to several large programs, including symbolic programs with irregular patterns of parallelism [4]. Typically, only a few lines need to be changed at key points by adding appropriate `using` clauses. In abstracting parallel patterns from sequential computations, evaluation strategies have some similarities with *algorithmic skeletons*. The key differences between evaluation strategies and typical skeleton approaches is that evaluation strategies do not mandate a specific parallel implementation (since they rely on semi-explicit parallelism, they provide hints to the runtime system rather than directives); and that they are completely user-programmable – everything above the `par` and `seq` primitives is programmed using standard Haskell code. Unlike most skeleton approaches, they may also be easily composed to give irregular nested parallel structures or phased parallel computations, for example.

The GUM Implementation of GpH

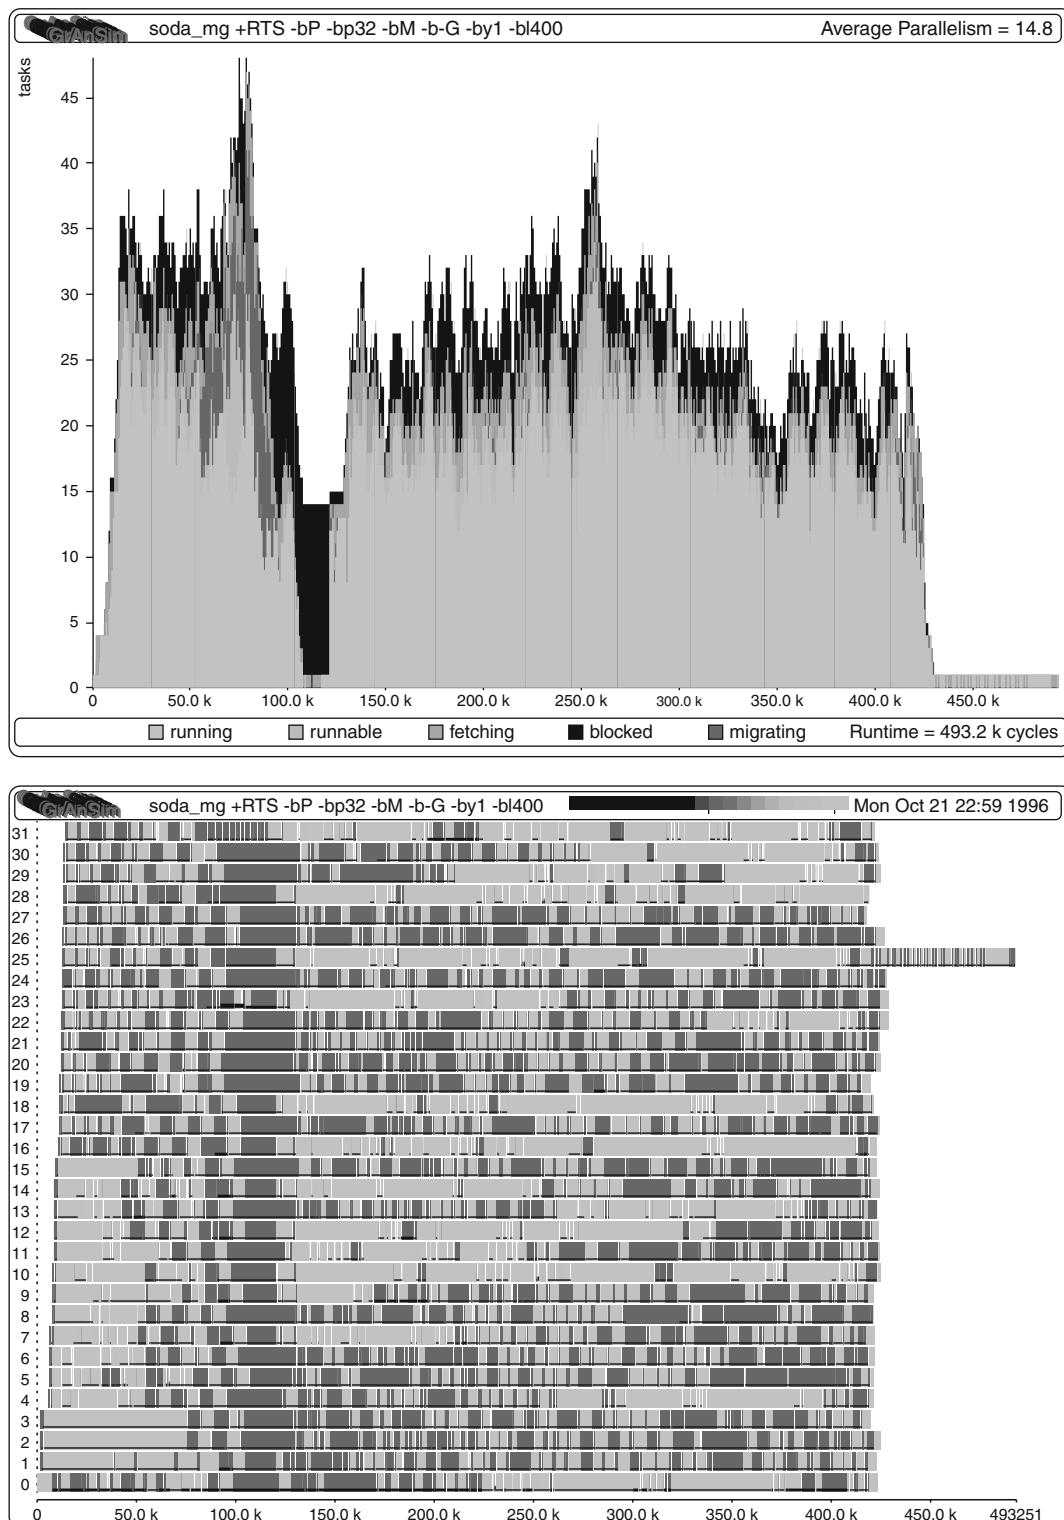

GUM is the original and most general implementation of GpH. It provides a virtual shared-memory abstraction for parallel graph reduction, using a message-passing implementation to target both physically shared-memory and distributed-memory systems. In the GUM model, the graph representing the program that is being evaluated is distributed among the set of processor elements (PEs) that are available to execute the program. These PEs usually correspond to the cores or processors that are available to execute the parallel program, but it is possible to map PEs onto multiple processes on the same core/processor, if required. Each PE manages its own execution environment, with its own local pools of sparks and threads, which it schedules as required. Sparks and threads are offloaded on demand to maintain good work balance.

A key feature of GUM is that it uses a two-level memory model: each PE has its own private heap that contains unshared program graph created by local threads. Within this heap, some graph nodes may be

shared with other PEs. These nodes are given *global addresses*, which identify the owner of the graph node. The advantage of this model is that it allows completely independent memory management: by keeping tables of global in-pointers, which are used as garbage collection roots into the local heap, each PE can garbage-collect its own local heap independently of all other PEs. This local garbage collection is conservative, as required, since even if a global in-pointer is no longer referenced by any other PE, it will still be treated as a garbage collection root. In order to collect global garbage, a separate scheme is used, based on distributed reference counting. Since the majority of the program graph never needs to be shared, this approach brings major efficiency gains over typical single-level memory management. In addition to the reduced need for synchronization during garbage collection, there is also no need to maintain global locks across purely local graph. Within each PE, GUM uses the same efficient (and sequential) garbage collector as the standard GHC implementation. This is currently a stop-and-copy generational collector based on Appel's collector.

Visualizing the Behavior of GpH Programs

Good visualization is an essential part of understanding parallel behavior. Runtime information can be visualized at a variety of levels to give progressively more detailed information. For example, Fig. 2 visualizes the overall and per-PE parallel activity for a 32-PE system running the soda application (a simple crossword-puzzle solver). Apart from the clear phase-transition about 25% into the execution, very few threads are blocked; and there are very few runnable, but not running threads. Those that are runnable are migrated to balance overall system load. The profile also reveals that relatively little time is spent fetching nonlocal data. The per-PE profile gives a more detailed view. It is obvious that the workload is well balanced and that the work-stealing mechanism is effective in distributing work. The example also shows where PEs are idle for repeated periods, and that only the main PE is active at the end of the computation (collating results to be written as the output of the program). It thus clearly identifies places where improvements could be made to the parallel program.

Glasgow Parallel Haskell (GpH). Fig. 2 Sample overall and per-PE Activity Profiles for a 32-PE machine

The GHC-SMP Implementation of GpH

A recent development is the GHC-SMP [6] implementation of GpH from Microsoft Research Labs, Cambridge, UK, which is integrated into the standard GHC distribution. This provides an implementation of **GpH** that specifically targets shared-memory and multicore systems. It uses a similar model of PEs and threads to the **GUM** implementation, including spark pools and runnable thread pools, and implements a similar spark-stealing model. The key difference from GUM is that GHC-SMP uses a physically shared heap, rather than a virtual shared heap with an underlying message-passing implementation. This heap is garbage-collected using a global stop-and-copy collector that requires the synchronization of all PEs, but which may itself be executed in parallel using the available processor cores. Also, unlike GUM, GHC-SMP exports threads to remote PEs based on the load of the local core, rather than on demand.

GRID-GUM and the SymGrid System

By replacing the low-level communications library with MPICH-G2, it is possible to execute GUM (or Eden – see below) not only on standard clusters of workstations, but also on wide-area computational grids, coordinated by the standard Globus grid middleware. The GRID-GUM and grid-enabled Eden implementations form the basis for the SymGrid-Par middleware [3], which aims to provide high-level support for computational grids for a variety of symbolic computing systems. The middleware coordinates symbolic computing engines into a coherent parallel system, providing high-level skeletons. The system uses a high-level data-exchange protocol (SCSCP) based on the standard OpenMath XML format for mathematical data. Results have been very promising to date, with superlinear performance being achievable for some mathematical applications, without changing any of the sequential symbolic computing engines.

The GranSim Simulator

The GranSim parallel simulator was developed in 1995 [1] as an efficient and accurate simulator for GpH running on a sequential machine, specifically to expose granularity issues. It is unusual in modifying the sequential GHC runtime system so that evaluating graph nodes also triggers the addition of sparks,

and simulates inter-PE communication. It thus follows the actual GUM implementation very precisely. It allows a range of communication costs to be simulated for a specific parallel application, ranging from zero (ideal communication) to costs that are similar to those Program execution times are also simulated, using a cost model that takes architectural characteristics into account. One of the key uses of GranSim is as the core of a parallel program development methodology, where a GpH program is first simulated under ideal parallel conditions, and then under communication cost settings for specific parallel machines: shared-memory, distributed-memory, etc. This allows the program to be gradually tuned for a specific parallel setting without needing access to the actual parallel machine, and in a way that is repeatable, can be easily debugged, and which provides detailed metrics.

GdH and Mobile Haskell

GdH [11] is a distributed Haskell dialect that builds on GpH. It adds explicit constructs for task creation on specific processors, with inter-processor communication through explicit mutable shared variables, that can be written on one processor and read on another. Internally, each processor runs a number of threads. The **GdH** implementation extends the GUM implementation with a number of explicit constructs. The main construct is `revalIO`, which constructs a new task on a specific processor. In conjunction with mutable variables, this can be used to construct higher-level constructs. For example, the `showSystem` definition below prints the names of all available PEs. The `getAllHostNames` function maps the `hostName` function over the list of all processor identifiers, returning an IO action that obtains the environment variable `HOST` on the specified PE. This is used in the `showSystem` IO operation which first obtains a list of all host names, then outputs them as a sorted list, with duplicates eliminated using the standard `nub` function.

```
getAllHostNames :: IO [String]
getAllHostNames = mapM hostName allPEId

hostName :: PEId -> IO String
hostName pe = evalIO (getEnv "HOST") pe

showSystem = do { hostnames <=
```

```
getAllHostNames; showHostNames hostnames}
  where
    showHostNames names = putStrLn
      (show (sort (nub names)))
```

At the language level, GdH is similar to Concurrent Haskell, which is designed to execute explicit concurrent threads on a single PE. The key language difference is the inclusion of an explicit PEID to allocate tasks to PEs, supported by a distributed runtime environment. GdH is also broadly similar to the industrial Erlang language, targeting a similar area of distributed programming, but is non-strict rather than strict and, since it is a research language, does not have the range of telecommunications-specific libraries that Erlang supports in the form of the Erlang/OTP development platform. Mobile Haskell [12] similarly extends Concurrent Haskell, adding higher-order communication channels (known as Mobile Channels), to support mobile computations across dynamically evolving distributed systems. The system uses a bytecode implementation to ensure portability, and serializes arbitrary Haskell values including (higher-order) functions, IO actions, and even mobile channels.

Eden

Eden [5] (described in a separate encyclopedia entry) is closely related to GpH. Like GpH, it uses an implicit communication mechanism, sharing values through program graph nodes. However, it uses an explicit process construct to create new processes and explicit process application to pass streams of values to each process. Unlike GpH, all data that is passed to an Eden process must be evaluated before it is communicated. There is also no automatic work-stealing mechanism, task migration, granularity agglomeration, or virtual shared graph mechanism. Eden, does, however, provide additional threading support: each output from the process is evaluated using its own parallel thread. It also provides mechanisms to allow explicit communication channels to be passed as first-class objects between processes.

Eden has been used to implement both algorithmic skeletons and evaluation strategies, where it has the advantage of providing more controllable parallelism but the disadvantage of losing adaptivity. One

particularly useful technique is to use Eden to implement a master-worker evaluation strategy, where a set of dynamically generated worker functions is allocated to a fixed set of worker processors using an explicitly programmed scheduler. This allows Eden to deal with varying thread granularities, without using a lazy thread creation mechanism, as in GpH.

While it does not need the advanced adaptivity mechanisms that GUM provides, the Eden implementation shares several basic components, in particular, the communication library and scheduler have very similar implementations.

G

Current Status

GpH has been adopted as a significant part of the Haskell community effort on parallelism. The evaluation strategies library has just been released as part of the mainstream GHC compiler release, building on the GHC-SMP implementation, and there has also been significant recent effort on visualization with the release of the EdenTV and ThreadScope visualizers for Eden and GHC-SMP, respectively. Work is currently underway to integrate GUM and GHC-SMP to give a wide-spectrum implementation for GpH, and Eden will also form part of this effort. The SymGrid-Par system is being developed as part of a major UK project to provide support for high-performance computing on massively parallel machines, such as HECToR.

Future Directions

The advent of multicore computers and the promise of manycore computers have changed the nature of parallel computing. The GpH model of lightweight multithreaded parallelism is well suited to this new order, offering the ability to easily generate large amounts of parallelism. The adaptivity mechanisms built into the GUM implementation mean that the parallel program can dynamically, and automatically, change its behavior to increase parallelism, improve locality, or throttle back parallelism as required.

Future parallel systems are likely to be built more hierarchically than present ones, with processors built from heterogeneous combinations of general-purpose cores, graphics processing units, and other specialist units, using several communication networks and a complex memory hierarchy. Proponents of manycore architectures anticipate that a single processor

will involve hundreds or even thousands of such units. Because of the cost of maintaining a uniform memory model across large numbers of systems, when deployed on a large scale these processors are likely to be combined hierarchically into multiple levels of clusters. These systems may then be used to form high performance “clouds.” Future parallel languages and implementations must therefore be highly flexible and adaptable, capable of dealing with multiple levels of communication latency and internal parallel structure, and perhaps fault tolerance. The GpH model with evaluation strategies, supported by adaptive implementations such as GUM forms a good basis for this, but it will be necessary to extend the existing models and implementations to cover more heterogeneous processor types, to deal with multiple levels of parallelism and additional program structure, and to focus more directly on locality issues.

Bibliographic Notes and Further Reading

The main venues for publication on GpH and other parallel functional languages are the International Conference on Functional Programming (ICFP) and its satellite events including the Haskell Symposium; the International Symposium on Implementation and Application of Functional Languages (IFL); the International Conference on Programming Language Design and Implementation (PLDI); and the Symposium on Trends in Functional Programming

(TFP). Papers also frequently appear in the Journal of Functional Programming (JFP). A survey of Haskell-based parallel languages and implementations, as of 2002, can be found in [16], and a general introduction to research in parallel functional programming, as of 1998, can be found in [2]. Some examples of the use of GpH in larger applications can be found in [4]. Much of this entry is based on private notes, e-mails, and final reports on the various research projects that have used GpH. The main paper on evaluation strategies is [14]. The main paper on the GUM implementation is [15], and the main paper on the GranSim simulator is [1]. Many subsequent papers have used these systems and ideas. For example, one recent paper describes the SymGrid-Par system [3]. Definition

Global Arrays is a high-performance programming model for scalable, distributed-memory, parallel computer systems. Global Arrays is based on the concept of globally accessible dense arrays that are logically shared, yet physically distributed onto the memories of a parallel distributed computer system (Fig. 1 illustrates this concept).

Discussion

Introduction

Global Arrays (GA) is a high-performance programming model for scalable, distributed-memory, parallel computer systems. GA is a library-based Partitioned Global Address Space (PGAS) programming model. The underlying supported sequential languages are Fortran, C, C++, and Python. GA provides *global view access* to very large dense arrays through API functions implemented for those languages, under a Single Program Multiple Data (SPMD) execution environment.

GA was originally developed as part of the underlying software infrastructure for the US Department of Energy's NWChem computational chemistry software package. Over time, it has been developed into a standalone package with a rich set of API functions (200+) that cater to many needs in scientific application development. GA has been used to enable scalable

Global Arrays Parallel Programming Toolkit. Fig. 1 Dual view of Global Arrays data structures

parallel execution for several major scientific applications including NWChem (computational chemistry, specifically electronic structure calculation), STOMP (Subsurface Transport Over Multiple Phases, a subsurface flow and transport simulator), ScalaBLAST (a more scalable, higher-performance version of BLAST), Molpro (quantum chemistry), TE²THYS (unstructured, implicit CFD and coupled fluid/solid mechanics finite volume code), Pagoda (Parallel Analysis of Geodesic Data), COLUMBUS (computational chemistry), and GAMESS-UK (computational chemistry).

GA's development has occurred over the last two decades. For this reason, the number of people involved and their contributions is large. GA's original development occurred as a co-design effort between the NWChem team and the computer science team focused on GA. The main designer and original developer of GA was Jarek Nieplocha. Robert Harrison led the main effort in the development of NWChem.

Basic Global Arrays

There are three classes of operations in Global Arrays: core operations, task parallel operations, and data-parallel operations. These operations have multiple language bindings, but provide the same functionality independent of the language. The current GA library contains approximately 200 operations that provide a rich set of functionality related to data management and computations involving distributed arrays. GA is interoperable with MPI, enabling the development of hybrid programs that use both programming models.

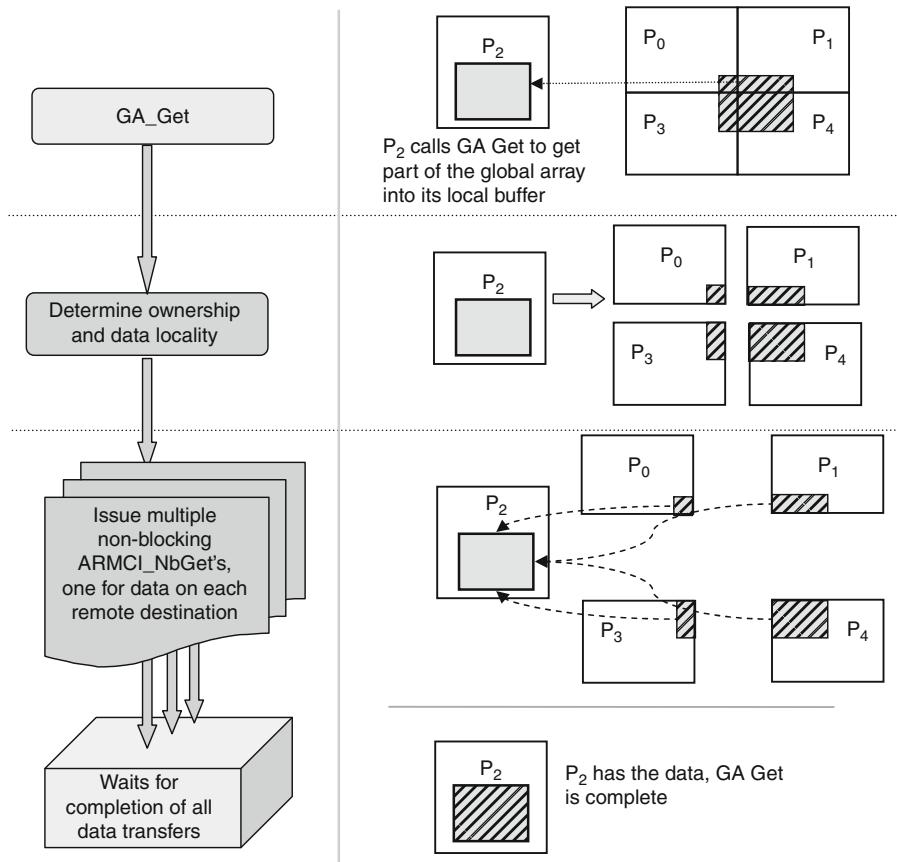

The basic components of the Global Arrays toolkit are function calls to create global arrays, copy data to, from, and between global arrays, and identify and access the portions of the global array data that are held locally. There are also functions to destroy arrays and free up the memory originally allocated to them. The basic function call for creating new global arrays is **nga_create**. The arguments to this function include the dimension of the array, the number of indices along each of the coordinate axes, and the type of data (integer, float, double, etc.) that each array element represents. The function returns an integer handle that can be used to reference the array in all subsequent operations. The allocation of data can be left completely to the toolkit, but if it is desirable to control the distribution

of data for load balancing or other reasons, additional versions of the **nga_create** function are available that allow the user to specify in detail how data is distributed between processors. The basic **nga_create** call provides a simple mechanism to control data distribution via the specification of an array that indicates the minimum dimensions of a block of data on each processor.

One of the most important features of Global Arrays is the ability to easily move blocks of data between global arrays and local buffers. The data in the global array can be referred to using a global indexing scheme and data can be moved in a single function call, even if it represents data distributed over several processors. The **nga_get** function can be used to move a block of distributed data from a global array to a local buffer. The arguments consist of the array handle for the array that data is being taken from, two integer arrays representing the lower and upper indices that bound the block of distributed data that is going to be moved, a pointer to the local buffer or a location in the local buffer that is to receive the data, and an array of strides for the local data. The **nga_put** call is similar and can be used to move data in the opposite direction.

The number of basic GA operations is fairly small and many parallel programs can be written with just the following ten routines:

- **GA_Initialize ()**: Initialize the GA library.
- **GA_Terminate ()**: Release internal resources and finalize execution of a GA program.
- **GA_Nnodes ()**: Return the number of GA compute processes (corresponds to the SPMD execution environment).
- **GA_Nodeid ()**: Return the GA process ID of the calling compute process, this is a number between 0 and **GA_Nnodes () - 1**.
- **NGA_Create ()**: Create an *n*-dimensional globally accessible dense array (global array instance).
- **NGA_Destroy ()**: Deallocate memory and resources associated with a global array instance.
- **NGA_Put ()**: Copy data from a local buffer to an array section within a global array instance in a one-sided manner.
- **NGA_Get ()**: Copy data from an array section within a global array instance to a local buffer in a

Global Arrays Parallel Programming Toolkit. Fig. 2 Left: `GA_Get` flow chart. Right: An example: Process P_2 issues `GA_Get` to get a chunk of data, which is distributed (partially) among P_0, P_1, P_3 , and P_4 (owners of the chunk)

one-sided manner (see Fig. 2 for a detailed description of how `get()` operates).

- `GA_Sync()`: Synchronize compute processes via a barrier and ensure that all pending GA operations are complete (in accordance to the GA *consistency model*).
- `NGA_Distribution()`: Returns the array section owned by a specified compute process.

Example GA Program

We present a parallel matrix multiplication program written in Global Arrays using the Fortran language interface. It uses most of the basic GA calls described before, in addition to some more advanced calls to create global array instances with specified data distributions. The program computes the result of $C = A \times B$. Some variable declarations have been omitted for brevity.

Discussion on the Example Program

The program is (mostly) a fully functional GA code, except for omitted variable declarations. It creates global array instances with specific data distributions, illustrates the use of the `nga_put()` and `nga_get()` primitives, as well as locality information through the `nga_distribution()` call. The code includes calls to initialize and terminate the MPI library, which are needed to provide the SPMD execution environment to the GA application. (It is possible to write a GA application that does not call the MPI library through the use of the TCGMSG simple message-passing environment included with GA.) The code includes the creation and use of local buffers to be used as sources and targets for put and get operations (1A, 1B, 1C), which in this case were allocated as Fortran 90 dynamic arrays.

Lines 43–69 contain the principal part of the example code and illustrate several of the features of

GA: data is being accessed using *global coordinates* (lines 54–55 and 63–66) that correspond to the global size of the global array instances that were created previously; in addition, the access to the global array data for arrays *g_a* and *g_b* in lines 54 and 55 is done *without requiring the participation* of the process where that data is allocated (one-sided access). [Figure 3](#) illustrates the concept of one-sided access.

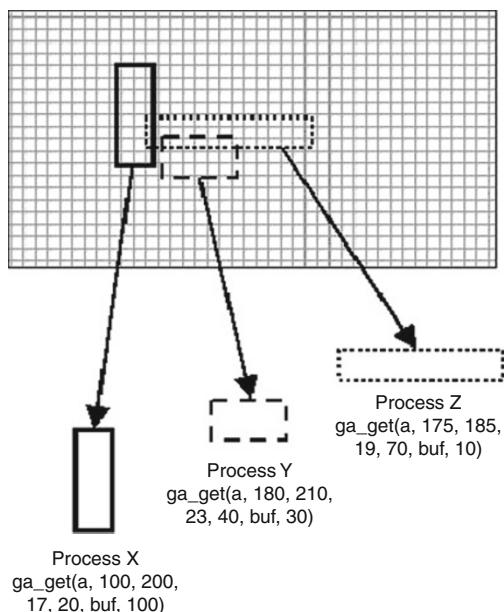

Global Arrays Concepts

GA allows the programmer to control data distribution and makes the locality information readily available to be exploited for performance optimization. For example, global arrays can be created by: (1) allowing the

library to determine the array distribution, (2) specifying the decomposition for only one array dimension and allowing the library to determine the others, (3) specifying the distribution block size for all dimensions, or (4) specifying an irregular distribution as a Cartesian product of irregular distributions for each axis. The distribution and locality information is always available through interfaces that allow the application developer to query: (1) which data portion is held by a given process, (2) which process owns a particular array element, and (3) a list of processes and the blocks of data owned by each process corresponding to a given section of an array.

The primary mechanisms provided by GA for accessing data are block copy operations that transfer data between layers of memory hierarchy, namely, global memory (distributed array) and local memory. Further, extending the benefits of using blocked data accesses and copying remote locations into contiguous local memory can improve cache performance by reducing both conflict and capacity misses [1]. In addition, each process is able to access directly the data held in a section of a Global Array that is locally assigned to that process. Data representing sections of the Global Array owned by other processes on SMP clusters can also be accessed directly using the GA interface, if desired. Atomic operations are provided that can be used to implement synchronization and assure correctness of an accumulate operation (floating-point sum reduction that combines local and remote data) executed concurrently by multiple processes and targeting overlapping array sections.

GA is extensible as well. New operations can be defined exploiting the low-level interfaces dealing with distribution, locality, and providing direct memory access (`nga_distribution`, `nga_locate_region`, `nga_access`, `nga_release`, `nga_release_update`). These, e.g., were used to provide

Global Arrays Parallel Programming Toolkit. Fig. 3 Any part of GA data can be accessed independently by any process at any time

additional linear algebra capabilities by interfacing with third-party libraries, e.g., ScaLAPACK [2].

Global Arrays Memory Consistency Model

In shared-memory programming, one of the issues central to performance and scalability is memory consistency. Although the sequential consistency model [3] is straightforward to use, weaker consistency models [4] can offer higher performance on modern architectures and they have been implemented on actual hardware. GA's nature as a one-sided, global-view programming model requires similar attention to memory consistency issues. The GA approach is to use a weaker-than-sequential consistency model that is still relatively straightforward to understand by an application programmer. The main characteristics of the GA approach include:

- GA distinguishes two types of completion of the store operations (i.e., put, scatter) targeting global shared memory: local and remote. The blocking store operation returns after the operation is completed locally, i.e., the user buffer containing the source of the data can be reused. The operation completes remotely after either a memory fence operation or a barrier synchronization is called. The fence operation is required in critical sections of the user code, if the globally visible data is modified.
- The blocking operations (get/put) are ordered only if they target overlapping sections of global arrays. Operations that do not overlap or access different arrays can complete in arbitrary order.
- The nonblocking get/put operations complete in arbitrary order. The programmer uses wait/test operations to order completion of these operations, if desired.

Global Arrays Extensions

To allow the user to exploit data locality, the toolkit provides functions identifying the data from the global array that is held locally on a given processor. Two functions are used to identify local data. The first is the **nga_distribution** function, which takes a processor ID and an array handle as its arguments and returns a set of lower and upper indices in the global address space representing the local data block. The second is the **nga_access** function, which returns an array index and an array of strides to the locally held

data. In Fortran, this can be converted to an array by passing it through a subroutine call. The C interface provides a function call that directly returns a pointer to the local data.

In addition to the communication operations that support task parallelism, the GA toolkit includes a set of interfaces that operate on either entire arrays or sections of arrays in the data-parallel style. These are collective data-parallel operations that are called by all processes in the parallel job. For example, movement of data between different arrays can be accomplished using a single function call. The **nga_copy_patch** function can be used to move a patch, identified by a set of lower and upper indices in the global index space, from one global array to a patch located within another global array. The only constraints on the two patches are that they contain equal numbers of elements. In particular, the array distributions do not have to be identical, and the implementation can perform, as needed, the necessary data reorganization (the so-called MxN problem [5]). In addition, this interface supports an optional transpose operation for the transferred data. If the copy is from one patch to another on the same global array, there is an additional constraint that the patches do not overlap.

Historical Development and Comparison with Other Programming Models

The original GA package [6–8] offered basic one-sided communication operations, along with a limited set of collective operations on arrays in the style of BLAS [9]. Only two-dimensional arrays and two data types were supported. The underlying communication mechanisms were implemented on top of vendor-specific interfaces. In the course of 10 years, the package evolved substantially and the underlying code was completely rewritten. This included separation of the GA internal one-sided communication engine from the high-level data structure. A new portable, general, and GA-independent communication library called ARMCI was created [10]. New capabilities were later added to GA without the need to modify the ARMCI interfaces. The GA toolkit evolved in multiple directions:

- Adding support for a wide range of data types and virtually arbitrary array ranks.
- Adding advanced or specialized capabilities that address the needs of some new application areas,

e.g., ghost cells or operations for sparse data structures.

- Expansion and generalization of the existing basic functionality. For example, mutex and lock operations were added to better support the development of shared-memory-style application codes. They have proven useful for applications that perform complex transformations of shared data in task parallel algorithms, such as compressed data storage in the multireference configuration interaction calculation in the COLUMBUS package [11].
- Increased language interoperability and interfaces. In addition to the original Fortran interface, C, Python, and a C++ class library were developed.
- Developing additional interfaces to third-party libraries that expand the capabilities of GA, especially in the parallel linear algebra area: ScaLAPACK [2] and SUMMA [12]. Interfaces to the TAO optimization toolkit have also been developed [13].
- Developed support for multilevel parallelism based on processor groups in the context of a shared-memory programming model, as implemented in GA [14, 15].

These advances generalized the capabilities of the GA toolkit and expanded its appeal to a broader set of applications. At the same time, the programming model, with its emphasis on a shared-memory view of the data structures in the context of distributed memory systems with a hierarchical memory, is as relevant today as it was in 1993 when the project started.

Comparison with Other Programming Models

The two predominant classes of programming models for parallel computers are distributed-memory, shared-nothing, and Uniform Memory Access (UMA) shared-everything models. Both the shared-everything and fully distributed models have advantages and shortcomings. The UMA shared-memory model is easier to use but it ignores data locality/placement. Given the hierarchical nature of the memory subsystems in modern computers, this characteristic can have a negative impact on performance and scalability. Careful code restructuring to increase data reuse and replacing fine-grained load/stores with block access to shared data can address the problem and yield performance for shared memory that is competitive with message passing [16].

However, this performance comes at the cost of compromising the ease of use that the UMA shared-memory model posits. Distributed, shared-nothing memory models, such as message-passing or one-sided communication, offer performance and scalability but they are more difficult to program. The classic message-passing paradigm not only transfers data but also synchronizes the sender and receiver. Asynchronous (nonblocking) send/receive operations can be used to diffuse the synchronization point, but cooperation between sender and receiver is still required. The synchronization effect is beneficial in certain classes of algorithms, such as parallel linear algebra, where data transfer usually indicates completion of some computational phase; in these algorithms, the synchronizing messages can often carry both the results and a required dependency. For other algorithms, this synchronization can be unnecessary and undesirable, and a source of performance degradation and programming complexity.

The Global Arrays toolkit [6–8] attempts to offer the best features of both models. It implements a *global-view* programming model, based on one-sided communication, in which data locality is managed by the programmer. This management is achieved by calls to functions that transfer data between a global address space (a distributed array) and local storage. In this respect, the GA model has similarities to the distributed shared-memory models that provide, e.g., an explicit acquire/release protocol [17]. However, the GA model acknowledges that remote data is slower to access than local data and allows data locality to be specified by the programmer and hence managed. GA is related to the global address space languages such as UPC [18], Titanium [19], and, to a lesser extent, Co-Array Fortran [20]. In addition, by providing a set of data-parallel operations, GA is also related to data-parallel languages such as HPF [21], ZPL [22], and Data Parallel C [23]. However, the Global Array programming model is implemented as a library that works with most languages used for technical computing and does not rely on compiler technology for achieving parallel efficiency. It also supports a combination of task and data parallelism and is fully interoperable with the message-passing (MPI) model. The GA model exposes to the programmer the hierarchical memory of modern high-performance computer systems [24], and by recognizing the communication overhead for remote data

transfers, it promotes data reuse and locality of reference. Virtually all scalable architectures possess nonuniform memory access characteristics that reflect their multilevel memory hierarchies. These hierarchies typically comprise processor registers, multiple levels of cache, local memory, and remote memory. Over time, both the number of levels and the cost (in processor cycles) of accessing deeper levels have been increasing. Scalable programming models must address memory hierarchy since it is critical to the efficient execution of applications.

Definition

GRAPE (GRAvity PipE) is the name of a series of special-purpose computers designed for the numerical simulation of gravitational many-body systems. Most of GRAPE machines consist of hardwired pipeline processors to calculate the gravitational interaction between particles and programmable computers to handle all other works. GRAPE-DR (Greatly Reduced Array of Processor Elements with Data Reduction) replaced the hardwired pipeline by simple SIMD programmable processors.

Discussion

Introduction

The improvement in the speed of computers has been a factor of 100 in every decade, for the last 60 years. In these 60 years, however, the computer architecture has become more and more complex. Pipelined architecture were introduced in 1960s, and vector architectures became the mainstream in 1970s. In 1980s, a number of parallel architectures appeared, but in the 1990s and 2000s, distributed memory parallel computers built from microprocessors have taken over.

The technological driving force of this evolution of computer architecture has been the increase of the number of available transistors in integrated circuits, at least after the invention of integrated circuits in 1960s. In the case of CMOS LSIs, the number of transistors in

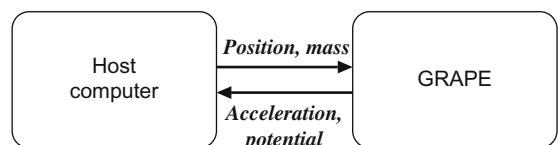

a chip doubles in every 18 months. Under the assumption of so-called CMOS scaling, this means that the switching speed doubles in every 36 months. In the last 30 years, the number of transistors available on an LSI chip increased by roughly a factor of one million.

One way to make use of this huge number of transistors is to implement application-specific pipeline processors into a chip. The GRAPE series of special-purpose computers is one of such efforts to make efficient use of large number of transistors available on LSIs.

In many scientific simulations, it is necessary to solve N -body problems numerically. The gravitational N -body problem is one such example, which describes the evolution of many astronomical objects from the solar system to the entire universe. In some cases, it is important to treat non-gravitational effects such as the hydrodynamical interaction, radiation, and magnetic fields, but the gravity is the primary driving force that shapes the universe.

To solve the gravitational N -body problem, one needs to calculate the gravitational force on each body (particle) in the system from all other particles in the system. There are many ways to do so, and if relatively low accuracy is sufficient, one can use the Barnes-Hut tree algorithm [3] or FMM [5]. Even with these schemes, the calculation of the gravitational interaction between particles (or particles and multipole expansions of groups of particles) is the most time-consuming part of the calculation. Thus, one can greatly improve the speed of the entire simulation, just by accelerating the speed of the calculation of particle-particle interaction. This is the basic idea behind GRAPE computers.

The basic idea is shown in Fig. 1. The system consists of a host computer and special-purpose hardware, and the special-purpose hardware handles the calculation of gravitational interaction between particles. The host computer performs other calculations such as the time integration of particles, I/O, and diagnostics.

GRAPE. Fig. 1 Basic structure of a GRAPE system

This architecture accelerates not only the simple algorithm in which the force on a particle is calculated by taking the summation of forces from all other particles in the system, but also the Barnes–Hut tree algorithms and FMM. Moreover, it can be used with individual timestep algorithms [1], in which particles have their own times and timesteps and integrated in an event-driven fashion. The use of individual timestep is critical in simulations of many systems including star clusters and planetary systems, where close encounters and physical collisions of two particles require very small timesteps for a small number of particles.

History

The GRAPE project started in 1988. The first machine completed, the GRAPE-1 [7], was a single-board unit on which around 100 IC and LSI chips were mounted and wire-wrapped. The pipeline processor of GRAPE-1 was implemented using commercially available IC and LSI chips. It was a natural consequence of the fact that project members lacked both money and experience to design custom LSI chips. In fact, none of the original design and development team of GRAPE-1 had the knowledge of electronic circuit more than what was learned in basic undergraduate course for physics students.

For GRAPE-1, an unusually short word format was used, to make the hardware as simple as possible. The input coordinates are expressed in 15-bit fixed point format. After subtraction, the result is converted to 8-bit logarithmic format, in which 3 bit are used for the “fractional” part. This format is used for all following operations except for the final accumulation. The final accumulation was done in 48-bit fixed point, to avoid overflow and underflow. The advantage of the short word format is that ROM chips can be used to implement complex functions that require two inputs. Any function of two 8-bit words can be implemented by one ROM chip with 16-bit address input. Thus, all operations other than the initial subtraction of the coordinates and final accumulation of the force were implemented by ROM chips.

The use of extremely short word format in GRAPE-1 was based on the detailed theoretical analysis of error propagation and numerical experiment [13]. There are three dominant sources of error in numerical simulations of gravitational many-body systems. The first one

is the error in the numerical integration of orbits of particles. The second one is the error in the calculated accelerations themselves. The third one comes from the fact that in many cases, the number of particles used is much smaller than the number of stars in the real systems such as a galaxy.

Whether or not the third one should be regarded as the source of error depends on the problem one wants to study. If the problem is, for example, merging of two galaxies, which takes place in relatively short timescale (compared to the orbital period of typical stars in galaxies), the effect of small number of particles can be, and should be, regarded as the numerical error.

On the other hand, if we want to study long-term evolution of a star cluster, which takes place in the timescale much longer than the orbital timescale, the evolution of orbits of individual stars is driven by close encounters with other stars. In this case, the effect of small (or finite) number of particles is not an numerical error but what is there in real systems.

Thus, the required accuracy of pairwise force calculation depends on the nature of the problem. In the case of the study of the merging of two galaxies, the average error can be as large as 100% of the pairwise force, if the error is guaranteed to be random. The average error of interaction calculated by GRAPE-1 is less than 10%, which was good enough for many problems. In the number format used in GRAPE-1, the positions of particles are expressed in the 16-bit fixed-point format, so that the force between two nearby particles, both far from the origin of coordinates, is still expressed with sufficient accuracy. Also, the accumulation of the forces from different particles is done in the 48-bit fixed-point format, so that there is no loss of effective bits during the accumulation. Thus, the primary source of error with GRAPE-1 is the low-accuracy pairwise force calculation. It can be regarded as random error.

Strictly speaking, the error due to the short word format cannot always be regarded as random, since it introduces correlation both in space and time. One could eliminate this correlation by applying random coordinate transformation, but the quantitative study of such transformation has not done yet.

GRAPE-1 used the GPIB (IEEE-488) interface for the communication with the host computer. It was fast enough for the use with simple direct summation. However, when combined with the tree algorithm, faster

communication was necessary. GRAPE-1A used VME bus for communication, to improve the performance. The speed of GRAPE-1 and 1A was around 300 Mflops, which is around 1/10 of the speed of fastest vector supercomputers of the time. Hardware cost of them was around 1/1,000 of supercomputers, or roughly equal to the cost of low-end workstations. Thus, these first-generation GRAPEs offered price-performance two orders of magnitude better than that of general-purpose computers.

GRAPE-2 is similar to GRAPE-1A, but with much higher numerical accuracy. In order to achieve higher accuracy, commercial LSI chips for floating-point arithmetic operations such as TI SN74ACT8847 and Analog Devices ADSP3201/3202 were used. The pipeline of GRAPE-2 processes the three components of the interaction sequentially. So it accumulates one interaction in every three clock cycles. This approach was adopted to reduce the circuit size. Its speed was around 40 Mflops, but it is still much faster than workstations or minicomputers at that time.

GRAPE-3 was the first GRAPE computer with a custom LSI chip. The number format was the combination of the fixed point and logarithmic format similar to what were used in GRAPE-1. The chip was fabricated using 1 μm design rule by National Semiconductor. The number of transistors on chip was 110 K. The chip operated at 20 MHz clock speed, offering the speed of about 0.8 Gflops. Printed-circuit boards with eight chips were mass-produced, for the speed of 6.4 Gflops per board. Thus, GRAPE-3 was also the first GRAPE computer to integrate multiple pipelines into a system. Also, GRAPE-3 was the first GRAPE computer to be manufactured and sold by a commercial company. Nearly 100 copies of GRAPE-3 have been sold to more than 30 institutes (more than 20 outside Japan).

With GRAPE-4, a high-accuracy pipeline was integrated into one chip. This chip calculates the first time derivative of the force, so that fourth-order Hermite scheme [10] can be used. Here, again, the serialized pipeline similar to that of GRAPE-2 was used. The chip was fabricated using 1 μm design rule by LSI Logic. Total transistor count was about 400 K.

The completed GRAPE-4 system consisted of 1,728 pipeline chips (36 PCB boards each with 48 pipeline chips). It operated on 32 MHz clock, delivering the speed of 1.1 Tflops. Completed in 1995, GRAPE-4 was

the first computer for scientific calculation to achieve the peak speed higher than 1 Tflops. Also, in 1995 and 1996, it was awarded the Gordon Bell Prize for peak performance, which is given to a real scientific calculation on a parallel computer with the highest performance. Technical details of machines from GRAPE-1 through GRAPE-4 can be found in [14] and references therein.

GRAPE-5 [9] was an improvement over GRAPE-3. It integrated two full pipelines which operate on 80 MHz clock. Thus, a single GRAPE-5 chip offered the speed eight times more than that of the GRAPE-3 chip, or the same speed as that of an eight-chip GRAPE-3 board. GRAPE-5 was awarded the 1999 Gordon Bell Prize for price-performance. The GRAPE-5 chip was fabricated with 0.35 μm design rule by NEC.

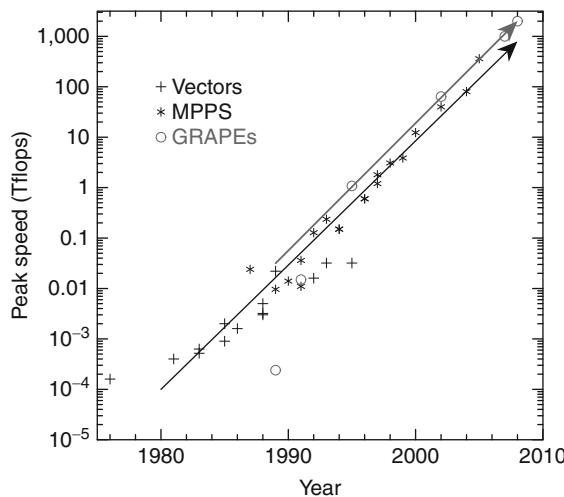

[Table 1](#) summarizes the history of GRAPE project. [Figure 2](#) shows the evolution of GRAPE systems and general-purpose parallel computers. One can see that evolution of GRAPE is faster than that of general-purpose computers.

The GRAPE-6 was essentially a scaled-up version of GRAPE-4 [15], with the peak speed of around 64 Tflops. The peak speed of a single pipeline chip was 31 Gflops. In comparison, GRAPE-4 consists of 1,728 pipeline chips, each with 600 Mflops. The increase of a factor of 50 in speed was achieved by integrating six pipelines into one chip (GRAPE-4 chip has one pipeline which needs three cycles to calculate the force from one particle) and using three times higher clock frequency. The advance of the device technology (from 1 μm to 0.25 μm) made these improvements possible. [Figure 3](#) shows the processor chip delivered in early 1999. The six pipeline units are visible.

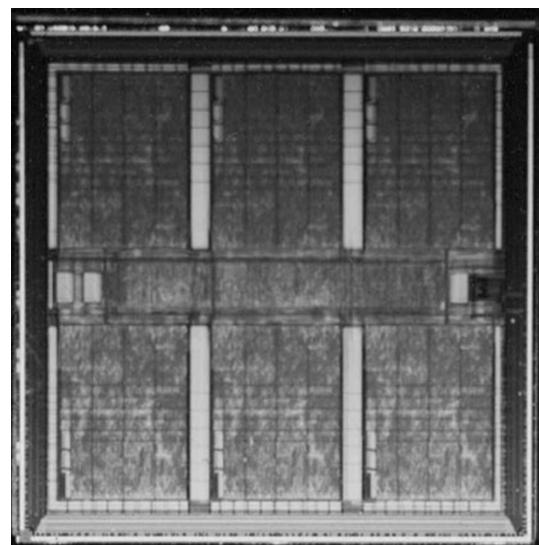

Starting with GRAPE-4, the concept of virtual multiple pipeline (VMP) is used. VMP is similar to simultaneous multithreading (SMT), in the sense that a single pipeline processor behaves as multiple processors. However, what is achieved is quite different. In the case of SMT, the primary gain is in the latency tolerance, since one can execute independent instructions with different threads. In the case of hardwired pipeline processors, there is no need to reduce the latency. With VMP, the bandwidth to the external memory is reduced, since the data of one particle which exerts force are shared by multiple virtual pipelines, each of which calculates the force on its own particle. This sharing of the

GRAPE. Table 1 History of GRAPE project

GRAPE-1	(89/4–89/10)	310 Mflops, low accuracy
GRAPE-2	(89/8–90/5)	50 Mflops, high accuracy(32 bit/64 bit)
GRAPE-1A	(90/4–90/10)	310 Mflops, low accuracy
GRAPE-3	(90/9–91/9)	18 Gflops, high accuracy
GRAPE-2A	(91/7–92/5)	230 Mflops, high accuracy
HARP-1	(92/7–93/3)	180 Mflops, high accuracy Hermite scheme
GRAPE-3A	(92/1–93/7)	8 Gflops/board some 80 copies are used all over the world
GRAPE-4	(92/7–95/7)	1 Tflops, high accuracy Some 10 copies of small machines
MD-GRAPE	(94/7–95/4)	1 Gflops/chip, high accuracy programmable interaction
GRAPE-5	(96/4–99/8)	5 Gflops/chip, low accuracy
GRAPE-6	(97/8–02/3)	64 Tflops, high accuracy

**GRAPE. Fig. 2** The evolution of GRAPE and general-purpose parallel computers. The peak speed is plotted against the year of delivery. Open circles, crosses, and stars denote GRAPEs, vector processors, and parallel processors, respectively

particle can be extended to physical multiple pipelines, as far as the total number of pipeline is not too large. Thus, special-purpose computers based on GRAPE-like pipeline have a unique advantage that their requirement of external memory bandwidth is much smaller than that of general-purpose computers with similar peak performance.

**GRAPE. Fig. 3** The GRAPE-6 processor chip

In the case of GRAPE-6, each of six physical pipelines is implemented as eight virtual pipelines. Thus, one GRAPE-6 chip calculates forces on 48 particles in parallel. The required memory bandwidth was 720 MB/s, for the peak speed of 31 Gflops. A traditional vector processor with the peak speed of 31 Gflops would require the memory bandwidth of 125

GB/s. Thus, GRAPE-6 requires the memory bandwidth around 1/200 of that of a traditional vector processor.

One processor board of GRAPE-6 housed 32 GRAPE-6 chips. Each GRAPE-6 chip has its own memory to store particles which exert the force. Thus, different processor chips on one processor board calculate the forces on the same 48 particles from different particles, and the partial results are summed up by an hardwired adder tree when the result is sent back to the host. Thus, the summation over 32 chips added only a small startup overhead (less than 1 μ s) per one force calculation, which typically requires several milliseconds.

The completed GRAPE-6 system consisted of 64 processor boards, grouped into 4 clusters with 16 boards each. Within a cluster, 16 boards are organized in a 4×4 matrix, with 4 host computers. They are organized so that the effective communication speed is proportional to the number of host computers. In a simple configuration, the effective communication speed becomes independent of the number of host computers. The details of the network used in GRAPE-6 are given in [11].

Machines for Molecular Dynamics

Classical MD calculation is quite similar to astrophysical N-body simulations since, in both cases, we integrate the orbit of particles (atoms or stars) which interact with other particles with simple pairwise force. In the case of Coulomb force, the force law itself is the same as that of the gravitational force, and the calculation of Coulomb force can be accelerated by GRAPE hardware.

However, in MD calculations, the calculation cost of van der Waals force is not negligible, though van der Waals force decays much faster than the Coulomb force (r^{-7} compared to r^{-2}).

It is straightforward to design a pipelined processor which can handle particle-particle force given by some arbitrary function of the distance between particles. In GRAPE-2A and its successors, a combination of table lookup and polynomial approximation is used.

GRAPE-2A and MD-GRAPE were developed in the University of Tokyo, following these lines of idea. GRAPE-2A was built using commercial chips and MD-GRAPE used a custom-designed pipeline chip.

Another difference between astrophysical simulations and MD calculations is that in MD calculations, usually the periodic boundary condition is applied. Thus, we need some way to calculate Coulomb forces

from image particles. The direct Ewald method is rather well suited for the implementation in hardware. In 1991, WINE-1 was developed. It is a pipeline to calculate the wave-space part of the direct Ewald method. The real-space part can be handled by GRAPE-2A or MD-GRAPE hardware.

In 1995, a group led by Toshikazu Ebisuzaki in RIKEN started to develop MDM [16], a massively parallel machine for large-scale MD simulations. Their primary goal was the simulation of protein molecules.

MDM consists of two special-purpose hardware, massively parallel version of MD-GRAPE (MDGRAPE-2) and that of WINE (WINE-2). The MDGRAPE-2 part consisted of 1,536 custom chips with four pipelines, for the theoretical peak speed of 25 Tflops. The WINE-2 part consists of 2,304 custom pipeline chips, for the peak speed of 46 Tflops.

The MDM effort was followed up by the development of MDGRAPE-3 [18], led by Makoto Taiji of RIKEN. MDGRAPE-3 achieved the peak speed of 1 Pflops in 2006.

Related Projects

The GRAPE project is not the first project to implement the calculation of pairwise force in particle-based simulations in hardware.

Delft Molecular Dynamics Processor [2] (DMDP) is one of the earliest efforts. It was completed in early 1980s. For the calculation of interaction between particles, it used the hardwired pipeline similar to that of GRAPE systems. However, in DMDP, time integration of orbits and other calculations are all done in the hardwired processors. Thus, in addition to the force calculation pipeline, DMDP had pipelines to update position, select particles for interaction calculation, and calculate diagnostics such as correlation function. FASTRUN [4] has the architecture similar to that of DMDP, but designed to handle more complex systems such as protein molecule.

To some extent, this difference in the designs of GRAPE computers and that of machines for molecular dynamics comes from the difference in the nature of the problem. In astronomy, the wide ranges in the number density of particles and timescale make it necessary to use adaptive schemes such as treecode and individual timesteps. With these schemes, the calculation cost per timestep per particle is generally higher than

that of fastest scheme optimized to shared timestep and near-uniform distribution of particles. The approach in which only the force calculation is done in hardware is more advantageous for astronomical N -body problems than for molecular dynamics.

Anton [17] is the latest effort to speed up the molecular dynamics simulation of proteins by specialized hardware. It is essentially the revival of the basic idea of DMDP, except that pipeline processors for operations other than force calculation were replaced by programmable parallel processors. It achieved the speed almost two orders of magnitude faster than that of general-purpose parallel computers for the simulation of protein molecules in water.

LSI Economics and GRAPE

GRAPE has achieved the cost performance much better than that of general-purpose computers. One reason for this success is simply that with GRAPE architecture, one can use practically all transistors for arithmetic units, without being limited by the memory wall problem. Another reason is the fact that arithmetic units can be optimized to their specific uses in the pipeline. For example, in the case of GRAPE-6, the subtraction of two positions is performed in 64-bit fixed point format, not in the floating-point format. Final accumulation is also done in fixed point. In addition, most of arithmetic operations to calculate the pairwise interactions are done in single precision. These optimizations made it possible to pack more than 200 arithmetic units into a single chip with less than 10 M transistors. The first microprocessor with fully pipelined double-precision floating-point unit, Intel 80860, required 1.2 M transistors for two (actually one and half) operations. Thus, the number of transistors per arithmetic unit of GRAPE is smaller by more than a factor of 10. When compared with more recent processors, the difference becomes even larger. The Fermi processor from NVIDIA integrates 512 arithmetic unit (adder and multiplier) with 3G transistors. Thus, it is five times less efficient than Intel 80860, and nearly 100 times less efficient than GRAPE-6. The difference in the power efficiency is even larger, because the requirement for the memory bandwidth is lower for GRAPE computers. As a result, performance per watt of GRAPE-6 chip, fabricated with the 250 nm design rule, is comparable to that of GPGPU chips fabricated with 40 nm design rule. Thus, as silicon

technology advances, the relative advantage of special-purpose architecture such as GRAPE becomes bigger.

However, there is another economical factor. As the silicon semiconductor technology advances, the initial cost to design and fabricate custom chip increases. In 1990, the initial cost for a custom chip was around 100 K USD. By 2000, it has become higher than 1 M USD. By 2010, the initial cost of a 45 nm chip is around 10 M USD. Roughly speaking, initial cost has been increasing as $n^{0.7}$, where n is the number of transistors one can fit into a chip.

The total budget for GRAPE-4 and GRAPE-6 projects is 3 and 4 M USD, respectively. Thus, a similar budget had become insufficient by early 2000s. The whole point of special-purpose computer is to be able to outperform “expensive” supercomputers, with the price of 10–100 M USD. Even if a special-purpose computer is 100–1,000 times faster, it is not practical to spend the cost of a supercomputer for a special-purpose computer which can solve only a narrow range of problems.

There are several possible solutions. One is to reduce the initial cost by using FPGA (Field-Programmable Gate Array) chips. An FPGA chip consists of a number of “programmable” logic blocks (LBs) and also “programmable” interconnections. A LB is essentially a small lookup table with multiple inputs, augmented with one flip-flop and sometimes full-adder or more additional circuits. The lookup table can express any combinatorial logic for input data, and with flip-flop, it can be part of a sequential logic. Interconnection network is used to make larger and more complex logic, by connecting LBs. The design of recent FPGA chips has become much more complex, with large functional units like memory blocks and multiplier (typically 18×18 bit) blocks.

Because of the need for the programmability, the size of the circuit that can be fit into an FPGA chip is much smaller than that for a custom LSI, and the speed of the circuit is also slower. Roughly speaking, the price of an FPGA chip per logic gate is around 50 times higher than that of a custom chip with the same design rule. If the relative advantage of a specialized architecture is much larger than this factor of 50, its implementation based on FPGA chips can outperform general-purpose computers.

In reality, there are quite a number of projects to use FPGAs for scientific computing, but most of them

turned out to be not competitive with general-purpose computers. The primary reason for this result is the relative cost of FPGA discussed above. Since the logic gate of FPGAs is much more expensive than that of general-purpose computers, the design of a special-purpose computer with FPGA must be very efficient in gate usage. FPGA-based systems which use standard double- or single-precision arithmetic are generally not competitive with general-purpose computers. In order to be competitive, it is necessary to use much shorter word length. GRAPE architecture with reduced accuracy is thus an ideal target for FPGA-based approach. Several successful approaches have been reported [6, 8].

GRAPE-DR

Another solution for the problem of the high initial cost is to widen the application range by some way to justify the high cost. GRAPE-DR project [12] followed that approach.

With GRAPE-DR, the hardwired pipeline processor of previous GRAPE systems was replaced by a collection of simple SIMD programmable processors. The internal network and external memory interface was designed so that it could emulate GRAPE processor efficiently and could be used for several other important applications, including the multiplication of dense matrices.

GRAPE-DR is an acronym of “Greatly Reduced Array of Processor Elements with Data Reduction.” The last part, “Data Reduction,” means that it has an on-chip tree network which can do various reduction operations such as summation, max/min, and logical and/or.

The GRAPE-DR project was started in FY 2004, and finished in FY 2008. The GRAPE-DR processor chip consists of 512 simple processors, which can operate at the clock cycle of 500 MHz, for the 512 Gflops of single precision peak performance (256 Gflops double precision). It was fabricated with TSMC 90 nm process and the size is around 300 mm². The peak power consumption is around 60 W. The GRAPE-DR processor board houses four GRAPE-DR chips, each with its own local DRAM chips. It communicates with the host computer through Gen1 16-lane PCI-Express interface.

To some extent, the difference between GRAPE and GRAPE-DR is similar to that between traditional GPUs and GPGPUs. In both cases, hardwired pipelines are replaced by simple programmable processors. The main

differences between GRAPE-DR and GPGPUs are (a) processor element of GRAPE-DR is much simpler, (b) external memory bandwidth of GRAPE-DR is much smaller, and (c) GRAPE-DR is designed to achieve near-peak performance in real scientific applications such as gravitational N-body simulation and molecular dynamics simulation, and also dense matrix multiplication. These differences made GRAPE-DR significantly more efficient in both transistor usage and power usage. GRAPE-DR chip, which was fabricated with 90 nm design rule and has 300 mm² area, integrates 512 processing elements. The NVIDIA Fermi chip, which is fabricated with 40 nm design rule and has > 500 mm² area, integrates the same 512 processing elements. Thus, there is about a factor of 10 difference in the transistor efficiency. This difference resulted in more than a factor of 2 difference in the power efficiency.

Whether or not the approach like GRAPE-DR will be competitive with other approaches, in particular GPGPUs, is at the time of writing rather unclear. The reason is simply that the advantage of a factor of 10 is not quite enough, because of the difference in other factors, among which the most important is the development cycle. New GPUs are announced roughly every year, while it is somewhat unlikely that one develops the special-purpose computers every year, even if there is sufficient budget. In 5 years, general-purpose computers become ten times faster, and GPGPUs will also become faster by a similar factor. Thus, a factor of 10 advantage will disappear while the machine is being developed. On the other hand, the transistor efficiency of general-purpose computers, and that of GPUs, has been decreasing for the last 20 years and probably will continue to do so for the next 10 years or so. GRAPE-DR can retain its efficiency when it is implemented with more advanced semiconductor technology, since, as in the case of GRAPE, one can use the increased number of transistors to increase the number of processor element. Thus, it might remain competitive.

Future Directions

Future of Special-Purpose Processors

In hindsight, 1990s was a very good period for the development of special-purpose architecture such as GRAPE, because of two reasons. First, the semiconductor technology reached the point where many

floating-point arithmetic units can be integrated into a chip. Second, the initial design cost of a chip was still within the reach of fairly small research projects in basic science.

By now, semiconductor technology reached to the point that one could integrate thousands of arithmetic units into a chip. On the other hand, the initial design cost of a chip has become too high.

The use of FPGAs and the GRAPE-DR approach are two examples of the way to tackle the problem of increasing initial cost. However, unless one can keep increasing the budget, GRAPE-DR approach is not viable, simply because it still means exponential increase in the initial, and therefore total, cost of the project.

On the other hand, such increase in the budget might not be impossible, since the field of computational science as a whole is becoming more and more important. Even though a supercomputer is expensive, it is still much less expensive compared to, for example, particle accelerators or space telescopes. Of course, computer simulation cannot replace the real experiments of observations, but computer simulations have become essential in many fields of science and technology.

In addition, there are several technologies available in between FPGAs and custom chips. One is what is called “structured ASIC.” It requires customization of typically just one metal layer, resulting in large reduction in the initial cost. The number of gates one can fit into the given silicon area falls between those of FPGAs and custom chips. Another possibility is just to use the technology one or two generations older.

Application Area of Special-Purpose Computers

Primary application area of GRAPE and GRAPE-DR has been the particle-based simulation, in particular that requires the evaluation of long-range interaction. It is suited to special-purpose computers because they are compute-intensive. In other words, the necessary bandwidth to the external memory is relatively small. Grid-based simulations based on schemes like finite-difference or finite-element methods are less compute-intensive and thus not suited to special-purpose computers.

However, the efficiency of large-scale parallel computers based on general-purpose microprocessors for these grid-based simulation has been decreasing rather quickly. There are two reasons for this decrease. One is the lack of the memory bandwidth. Currently, the memory bandwidth of microprocessors normalized by the calculation speed is around 0.3 bytes/flops, which is not enough for most of grid-based simulations. Even so, this ratio will become smaller and smaller in the future. The other reason is the latency of the communication between processors.

One possible solution for these two problems is to integrate the main memory, processor cores, and communication interface into a single chip. This integration gives practically unlimited bandwidth to the memory, and the communication latency is reduced by one or two orders of magnitude.

Obvious disadvantage of this approach is that the total amount of memory would be severely limited. However, in many application of grid-based calculation, very long time integrations of relatively small systems are necessary. Many of such applications requires memory much less than one TB, which can be achieved by using several thousand custom processors each with around 1 GB of embedded DRAM.

Discussion

Parallel Graph Algorithms

Relationships in real-world situations can often be represented as graphs. Efficient parallel processing of graph problems has been a focus of many algorithm researchers. A rich collection of parallel graph algorithms have been developed for various problems on different models. The majority of them are based on the parallel random access machine (PRAM). PRAM is a shared-memory model where data stored in the global memory can be accessed by any processor. PRAM is

synchronous, and in each unit of time, each processor either executes one instruction or stays idle.

Techniques

Graph problems are diverse. Given a graph $G = (V, E)$, where $|V| = n$ and $|E| = m$, several techniques are frequently used in designing parallel graph algorithms. The basic techniques are described as follows (Detailed descriptions can be found in [24]).

Prefix Sum

Given a sequence of n elements s_1, s_2, \dots, s_n with a binary associative operator denoted by \oplus , the prefix sums of the sequence are the partial sums defined by

$$S_i = s_1 \oplus s_2 \oplus \dots \oplus s_i, 1 \leq i \leq n$$

Using the balanced tree technique, the prefix sums of n elements can be computed in $O(\log n)$ time with $O(n/\log n)$ processors. Fast prefix sum is of fundamental importance to the design of parallel graph algorithms as it is frequently used in algorithms for more complex problems.

Pointer Jumping

Pointer jumping, also sometimes called path doubling, is useful for handling computation on rooted forests. For a rooted forest, there is a parent function P defined on the set of vertices. $P(r)$ is set to r when r does not have a parent. When finding the root of each tree, the pointer jumping technique updates the parent of each node by that node's grandparent, that is, set $P(r) = P(P(r))$. The algorithm runs in $O(\log n)$ time with $O(n)$ processors. Pointer jumping can also be used to compute the distance between each node to its root. Pointer jumping is used in several connectivity and tree algorithms (e.g., see [29, 31]).

Divide and Conquer

The divide-and-conquer strategy is recognized as a fundamental technique in algorithm design (not limited to parallel graph algorithms). The frequently used quicksort algorithm is based on divide and conquer. The strategy partitions the input into partitions of roughly equal size and recursively works on each partition concurrently. There is usually a final step to combine the solutions of the subproblems into a solution for the original problem.

Pipelining

Like divide-and-conquer, the use of pipelining is not limited to parallel graph algorithm design. It is of critical importance in computer hardware and software design. Pipelining breaks up a task into a sequence of smaller tasks (subtasks). Once a subtask is complete and moves to the next stage, the ones following it can be processed in parallel. Insertion and deletion with 2-3 trees demonstrate the pipelining technique [27].

Deterministic Coin Tossing

Deterministic coin tossing was proposed by Cole and Vishkin [9] to break the symmetry of a directed cycle without using randomization. Consider the problem of finding a three-coloring of graph G . A k -coloring of G is a mapping $c : V \rightarrow \{0, 1, \dots, k - 1\}$ such that $c(i) \neq c(j)$ if $\langle i, j \rangle \in E$. Initially, the cycle has a trivial coloring with $n = |V|$ colors. The apparent symmetry in the problem (i.e., the vertices cannot be easily distinguished) presents the major difficulty to reducing the number of colors needed for the coloring. Deterministic coin tossing uses the binary representation of an integer $i = \cdots i_k \cdots i_1 i_0$ to break the symmetry. For example, suppose t is the least significant bit position in which $c(i)$ and $c(S(i))$ differ ($S(i)$ is the successor of i in the cycle), then the new coloring for i can be set as $2t + c(i)_t$.

Accelerating Cascades

Accelerating cascades was presented together with deterministic coin tossing in [9] for the design of faster algorithms for list ranking and other problems. This technique combines two algorithms, one optimal and the other super fast, for the same problem to get a optimal and very fast algorithm. The general strategy is to start with the optimal algorithm to reduce the problem size and then apply the fast but nonoptimal algorithm.

Other Building Blocks for Parallel Graph Algorithms

List ranking determines the position, or rank, of the list items in a linked list. A generalized list-ranking problem is defined as follows. Let X be an array of n elements stored in arbitrary order. For each element i , let $X(i).value$ be its value and $X(i).next$ be the index of its successor. Then, for any binary associative operator \oplus , compute $X(i).prefix$ such that $X(head).prefix = X(head).value$ and $X(i).prefix =$

$X(i).value \oplus X(predecessor).prefix$, where $head$ is the first element of the list, i is not equal to $head$, and $predecessor$ is the node preceding i in the list. Pointer jumping can be applied to solve the list-ranking problem. An optimal list-ranking algorithm is given in [10].

The Euler tour technique is another of the basic building blocks for designing parallel algorithms, especially for tree computations. For example, postorder/preorder numbering, computing the vertex level, computing the number of descendants, etc., can be done work-time optimally on EREW PRAM by applying the Euler tour technique. As suggested by its name, the power of the Euler tour technique comes from defining a Eulerian circuit on the tree. In Tarjan and Vishkin's biconnected components paper [31] that originally introduced the Euler tour technique, the input to their algorithm is an edge list with the cross-pointers between twin edges $\langle u, v \rangle$ and $\langle v, u \rangle$ established. With these cross-pointers it is easy to derive an Eulerian circuit. The Eulerian circuit can be treated as a linked list, and by assigning different values to each edge in the list, list ranking can be used for many tree computation. For example, when rooting a tree, the value 1 is associated with each edge. After list ranking, simply inspecting the list rank for $\langle u, v \rangle$ and $\langle v, u \rangle$ can set the correct parent relationship for u and v .

Tree contraction systematically shrinks a tree into a single vertex by successively shrinking parts of the tree. It can be used to solve the expression evaluation problem. It is also used in other algorithm, for example, computing the biconnected components [31].

Classical Algorithms

The use of the basic techniques are demonstrated in several classical graph algorithms for spanning tree, minimum spanning tree, and biconnected components.

Various deterministic and randomized techniques have been given for solving the spanning tree problem (and the closely related connected components problem) on PRAM models. A brief survey of these algorithms can be found in [3]. The Shiloach–Vishkin algorithm (SV) algorithm is representative of several connectivity algorithms in that it adapts the widely used graft-and-shortcut approach. Through carefully designed grafting schemes, the algorithm achieves complexities of $O(\log n)$ time and $O((m+n)\log n)$

work under the arbitrary CRCW PRAM model. The algorithm takes an edge list as input and starts with n isolated vertices and m processors. Each processor P_i ($1 \leq i \leq m$) inspects edge $e_i = \langle v_{i_1}, v_{i_2} \rangle$ and tries to graft vertex v_{i_1} to v_{i_2} under the constraint that $v_{i_1} < v_{i_2}$. Grafting creates $k \geq 1$ connected components in the graph, and each of the k components is then shortcut to a single super-vertex. Grafting and short-cutting are iteratively applied to the reduced graphs $G' = (V', E')$ (where V' is the set of super-vertices and E' is the set of edges among super-vertices) until only one super-vertex is left.

Minimum spanning tree (MST) is one of the most studied combinatorial problems with practical applications. While several theoretic results are known for solving MST in parallel, many are considered impractical because they are too complicated and have large constant factors hidden in the asymptotic complexity. See for a survey of MST algorithms. Many parallel algorithms are based on the Boruvka algorithm. Boruvka's algorithm is comprised of Boruvka iterations that are used in many parallel MST algorithms. A Boruvka iteration is characterized by three steps: *find-min*, *connected-components*, and *compact-graph*. In *find-min*, for each vertex v the incident edge with the smallest weight is labeled to be in the MST; *connect-components* identifies connected components of the induced graph with the labeled MST edges; *compact-graph* compacts each connected component into a single supervertex, removes self-loops and multiple edges, and relabels the vertices for consistency.

A connected graph is said to be *separable* if there exists a vertex v such that removal of v results in two or more connected components of the graph. Given a connected, undirected graph G , the biconnected components problem finds the maximal-induced subgraphs of G that are not *separable*. Tarjan [30] presents an optimal $O(n + m)$ algorithm that finds the biconnected components of a graph based on depth-first search (DFS). Eckstein [17] gave the first parallel algorithm that takes $O(d \log^2 n)$ time with $O((n + m)/d)$ processors on CREW PRAM, where d is the diameter of the graph. Tarjan and Vishkin [31] present an $O(\log n)$ time algorithm on CRCW PRAM that uses $O(n + m)$ processors. This algorithm utilizes many of the fundamental primitives including prefix sum, list ranking, sorting, connectivity, spanning tree, and tree computations.

Communication Efficient Graph Algorithms

Communication-efficient parallel algorithms were proposed to address the “bottleneck of processor-to-processor communication” (e.g., see [15]). Goodrich [19] presented a communication-efficient sorting algorithm on weak-CREW BSP that runs in $O(\log n / \log(h+1))$ communication rounds (with at most h data transported by each processor in each round) and $O((n \log n)/p)$ local computation time, for $h = \Theta(n/p)$. Goodrich's sorting algorithm is frequently used in communication-efficient graph algorithms. Dehne et al. designed an efficient list-ranking algorithm for coarse-grained multicomputers (CGM) and BSP that takes $O(\log p)$ communication rounds with $O(n/p)$ local computation. In the same study, a series of communication-efficient graph algorithms such as connected components, ear decomposition, and biconnected components are presented using the list-ranking algorithm as a building block. On the BSP model, Adler et al. [1] presented a communication-optimal MST algorithm. The list-ranking algorithm and the MST algorithm take similar approaches to reduce the number of communication rounds. They both start by simulating several (e.g., $O(\log p)$ or $O(\log \log p)$) steps of the PRAM algorithms on the target model to reduce the input size so that it fits in the memory of a single node. A sequential algorithm is then invoked to process the reduced input of size $O(n/p)$, and finally the result is broadcast to all processors for computing the final solution.

Practical Implementation

Many real-world graphs are large and sparse. These instances are especially hard to process due to the characteristics of the workload. Although fast theoretic algorithms exist in the literature, large and sparse graph problems are still challenging to solve in practice. There remains a significant gap between algorithmic model and architecture. The mismatch between memory access pattern and cache organization is the most outstanding barrier to high-performance graph analysis on current systems.

Graph Workload

Compared with traditional scientific applications, graph analysis is more memory intensive. Graph algorithms put tremendous pressure on the memory subsystem

to deliver data to the processor. [Table 1](#) shows the percentages of memory instructions executed in the SPLASH2 benchmarks [34] and several graph algorithms. SPLASH2 represents typical scientific applications for shared-memory environments. On IBM Power5, on average, about 10% more memory instructions are executed in the graph algorithms. For biconnected components, the number is over 59%.

For memory-intensive applications, the locality behavior is especially crucial to the performance. Unfortunately, most graph algorithms exhibit erratic memory access patterns that result in poor performance, as shown in [Table 2](#). [Table 2](#) is the cycles per instruction (CPI) construction [13] for three graph algorithms on IBM Power5. The algorithms studied are betweenness centrality (BC), biconnected components (BiCC), and minimum spanning tree (MST). CPI construction attributes in percentage cycles to categories such as completion, instruction cache miss penalty, and stall. In [Table 2](#), for all algorithms, significant amount of cycles are spent on pipeline stalls. About 60–70% of the cycles are wasted on the load-store unit stalls, and more than 50% of the cycles are spent on stalls due to data cache misses. [Table 2](#) clearly shows that graph algorithms perform poorly on current cache-based architectures, and the culprit is the memory access pattern. The floating-point stalls (FPU STL) column is revealing about one other prominent feature of graph algorithms.

FPU STL is the percentage of cycles wasted on floating-point unit stalls. In [Table 2](#), BiCC and MST do not incur any FPU stalls. Unfortunately, this does not mean that the workload fully utilizes the FPU. Instead, as there are no floating-point operations in these algorithms, the elaborately designed floating point units lay idle. CPI construction shows that graph workloads spent most of the time waiting for data to be delivered, and there are not many other operations to hide the long latency to main memory. In fact, of the three algorithms, only BC incurs execution of a few floating-point instructions.

G

Implementation on Shared-Memory Machines

It is relatively straightforward to map PRAM algorithms on to shared-memory machines such as symmetric multiprocessors (SMPs), multi-core and many core systems. While these systems are of shared-memory architecture, they are by no means the PRAM used in theoretical work – synchronization cannot be taken for granted, memory bandwidth is limited, and performance requires a high degree of locality. Practical design choices need to be made to achieve high performance on such systems.

Adapting to the Available Parallelism

Nick's Class (\mathcal{NC}) is defined as the set of all problems that run in polylog-time with a polynomial number of processors. Whether a problem P is in \mathcal{NC} is a fundamental question. The PRAM model assumes an

Graph Algorithms. Table 1 Percentages of load-store instructions for the SPLASH2 benchmark and the graph problems. ST, MST, BiCC, and CC stand for spanning tree, minimum spanning tree, biconnected components, and connected components, respectively

Benchmark	SPLASH2				Graph problems			
	Barnes	Cholesky	Ocean	Raytrace	ST	MST	BiCC	CC
Load	20.3%	20.6%	21.4%	25.1%	45.6%	28.6%	40.4%	44.5%
Store	15.6%	5.2%	17.8%	9.5%	2%	15.2%	19.2%	1.4%
Load+store	35.9%	25.8%	39.2%	34.6%	47.6%	43.8%	59.6%	45.9%

Graph Algorithms. Table 2 CPI construction for three graph algorithms. Base cycles are for “useful” work. The “Stall” columns show the percentages of cycles on pipeline stalls followed by stalls due to load-store unit, data cache miss, floating-point unit, fix point unit, respectively

Algorithm	Base	GCT	Stall	LSU STL	DCache STL	FPU STL	FXU STL
BC	0.099	0.011	0.888	0.797	0.558	0.030	0.016
BiCC	0.170	0.066	0.762	0.600	0.445	0.000	0.060
MST	0.106	0.037	0.855	0.713	0.600	0.000	0.015

unlimited number of processors and explores the maximum inherent parallelism of P . Acknowledging the practical restriction of limited parallelism provided by real computers, Kruskal et al. [26] argued that non-polylogarithmic time algorithms (e.g., sublinear time algorithms) could be more suitable than polylog algorithms for implementation with practically large input size. \mathcal{EP} (short for *efficient parallel*) algorithms, by the definition in [26], is the class of algorithms that achieve a polynomial reduction in running time with a polylogarithmic inefficiency. With \mathcal{EP} algorithms, the design focus is shifted from reducing the complexity factors to solving problems of realistic sizes efficiently with a limited number of processors.

Reducing Synchronization

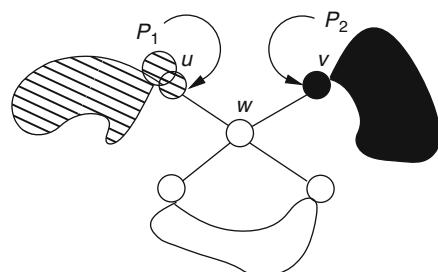

When adapting a PRAM algorithm to shared-memory machines, a thorough understanding of the algorithm usually suffices to eliminate unnecessary synchronization such as barriers. Reducing synchronization thus is an implementation issue. Asynchronous algorithm design, however, is more aggressive in reducing synchronization. It sometimes allows nondeterministic intermediate results but deterministic solutions.

In a parallel environment, to ensure correct final results oftentimes a total ordering on all the events is not necessary, and a partial ordering in general suffices. Relaxed constraints on ordering reduce the number of synchronization primitives in the algorithm.

Bader and Cong presented a largely asynchronous spanning tree algorithm in [3] that employs a constant number of barriers. The spanning tree algorithm for shared-memory machines has two main steps: (1) stub spanning tree and (2) work-stealing graph traversal. In the first step, one processor generates a stub spanning tree, that is, a small portion of the spanning tree by randomly walking the graph for $O(p)$ steps. The vertices of the stub spanning tree are evenly distributed into each processor's queue, and each processor in the next step will traverse from the first element in its queue. After the traversals in step 2, the spanning subtrees are connected to each other by this stub spanning tree. In the graph traversal step, each processor traverses the graph (by coloring the nodes) similar to the sequential algorithm in such a way that each processor finds a subgraph of the final spanning tree. Work-stealing is used to balance the load for graph traversal.

One problem related to synchronization is that there could be portions of the graph traversed by multiple processors and be in different subgraphs of the spanning tree. The immediate remedy is to synchronize using either locks or barriers. With locks, coloring the vertex becomes a critical section, and a processor can only enter the critical section when it gets the lock. Although the nondeterministic behavior is now prevented, it does not perform well on large graphs due to an excessive number of locking and unlocking operations.

In the proposed algorithm, no barriers are introduced in graph traversal. The algorithm runs correctly without barriers even when two or more processors color the same vertex. In this situation, each processor will color the vertex and set as its parent the vertex it has just colored. Only one processor succeeds at setting the vertex's parent to a final value. For example, using Fig. 1, processor P_1 colored vertex u , and processor P_2 colored vertex v , and at a certain time they both find w unvisited and are now in a race to color vertex w . It makes no difference which processor colored w last because w 's parent will be set to either u or v (and it is legal to set w 's parent to either of them; this will not change the validity of the spanning tree, only its shape). Further, this event does not create cycles in the spanning tree under sequential consistency model. Both P_1 and P_2 record that w is connected to each processor's own tree. When each of w 's unvisited children are visited by various processors, its parent will be set to w , independent of w 's parent.

Graph Algorithms. Fig. 1 Two processors P_1 and P_2 see vertex w as unvisited, so each is in a race to color w and set w 's parent pointer. The shaded area represents vertices colored by P_1 , the black area represents those marked by P_2 , and the white area contains unvisited vertices

Choosing Between Barriers and Locks

Locks and barriers are two major types of synchronization primitives. In practice, the choice of using locks or barriers may not be very clear. Take the “graft and shortcut” spanning tree algorithm for example. For graph $G = (V, E)$ represented as an edge list, the algorithm starts with n isolated vertices and $2m$ processors. For edge $e_i = \langle u, v \rangle$, processor P_i ($1 \leq i \leq m$) inspects u and v , and if $v < u$, it grafts vertex u to v and labels e_i to be a spanning tree edge. The problem here is that for a certain vertex v , its multiple incident edges could cause grafting v to different neighbors, and the resulting tree may not be valid. To ensure that v is only grafted to one of the neighbors, locks can be used. Associated with each vertex v is a flag variable protected by a lock that shows whether v has been grafted. In order to graft v a processor has to obtain the lock and check the flag, thus race conditions are prevented. A different solution uses barriers [31] in a two-phase election. No checking is needed when a processor grafts a vertex, but after all processors are done (ensured with barriers), a check is performed to determine which one succeeds and the corresponding edge is labeled as a tree edge. Whether to use a barrier or lock is dependent on the algorithm design as well as the barrier and lock implementations. Locking typically introduces large memory overhead. When contention among processors is intense, the performance degrades significantly.

Cache Friendly Design

The increasing speed difference between processor and main memory makes cache and memory access patterns important factors for performance. The fact that modern processors have multiple levels of memory hierarchy is generally not reflected by most of the parallel models. As a result, few parallel algorithm studies have touched on the cache performance issue. The SMP model proposed by Helman and JáJa is the first effort to model the impact of memory access and cache over an algorithm’s performance [21]. The model forces an algorithm designer to reduce the number of noncontiguous memory accesses. However, it does not give hints to the design of cache-friendly parallel algorithms.

Chiang et al. [7] presented a PRAM simulation technique for designing and analyzing efficient external-memory (sequential) algorithms for graph problems. This technique simulates the PRAM memory by

keeping a task array of $O(N)$ on disk. For each PRAM step, the simulation sorts a copy of the contents of the PRAM memory based on the indices of the processors for which they will be operands, and then scans this copy and performs the computation for each processor being simulated. The following can be easily shown:

Theorem 1 *Let A be a PRAM algorithm that uses N processors and $O(N)$ space and runs in time T . Then A can be simulated in $O(T \cdot \text{sort}(N))$ I/Os [7].*

Here, $\text{sort}(N)$ represents the optimal number of I/Os needed to sort N items striped across the disks, and $\text{scan}(N)$ represents the number of I/Os needed to read N items striped across the disks. Specifically,

$$\text{sort}(x) = \frac{x}{DB} \log_{\frac{M}{B}} \frac{x}{B}$$

$$\text{scan}(x) = \frac{x}{DB}$$

where $M = \#$ of items that can fit into main memory, $B = \#$ of items per disk block, and $D = \#$ of disks in the system.

A similar technique can be applied to the cache-friendly parallel implementation of PRAM algorithms for large inputs. I/O efficient algorithms exhibit good spatial locality behavior that is critical to good cache performance. Instead of having one processor simulate the PRAM step, $p \ll n$ processors may perform the simulation concurrently. The simulated PRAM implementation is expected to incur few cache block transfers between different levels. For small input sizes, it would not be worthwhile to apply this technique as most of the data structures can fit into cache. As the input size increases, the cost to access memory becomes more significant, and applying the technique becomes beneficial.

Algorithmic Optimizations

For most problems, parallel algorithms are inherently more complicated than the sequential counterparts, incurring large overheads with many algorithm steps. Instead of lowering the asymptotic complexities, in many cases, reducing the constant factors improves performance. Cong and Bader demonstrates the benefit of such optimizations with their biconnected components algorithm [11].

The algorithm eliminates edges that are not essential in computing the biconnected components. For any

input graph, edges are first eliminated before the computation of biconnected components is done so that at most $\min(m, 2n)$ edges are considered. Although applying the filtering algorithm does not improve the asymptotic complexity, in practice, the performance of the biconnected components algorithm can be significantly improved.

An edge e is considered as *nonessential* for biconnectivity if removing e does not change the biconnectivity of the component to which it belongs. Filtering out *nonessential* edges when computing biconnected components (these edges are put back in later) yields performance advantages. The Tarjan–Vishkin algorithm (TV) is all about finding the equivalence relation R'_c^* [24, 31]. Of the three conditions for R'_c , it is trivial to check for condition 1 which is for a tree edge and a non-tree edge. Conditions 2 and 3, however, are for two tree edges, and checking involves the computation of *high* and *low* values. To compute *high* and *low*, every non-tree edge of the graph is inspected, which is very time consuming when the graph is not extremely sparse. The fewer edges the graph has, the faster the *Low-high* step. Also, when building the auxiliary graph, the fewer edges in the original graph means the smaller the auxiliary graph and the faster the *Label-edge* and *Connected-components* steps.

Combining the filtering algorithm for eliminating *nonessential* edges and TV, the new biconnected components algorithm runs in $\max(O(d), O(\log n))$ time with $O(n)$ processors on CRCW PRAM, where d is the diameter of the graph. Asymptotically, the new algorithm is not faster than TV. In practice, however, parallel speedups up to 4 with 12 processors are achieved on SUN Enterprise 4500 using the filtering technique.

Implementation on Multithreaded Architectures

Graph algorithms have been observed to run well on multi-threaded architectures such as the CRAY MTA-2 [5] and its successor, the Cray XMT. The Cray MTA [14] is a flat, shared-memory multiprocessor system. All memory is accessible and equidistant from all processors. There is no local memory and no data caches. Parallelism, and not caches, is used to tolerate memory and synchronization latencies.

An MTA processor consists of 128 hardware streams and one instruction pipeline. Each stream can have up to 8 outstanding memory operations. Threads from the

same or different programs are mapped to the streams by the runtime system. A processor switches among its streams every cycle, executing instructions from non-blocked streams in a fair manner. As long as one stream has a ready instruction, the processor remains fully utilized.

Bader et al. compared the performance of list-ranking algorithm on SMPs and MTA [5]. For list ranking, they used two classes of list to test the algorithms: *Ordered* and *Random*. Ordered places each element in the array according to its rank; thus, node i is the i^{th} position of the array and its successor is the node at position $(i + 1)$. Random places successive elements randomly in the array. Since the MTA maps contiguous logical addresses to random physical addresses, the layout in physical memory for both classes is similar, the performance on the MTA is independent of order. This is in sharp contrast to SMP machines which rank Ordered lists much faster than Random lists. On the SMP, there is a factor of 3–4 difference in performance between the best case (an ordered list) and the worst case (a randomly-ordered list). On the ordered lists, the MTA is an order of magnitude faster than the SMP, while on the random list, the MTA is approximately 35 times faster.

Implementation on Distributed Memory Machines

As data partitioning and explicit communication are required, implementing highly irregular algorithms is hard on distributed-memory machines. As a result, although many fast theoretic algorithms exist in the literature, few experimental results are known. As for performance, the adverse impact of irregular accesses is magnified in the distributed-memory environment when memory requests served by remote nodes experience long network latency. Two studies have demonstrated reasonable parallel performance with distributed-memory machines [28, 35]. Both studies implement parallel breadth-first search (BFS), one on BlueGene/L [2] and the other on CELL/BE [22]. The CELL architecture resembles a distributed-memory setting as explicit data transfer is necessary between the local storage on an SPE and the main memory. Neither study establishes a strong evidence for fast execution of parallel graph algorithms on distributed-memory systems. The individual CPU in BlueGene and the PPE

of CELL are weak compared with other Power processors or the SPE. It is hard to establish a meaningful baseline to compare the parallel performance against. Indeed, in both studies, either only wall clock times or speedups compared with other reference architectures are reported.

Partitioned global address space (PGAS) languages such as UPC and X10 [6, 32] have been proposed recently that present a shared-memory abstraction to the programmer for distributed-memory machines. They allow the programmer to control the data layout and work assignment for the processors. Mapping shared-memory graph algorithms onto distributed-memory machines is straightforward with PGAS languages.

Performance wise, straightforward PGAS implementation for irregular graph algorithms does not usually achieve high performance due to the aggregate startup cost of many small messages. Cong, Almasi, and Saraswat presented their study in optimizing the UPC implementation of graph algorithm in [12]. They improve both the communication efficiency and the cache performance of the algorithm through improving the locality behavior.

Some Experimental Results

Greiner [20] implemented several connected components algorithms using NESL on the Cray Y-MP/C90 and TMC CM-2. Hsu, Ramachandran, and Dean [23] also implemented several parallel algorithms for connected components. They report that their parallel code runs 30 times slower on a MasPar MP-1 than Greiner's results on the Cray, but Hsu et al.'s implementation uses one-fourth of the total memory used by Greiner's approach. Krishnamurthy et al. [25] implemented a connected components algorithm (based on Shiloach-Vishkin [29]) for distributed memory machines. Their code achieved a speedup of 20 using a 32-processor TMC CM-5 on graphs with underlying 2D and 3D regular mesh topologies, but virtually no speedup on sparse random graphs. Goddard, Kumar, and Prins [18] implemented a connected components algorithm for a mesh-connected SIMD parallel computer, the 8192-processor MasPar MP-1. They achieve a maximum parallel speedup of less than two on a random graph with 4,096 vertices and about one-million edges. For a

random graph with 4,096 vertices and fewer than a half-million edges, the parallel implementation was slower than the sequential code.

Chung and Condon [8] implemented a parallel minimum spanning tree (MST) algorithm based on Boruvka's algorithm. On a 16-processor CM-5, for geometric graphs with 32,000 vertices and average degree 9 and graphs with fewer vertices but higher average degree, their code achieved a parallel speedup of about 4, on 16-processors, over the sequential Boruvka's algorithm, which was 2–3 times slower than their sequential Kruskal algorithm.

Dehne and Götz [16] studied practical parallel algorithms for MST using the BSP model. They implemented a dense Boruvka parallel algorithm, on a 16-processor Parsytec CC-48, that works well for sufficiently dense input graphs. Using a fixed-sized input graph with 1,000 vertices and 400,000 edges, their code achieved a maximum speedup of 6.1 using 16 processors for a random dense graph. Their algorithm is not suitable for sparse graphs.

Woo and Sahni [33] presented an experimental study of computing biconnected components on a hypercube. Their test cases are graphs that retain 70 and 90% edges of the complete graphs, and they achieved parallel efficiencies up to 0.7 for these dense inputs. The implementation uses adjacency matrix as input representation, and the size of the input graphs is limited to less than 2K vertices.

Bader and Cong presented their studies [3, 4, 11] of the spanning tree, minimum spanning tree, and biconnected components algorithms on SMPs. They achieved reasonable parallel speedups on the large, sparse inputs compared with the best sequential implementations.

Graph Partitioning

BRUCE HENDRICKSON

Sandia National Laboratories, Albuquerque, NM, USA

Definition

Graph partitioning is a technique for dividing work amongst processors to make effective use of a parallel computer.

Discussion

When considering the data dependencies in a parallel application, it is very convenient to use concepts from graph theory. A *graph* consists of a set of entities called *vertices*, and a set of pairs of entities called *edges*. The entities of interest in parallel computing are small units of computation that will be performed on a single processor. They might be the work performed to update the state of a single atom in a molecular dynamics simulation, or the work required to compute the contribution of a single row of a matrix to a matrix-vector multiplication. Each such work unit will be a vertex in the graph which describes the computation. If two units have a data dependence between them (i.e., the output of one computation is required as input to the other), then there will be an edge in the graph that joins the two corresponding vertices.

For a computation to perform efficiently on a parallel machine each of the P processors needs to have about the same amount of work to perform, and the amount of inter-processor communication must be small. These two conditions can be viewed in terms of the computational graph. The vertices of the graph (signifying

units of work) need to be divided into P sets with about the same number of vertices in each. Additionally, the number of edges that connect vertices in two different sets needs to be kept small since these will reflect the need for interprocessor communication. This problem is known as *graph partitioning* and is an important approach to the parallelization of many applications.

More generally, the vertices of the graph can have weights associated with them, reflecting different amounts of computation, and the edges can also have weights corresponding to different quantities of communication. The graph partitioning problem involves dividing the set of vertices into P sets with about the same amount of total vertex weight, while keeping small the total weight of edges that cross between partitions. This problem is known to be NP-hard, but a number of heuristics have been devised that have proven to be effective for many parallel computing applications. Several software tools have been developed for this problem, and they are an important piece of the parallel computing ecosystem. Important algorithms and tools are discussed below.

Parallel Computing Applications of Graph Partitioning

Graph partitioning is a useful technique for parallelizing many scientific applications. It is appropriate when the calculation consists of a series of steps in which the computational structure and data dependencies do not vary much. Under such circumstances the expense of partitioning is rewarded by improved parallel performance for many computational steps.

The partitioning model is most applicable for bulk synchronous parallel applications in which each step consists of local computation followed by a global data exchange. Fortunately, many if not most scientific applications exhibit this basic structure. Particle simulations are one such important class of applications. The particles could be atoms in a material science or biological simulation, stars in a simulation of galaxy formation, or units of charge in an electromagnetic application.

But by far the most common uses of graph partitioning involve computational meshes for the solution of differential equations. Finite volume, finite difference, and finite element methods all involve the decomposition of a complex geometry into simple shapes that interact only with near neighbors. Various graphs can be

constructed from the mesh and a partition of the graph identifies subregions to be assigned to processors. The numerical methods associated with such approaches are often very amenable to the graph partitioning approach. These ideas have been used to solve problems from many areas of computational science including fluid flow, structural mechanics, electromagnetics, and many more.

Graph Partitioning Algorithms for Parallel Computing

A wide variety of graph partitioning algorithms have been proposed for parallel computing applications. Here we review some of the more important approaches.

Geometric partitioning algorithms are very fast techniques for partitioning sets of entities that have an underlying geometry. For parallel computing applications involving simulations of physical phenomena in two or three dimensions, the corresponding data structures typically have geometric coordinates associated with each entity. Examples include molecules in atomistic simulations, masses in gravitational models, or mesh points in a finite element method. Recursive coordinate partitioning is a method in which the elements are recursively divided by planar cuts that are orthogonal to one of the axes [1]. This has the advantage of producing geometrically simple subdomains – just rectangular parallelepipeds. Recursive inertial bisection also uses planar cuts, but instead of being orthogonal to an axis, they are orthogonal to the direction of greatest inertia [9]. Intuitively, this is a direction in which the point set is elongated, so cutting perpendicular to this direction is likely to produce a smaller cut. Yet another alternative is to cut with circles or spheres instead of planes [8]. Geometric methods tend to be very fast, but produce low-quality partitions. They can be improved via local refinement methods like the approach of Fiduccia-Mattheyses discussed below.

A quite different set of approaches uses eigenvectors of a matrix associated with the graph. The most popular method in this class uses the second-smallest eigenvector of the Laplacian matrix of the graph [9]. A justification for this approach is beyond the scope of this article, but spectral methods generally produce partitions of fairly high quality. In a global sense, they find attractive regions for cutting a graph, but they are often poor

in the fine details. This can be rectified by the application of a local refinement method. The main drawback of spectral methods is their high computational cost.

Local refinement methods are epitomized by the approach proposed by Fiduccia and Mattheyses [5] (FM). This method works by iteratively moving vertices between partitions in a manner that maximally reduces the size of the set of cut edges. Moves are considered even if they make the cut size larger since they may enable subsequent moves that lead to even better partitions. Thus, this method has a limited ability to escape from local minima to search for even better solutions. The key advance underlying FM is the use of clever data structures that allow all the moves and their consequences to be explored and updated efficiently. The FM algorithm is quite fast, and consistently improves results generated by other approaches. But since it only explores sets of partitions that are not far from the initial one, it is generally limited to making small changes and will not find better partitions that are quite different.

The most widely used class of graph partitioning techniques are multilevel algorithms as they provide a good balance between speed and quality. They were independently invented by several research groups more or less simultaneously [2, 4, 7]. Multilevel algorithms work by applying a local refinement method like FM at multiple scales. This largely overcomes the myopia that limits the effectiveness of local methods. This is accomplished by constructing a series of smaller and smaller graphs that roughly approximate the original graph. The most common way to do this is to merge small clusters of vertices within the original graph (e.g., combine two vertices sharing an edge into a single vertex). Once this series of graphs is constructed, the smallest graph is partitioned using any global method. Then the partition is refined locally and extended to the next larger graph. The refinement/extension process is repeated on larger and larger graphs until a partitioning of the original graph has been produced.

A number of general purpose global optimization approaches have been proposed for graph partitioning including simulated annealing, genetic algorithms, and tabu search. These methods can produce high-quality partitions but are usually very expensive and so are limited to niche applications within parallel computing.

Graph partitioning is often used as a preprocessing step to set up a parallel computation. The output of a

graph partitioner determines which objects are assigned to which processors, and appropriate input files and data structures are prepared for a parallel run. However, there are several situations in which the partitioning must be done in parallel. For a very large problem, the memory of a serial machine may be insufficient to hold the graph that needs to be partitioned. Also, for some classes of applications the structure of the computation changes over time. Examples include adaptive mesh simulations, or particle methods in which the particles move significantly. For such problems the work load must be periodically redistributed across the processors, and a parallel partitioning tool is required. Simple geometric algorithms have the advantage of being easy to parallelize, but multilevel partitioners have also been parallelized to provide higher-quality solutions. Techniques for effectively parallelizing such methods is an ongoing area of research.

A variety of open source graph partitioning tools have been developed in serial or parallel including Chaco, METIS, Jostle, and SCOTCH. Several of these are discussed in companion articles.

Limitations of Graph Partitioning

Although widely used to enable the parallelization of scientific applications, graph partitioning is an imperfect abstraction. For a parallel application to perform well, the work must be evenly distributed among processors and the cost of interprocessor communication must be minimized. Graph partition provides only a crude approximation for achieving these objectives.

In the graph partitioning model, each vertex is assigned a weight that is supposed to represent the time required to perform a piece of computation. On modern processors with complex memory hierarchies it is very difficult to accurately predict the runtime of a piece of code *a priori*. Cache performance can dominate runtime, and this is very hard to predict in advance. So the weights assigned to vertices in the graph partitioning model are just rough approximations.

An even more significant shortcoming of graph partitioning has to do with communication. For most applications, a vertex has data that needs to be known by all of its neighbors. If two of those neighbors are owned by the same processor, then that data need only be communicated once. In the graph partitioning model, two

edges would be cut and so the actual volume of communication would be over-counted. Several alternatives to standard graph partitioning have been proposed to address this problem. In one approach, the number of vertices with off-processor neighbors is counted instead of the number of edges cut. A more powerful and elegant alternative uses hypergraphs and is sketched below.

Yet another deficiency in graph partitioning is that it emphasizes the total volume of communication. In many practical situations, latency is the performance-limiting factor, so it is the number of messages that matters most, not the size of messages.

As discussed above, graph partitioning is most appropriate for bulk synchronous applications. If the calculation involves complex interleaving of computations with communication or partial synchronizations then graph partitioning is less useful. An important application with this character is the factorization of a sparse matrix.

Finally, graph partitioning is only appropriate for applications in which the work and communication pattern are predictable and stable. This happens to be the case for many important scientific computing kernels, but there are other applications that do not fit this model.

Hypergraph Partitioning

A hypergraph is a generalization of a graph. Whereas a graph edge connects exactly two vertices, a *hyperedge* can connect any subset of vertices. This seemingly simple generalization leads to improved and more general partitioning models for parallel computing [3].

Consider a graph in which vertices represent computation and edges represent data dependencies. For each vertex, replace all the edges connected to it with a single hyperedge that joins the vertex and all of its neighbors. When the vertices are partitioned, if a particular vertex is separated from any of its neighbors, the corresponding hyperedge will be cut. For the common situation in which the vertex needs to communicate the same information to all of its neighbors, this single hyperedge will reflect the amount of data that needs to be shared with another processor. Thus, the number of cut hyperedges (or more generally the total weight of cut hyperedges) correctly captures the total volume of communication induced by a partitioning. In this way, the

hypergraph model resolves an important shortcoming of standard graph partitioning.

Hypergraphs also address a second deficiency of the graph model. If the communication is not symmetric (e.g., vertex i needs to send data to j , but j does not need to send data to i), then the graph model has difficulty capturing the communication requirements. The hypergraph model does not have this problem. A hyper-edge simply spans a vertex i and every other vertex that i needs to send data to. There is no implicit assumption of symmetry in the construction of the hypergraph model.

Graph and hypergraph partitioning models, algorithms, and software continue to be active areas of research in parallel computing. PaToH and hMETIS are widely used hypergraph partitioning tools for parallel computing.

Bibliographic Notes and Further Reading

Graph partitioning is a well-studied problem in theoretical computer science and is known to be difficult to solve optimally. For parallel computing, the challenge is to find algorithms that are effective in practice. Algebraic methods like Laplacian partitioning [9] are an important class of techniques, but can be expensive. Local refinement techniques like FM are also important [5], but get caught in local optima. Multilevel methods seem to offer the best trade off between cost and performance [2, 4, 7].

Hypergraph partitioning provides an important alternative to graph partition in many instances [3]. A survey of different partitioning models can be found in the paper by Hendrickson and Kolda [6].

Several good codes for graph partitioning are available on the Internet including Chaco, METIS, PaToH, and Scotch.

Definition

Green Flash is a research project focused on an application-driven manycore chip design that leverages commodity-embedded circuit designs and hardware/software codesign processes to create a highly programmable and energy-efficient HPC design. The project demonstrates how a multidisciplinary hardware/software codesign process that facilitates close interactions between applications scientists, computer scientists, and hardware engineers can be used to develop a system tailored for the requirements of scientific computing. By leveraging the efficiency gained from application-driven design philosophy, advanced processor synthesis tools from Tensilica, FPGA-accelerated architectural simulation from RAMP, auto-tuning for rapid optimization of the software implementation, the project demonstrated how a hardware/software codesign process can achieve a 100× increase in energy efficiency over its contemporaries using cost-effective commodity-embedded building blocks. To demonstrate application-driven design process, *Green Flash* was tailored for high-resolution global cloud resolving models, which are the leading justification for exascale computing systems. However, the approach can be generalized to a broader array of scientific applications. As such, *Green Flash* represents a vision of a new design process that could be used to develop effective exascale-class HPC systems.

Discussion

Introduction

The scientific community is facing one of its greatest challenges in the prediction of global climate change –

a question whose answer has staggering economic, political, and sociological ramifications. The computational power required to inform such critical policy decisions requires a new breed of extreme scale computers to accurately model the global climate. The “business as usual” approach of using commercial off-the-shelf (COTS) hardware to build ever-larger clusters is increasingly unsustainable beyond the petaflop scale due to the constraints of power and cooling. Some estimates indicate an exaflop-capable machine would consume close to 180 MW of power. Such unreasonable power costs drive the need for a radically new approach to HPC system design. *Green Flash* is a theoretical system designed with an application-driven hardware and software codesign for HPC systems that leverages the innovative and low-power architectures and design processes of the low-power/embedded computing industry. *Green Flash* is the result of Berkeley Lab’s research into energy-efficient system design – many details that are common to all system design, such as power, cooling, mechanical design, etc. are not addressed in this research as they are not unique to *Green Flash* and are challenges that would need to be overcome regardless of system architecture. The work presented here represents the energy efficiency gained through application-tailored architectures that leverage embedded processors to build energy efficient manycore processors.

History

In 2004, a group of University of California researchers, with backgrounds ranging from circuit design, computer architecture, CAD, embedded hardware/software, programming languages, compilers, applied math, to HPC, met for a period of two years to consider how current constraints on device physics at the silicon level would affect CPU design, system architecture, and programming models for future systems. The results of the discussions are documented in the University of California Berkeley Technical Report entitled “The Landscape of Parallel Computing Research: A View from Berkeley.” This report was the genesis of the UC Berkeley ParLab, which was funded by Intel and Microsoft as well as the *Green Flash* project. Whereas the ParLab carried the work of the View from Berkeley forward for desktop and handheld applications,

the Green Flash project took the same principles and applied them to the design of energy-efficient scientific computing systems.

Hardware/software codesign, a methodology that allows both software optimization and semi-specialized processor design to be simultaneously developed, has long been a feature of power-sensitive embedded system designs, but thus far has seen very little application in the HPC space. However, given power has become the leading design constraint of future HPC systems and codesign, and other application-driven design processes have received considerably more attention. Green Flash leverages tools that were developed by Tensilica for rapid-synthesis of application-optimized CPU designs, and retargets them to designing processors that are optimized for scientific applications. The project also created novel inter-processor communication to enable that easier-to-program environment than its GPU contemporaries – providing hardware support for more natural programming environments based on partitioned global address space programming models.

Approach

It is widely agreed that architectural specialization can significantly improve efficiency, however, creating full-custom designs of HPC systems has often proven impractical due to excessive design/verification costs and lead-times. The embedded processor market relies on architectural customization to meet the demanding cost and power efficiency requirements of its products with a short turn-around time. With time to market a key element in profitability, sophisticated toolchains have been developed to enable rapid and cost-effective turn-around of power-efficient semicustom designs implementations appropriate to each specific processor design. Green Flash leverages these same toolchains to design power-efficient exascale systems, tailoring embedded chips to target scientific applications and providing a feedback path from the application programmer to the hardware design enabling a tight hardware/software codesign loop that is unprecedented in the HPC industry. *Auto-tuning* technologies are used to automate the software tuning process and maintain portability across the differing architectures produced inside the codesign loop. Auto-tuners can automatically search over a broad parameter space

of optimizations to improve the computational efficiency of application kernels and help produce a more balanced architecture. To enable fast, accurate performance evaluation a Field Programmable Gate Array (FPGA) based hardware emulation platform will be used to allow an experimental architecture to be evaluated at speeds 1,000× faster than typical software-based simulation methods – fast enough to allow execution of a real application rather than an arbitrary benchmark.

High-resolution global cloud system resolving models are the target application that will motivate Green Flash's architectural decisions. A truly exascale problem, a 1.5 km scale model would decompose the earth's atmosphere into twenty-billion individual cells and a machine with unprecedented performance would need to be realized in order for the model to run faster than real time. While using more power-efficient, off-the-shelf, embedded processors is a crucial first in meeting this challenge it is still insufficient. Green Flash will offer many other novel optimizations, both hardware and software, including alternatives to cache coherence that enable far more efficient inter-processor communication than a conventional symmetric multiprocessing (SMP) approach and aggressive, architecture-specific software optimization through auto-tuning. All these specialization techniques will allow Green Flash to efficiently meet the exascale computation requirements of global climate change prediction.

Modeling the Earth's Climate System

Current generation climate models are comprehensive representations of the various systems that determine the Earth's climate. Models prepared for the fourth report of the Intergovernmental Panel on Climate Change coupled submodels of the atmosphere, ocean, and sea ice together to provide simulations of the past, present, and future climate. It is expected that the major remaining components of the climate system, the terrestrial and oceanic biosphere, the Greenland and Antarctic ice sheets, and certain aspects of atmospheric chemistry will be represented in models currently being prepared for the next report. Each of the subsystem models has their own strengths and weaknesses, and each introduces a certain amount of uncertainty into projections of the future. Current computational resources limit the resolution of these submodels and are a contributor to these uncertainties. In

particular, resolution constraints on models of atmospheric processes do not allow clouds to be resolved forcing model developers to rely on sub-grid scale parameterizations based on statistical methods. However, simulations of the recent past produce cloud distributions that do not agree well with observations. These disagreements, traceable to the cumulus convection parameterizations, lead to other errors in patterns of the Earth's radiation and moisture budgets. Current global atmospheric models have resolutions of order 200 km, obviously many times larger than individual clouds. Development of models at the limit of the validity of cumulus parameterization (~ 25 km) is now underway by a few groups, although the necessary century scale integrations are just barely feasible on the largest current computing platforms. It is expected that many issues will be rectified by this increase in horizontal fidelity but that the fundamental limitations of cumulus parameterization will remain. The solution to this problem is to directly simulate cloud processes rather than attempt to model them statistically. At horizontal grid spacing of order ~ 1 km, cloud systems can be individually resolved providing this direct numerical simulation. However, the computation burden of fluid dynamics algorithms scales nonlinearly with the number of grid points due to time step limitations imposed by numerical stability requirements. Hence, the computational resources necessary to carry out century scale simulations of the Earth's climate dwarfs any traditional machine currently under development.

Climate Model Requirements

Extrapolation from measured computational requirements of existing atmospheric models allow estimates of what would be necessary at resolutions of order 1 km to support Global Cloud Resolving Models. To better make these estimates, the Green Flash project has partnered with Prof. David Randall's group at the Colorado State University (CSU). In their approach, the globe is represented by a mesh based on an icosahedron as the starting point. By successively bisecting the sides of the triangles making up this object, a remarkably uniform mesh on the sphere can be generated. However, this is not the only way to discretize the globe at this resolution and it will be important to have a variety of independent cloud system-resolving models if projections of the future are to have any credibility. For this reason it

is important to emphasize that Green Flash will not be built to only run this particular discretization. Rather, this approach calls for optimizing a system for a class of scientific applications; therefore, Green Flash will be able to efficiently run most global climate models.

Extrapolation based on today's cluster-based, general purpose, HPC systems produce estimates that the *sustained* computational rate necessary to simulate the Earth's climate 1,000 times faster than it actually occurs was 10 Pflops. A tentative estimate from the CSU model is as much as 70 Pflops. This difference can be regarded as one measure of the considerable uncertainty in making these estimates. As the CSU model matures, there will be the opportunity to determine this rate much more accurately. Multiple realizations of individual simulations are necessary to address the statistical complexities of climate system. Hence, an exaflop scale machine would be necessary to carry out this kind of science. The exact peak flop rate required depends greatly on the efficiency that the machine could be used.

These enormous sustained computational rates are not even imaginable if there is not enough parallelism in the climate problem. Fortunately, cloud system resolving models at the kilometer scale do offer plenty of opportunity to decompose the physical domain. Bisection of the triangles composing the icosahedron twelve successive times produces a global mesh with 167,772,162 vertices spaced between 1 and 2 km apart. A logically rectangular two-dimensional domain decomposition strategy can be applied horizontally to the icosahedral grid. Choosing square segments of the mesh containing 64 grid points each (8×8) results in 2,621,440 horizontal domains. The vertical dimension offers additional parallelism. Assuming that 128 layers could be decomposed in 8 separate vertical domains, the total number of physical sub-domains could be 20,971,520.

Twenty-one million way parallelism may seem mind-boggling but this particular strawman decomposition was devised with practical constraints on the performance of an individual core in an SMP in mind. Each of the 21-million cores in this system will be assigned a small group of sub-domains on which they will execute the full (physics, dynamics, etc.) climate model. Flops per watt is the key performance metric for designing the SMP for Green Flash, and the goal of $100\times$ energy efficiency over existing machines will be achieved by

tailoring the architecture to the needs of the climate model. One example that drives the need for a high core count per socket is the model's communication pattern. While the model is nearest-neighbor dominated, the majority of the more latency-sensitive communication occurs between the vertical layers. By keeping this communication on-chip the more latency tolerant horizontal communication can be sent off-chip with less performance penalty. Looking at per-core features, by running with a lower (500 MHz) clock speed relative to today's server-class processors Green Flash gains a cubic improvement in power consumption. Removal of processor features that are nonoptimal for science such as Translation Look-aside Buffers (TLBs) and Out of Order (OOO) processing creates a smaller die, which reduces leakage to help further reduce power.

Hardware Design Flow

Verification costs are quickly becoming the dominant force in custom hardware solutions. Large arrays of simple processors again hold a significant advantage here, as the work to verify to a simple processing element and then replicate them on die is significantly lower. The long lead times and high costs of doing custom designs has generally dissuaded the HPC community from custom solutions and pushed more for clusters of COTS (Commercial off-the-self) hardware. The traditional definition of COTS in the HPC space is typically at the board or socket level; Green Flash seeks to redefine this notion of COTS and asserts that a custom processor made up of pre-verified building blocks can still be considered COTS hardware. This fine grained view permits Green Flash to benefit from both the architectural specialization afforded by these specialized processing elements and the shorter lead times and reduced verification costs that come with using a building block approach.

The constraints of power have long directed the development of embedded architectures and so it is advantageous to begin with an embedded core and leverage the sophisticated tool chains developed to minimize time from architectural specifications to ASIC. These toolchains start with a collection of pre-verified functional units and allow them to be combined in a myriad of ways rapidly producing power-efficient semi-custom designs. For instance, starting with a base architecture a designer may wish to add floating-point

support to a processor, or perhaps add a larger cache or local store. These functional units can be added to a processor design as easily as clicking a checkbox or dropdown menu. The tool will then select the correct functional unit from its library and integrate it into the design – all without the designer needing to intervene. These tools eliminate large amounts of not only boilerplate, but also full custom logic that once needed to be written and re-written in order to change a processor's architecture. Of course the tools are not boundless and are subject to the same design limitations as any other physical design process – for instance, one cannot efficiently have hundreds of read ports from a single memory, but the amount of flexibility created through these tools vastly outweighs any inherent limitations.

The rapid generation of processor cores alone makes these tools very interesting, however, the overhead of generating a usable software stack for each processor would negate the time saved developing the hardware. While adding caches or changing bus widths has little effect on the ISA, and therefore a minimal software impact, adding a new functional unit such as floating-point or integer division has a large impact on the software flow. Building custom hardware creates significant work not only in the creation of a potentially complex software stack but also a time-consuming verification process. As with the software stack, without a method to jump-start the verification process the tools would begin to lose their effectiveness. To address both of these critical issues these tools generate optimizing compilers, test benches as well as a functional simulator in parallel with the RTL for the design. Having the processor constructed of pre-verified building blocks combined with the automatic generation of test benches greatly reduces the risk and time required for formal verification. To help maintain backward and general purpose compatibility the processor's ISA is restricted to one that is functionally complete and allows for the execution of general purpose code.

A Science Optimized Processor Design

The processor design for Green Flash is driven by efficiency and the best way to reduce power consumption and increase efficiency is to reduce waste. With that in mind, the target architecture calls for a very simple, in order core with no branch prediction. The heavy memory and communication requirements demanded by the

climate model have imparted the greatest influence on the design of the Green Flash core. Building on prior work from Williams et al. where it was shown that for memory-intensive applications, cores with a local store, such as Cell, were able to utilize a higher percentage of the available DRAM bandwidth, the target processor architecture includes a local store. In the Green Flash SMP design there will be two on-chip networks – as illustrated in Fig. 1. As can be somewhat expected, the majority of communication that occurs between sub-domains within the climate model is nearest neighbor. Building on work from both Balfour and Dally [11] a packet switched network with a concentrated torus topology was chosen for the SMP as it has been shown to provide superior performance and energy efficiency for codes where the dominant communication pattern is nearest neighbor.

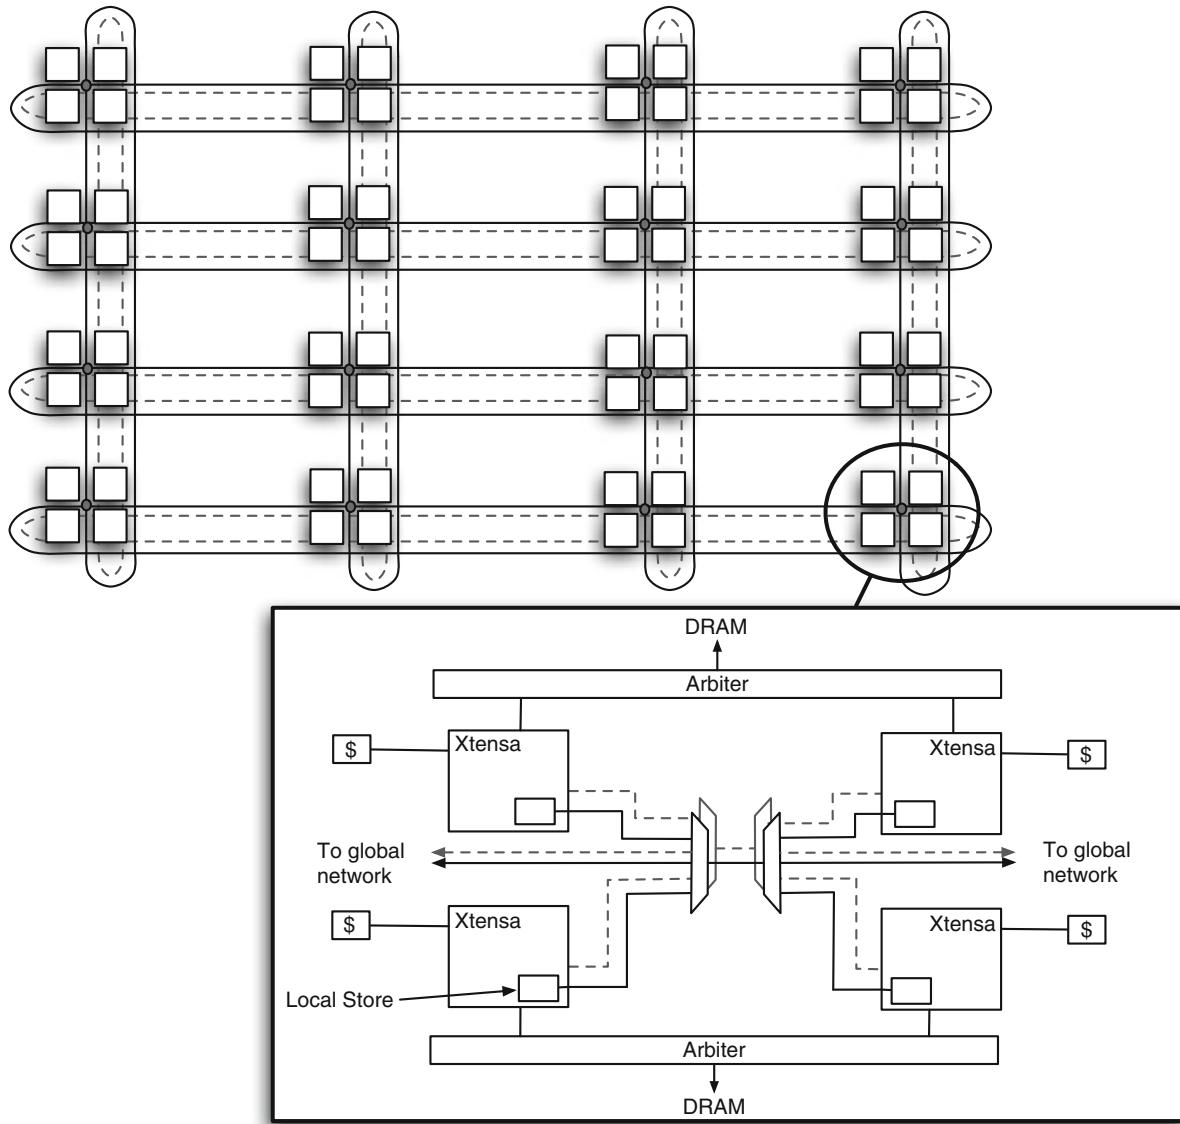

To further optimize the Green Flash processor for science the programming model is being considered a first class citizen when designing the architecture. Traditional cache coherent models found in many modern SMPs do not allow fine-grained synchronization between cores. In fact, when benchmarking the current climate model on present day machines it is shown that greater than 90% of execution time is spent in communication. By creating an architecture where an individual core will not pay a huge overhead penalty for sending or receiving a relatively small message the amount of time spent in communication can be greatly reduced. The processing cores used in the Green Flash SMP have powerful, flexible streaming interfaces. Each processor can have multiple, designer defined ports with a simple FIFO-like interface with each port capable of sending and receiving a packet of data on each clock. This low-overhead streaming interface will bypass the cache and connect to one of the torus networks on chip. This narrow network can be used for exchange of addresses, while the wider torus network is used for exchange of data. Following a Partitioned Global Address Space (PGAS) model the address space for each processor's local store is mapped into the global address space and the data exchange is done as a DMA from local store to local store. This allows the communication between processors to map very well to a MPI send/receive model used by the climate model and many other scientific codes. The view to the programmer will be as though all processors are directly connected to their

neighbors. To further simplify programming, a traditional cache hierarchy is also in place to allow codes to be slowly ported to the more efficient local-store based interprocessor network. In order to minimize power, the use of photonic interlinks for the inter-core network is being investigated as an efficient method of transferring long messages. In the case of Green Flash, the data network is one cache line in width and will consist of several phases per message.

Hardware/Software Codesign Strategy

Conventional approaches to hardware design generally have a long latency between hardware design and software development/optimization so designers frequently rely on benchmark codes to find a power-efficient architecture. However, modern compilers fail to generate even close to optimal code for target machines. Therefore, a benchmark-based approach to hardware design does not exploit the full performance potential of the architecture design points under consideration leading to possibly sub-optimal hardware solutions. The success of auto-tuners has shown that it is still possible to generate efficient code using domain knowledge. In combination with the ability to rapidly produce semi-custom hardware designs a tight, effective hardware/software codesign loop can be created. The codesign approach, as shown in Fig. 2 incorporates extensive software tuning into the process of hardware design. Hardware design space exploration is routinely done to tailor the hardware design parameters to the target applications. The auto-tuned software tailors the application to the hardware design point under consideration by empirically searching over a range of software implementations to find the best mapping of the software to the micro-architecture. One of the hindrances toward the practical relevance of codesign is the large hardware/software design space exploration. Conventional hardware design approaches use software simulation of hardware to perform hardware design space exploration. Because codesign involves searching over a much larger design space (there is now a need to explore the software design space at each hardware design point), codesign is impractical if software simulation of hardware is used.

Rather than be constrained by the limitations of a software simulation environment, it is possible instead to take advantage of the processor generation

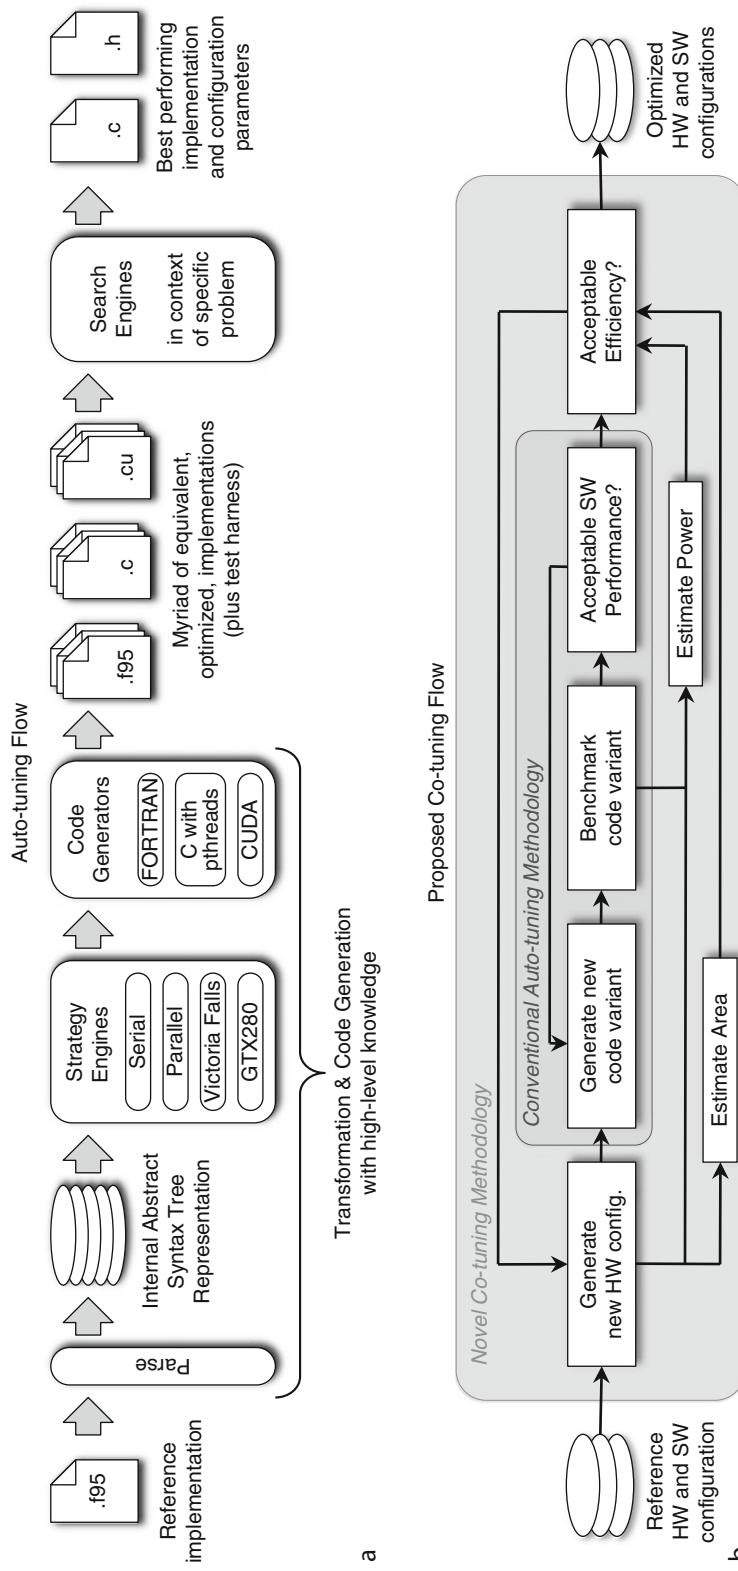

Green Flash: Climate Machine (LBNL). Fig. 1 A concentrated torus network fabric yields the highest performance and most power efficient design for scientific codes

toolchain's ability to create synthesizable RTL for any given processor. By loading this design onto an FPGA, a potential processor design can be emulated running 500 \times faster than a functional simulator. This speedup allows the benchmarking of true applications rather than being forced to rely on representative code snippets or statically defined benchmarks. Furthermore, this speed advantage does not come at the expense of accuracy; to the contrary, FPGA emulation is arguably much

more accurate than a software simulation environment as it truly represents the hardware design. This fast accurate emulation environment provides the ability to run and benchmark the actual climate model as it is being developed and allows the codesign infrastructure to quickly search a large design space.

The speed and accuracy advantages of using FPGAs have typically been dwarfed by the increased complexity of coding in Verilog or VHDL versus C++ or Python

Green Flash: Climate Machine (LBNL). Fig. 2 The result of combining an existing auto-tuning framework (a) with a rapid hardware design cycle and FPGA emulation is (b) a proposed hardware/software codesign flow

as well as the ability to emulate large designs due to limitations in FPGA area/LUT count. The practicality of using FPGAs for large system emulation has increased dramatically over the past decade. The ability to access relatively large dynamic memories, such as DDR, has always been a difficult challenge with FPGAs due to the tight timing requirements. FPGA vendors, such as Xilinx, have eased this difficulty by providing IP through its Memory Interface Generator (MIG) tool and adding IO features to the Virtex-5 series. Freely available Verilog IP libraries – whether they are Xilinx CoreGen, or the RAMP group's GateLib – allow for a modular, building block approach to HW design. Finally, while commercial microprocessors are experiencing a plateau in their clock rates and power consumption, FPGAs are not. FPGA LUT count continues to increase allowing the emulation of more complex designs and FPGA clocks, while traditionally significantly slower than commercial microprocessor clock rates have been growing steadily, closing the gap between emulated and production clock rates. In the case of Green Flash, the relatively low target clock frequency (500 MHz) of the final ASIC is an additional motivation to target an FPGA emulation environment. The current emulated processor design runs at 33 MHz – a significant fraction of the target clock rate. This relatively high speed enables the efficient benchmarking of an entire application rather than a representative portion.

While the steady growth in LUT count on FPGAs has enabled the emulation of more complex designs, with a strawman architecture of 128 cores per socket it is necessary to emulate more than the two or four cores that will fit on a single FPGA. To scale beyond the cores that will fit on a single FPGA a multi-FPGA system, such as the Berkeley Emulation Engine (BEE3) can be used. The BEE3 board has four Virtex-5 155 FPGAs connected in a ring with a cross-over connection. Each FPGA has access to two channels of DDR2 memory allowing 4 GB of memory per FPGA. The BEE3 will allow effective emulation of eight cores with the appropriate NoC infrastructure per board. To scale beyond eight cores, the BEE3 includes 10 Gb connections allowing the boards to be linked and emulation of an entire socket becomes possible. There is significant precedence for emulation of massively multithreaded architectures across multiple FPGAs. One recent example was demonstrated by the Berkeley RAMP Blue project

where over 1,000 cores were emulated using a stack of 16 BEE2 boards.

Hardware Support for New Programming Models

Applications and algorithms will need to rely increasingly on fine-grained parallelism and strong scaling and support fault resilience to accommodate the massive growth of explicit on-chip parallelism and constrained bandwidth anticipated for future chip architectures. History shows that the application-driven approach offers the most productive strategy for evaluating and selecting among the myriad choices for refactoring algorithms for full scientific application codes as the industry moves through this transitional phase. Green Flash functions as a testbed to explore novel programming models together with hardware support to express fine-grained parallelism to achieve performance, productivity, and correctness for leading-edge application codes in the face of massive parallelism and increasingly hierarchical hardware. The goal of this development thrust is to create a new software model that can provide a stable platform for software development for the next decade and beyond for all scales of scientific computing.

The Green Flash design created direct hardware support for both the message passing interface (MPI) and partitioned global address space (PGAS) programming models to enable scaling of these familiar single program, multiple data (SPMD) programming styles to much larger-scale systems. The modest hardware support enables relatively well-known programming paradigms to utilize massive on-chip concurrency and to use hierarchical parallelism to enable use of larger messages for interchip communication.

However, not all applications will be able to express parallelism through simple divide-and-conquer problem partitioning. So the message-queues and software-managed memories that are used to implement PGAS are also being used to explore new asymmetric and asynchronous approaches to achieving strong-scaling performance improvements from explicit parallelism. Techniques that resemble class static dataflow methods are garnering renewed interest because of their ability to flexibly schedule work and to accommodate state migration to correct load imbalances and failures. In the case of the climate code, dataflow techniques can be used to concurrently schedule the physics computations

with the dynamic core of the climate code, thereby doubling the effective concurrency without moving to a finer domain decomposition. This approach also benefits from the unique interprocessor communication interfaces developed for Green Flash.

Fault Resilience

A question that comes up when proposing a 20 million processor computing system is how to deal with fault resilience. While trying not to trivialize the issue, it should be noted that this is a problem for everyone designing large-scale machines. The proposed approach of using many simpler cores does not introduce any unique challenges that are different than the challenges faced for aggregating conventional server chips into large-scale systems provided the total number of discrete chips in the system is not dramatically different. The following observations are made to qualify this point.

For a given silicon process (e.g., a 65 nm process and same design rules)

1. Hard failure rates are primarily proportional to the number of sockets in a system (e.g., solder joint failures, weak wire bonds, and a variety of mechanical and electrical issues) and secondarily related to the total chip surface area (probability of defect vs tolerance of the design rules to process variation). It is not proportional to the number of processor cores per se given that the cores come in all shapes and sizes.
2. Soft error rates caused by cosmic rays roughly proportional to chip surface area when comparing circuits that employ the same process technology (e.g., 65 nm).
3. Bit error rates for data transfer tend to increase proportionally with clock rate.
4. Thermal stress is also a source of hard errors.

For hard errors:

1. Spare cores can be designed into each ASIC to tolerate defects due to process variation. This approach is already used by the 188 core Cisco Metro chip, which incorporates 8 spare cores (192 cores in total) to cover chip defects.
2. Each chip is expected to dissipate a relatively small 7–15 W (or that is the target) subjecting them to less mechanical/thermal stress.
3. It has been demonstrated that Green Flash can achieve more *delivered* performance out of fewer

sockets, which reduces exposure to hard-failures due to bad electrical connections or other mechanical/electrical defects.

4. Like BlueGene, memory and CPUs can be flow-soldered onto the board to reduce hard and soft failure rates for electrical connections given removable sockets are far more susceptible to both kinds of faults. So eliminating removable sockets can greatly reduce error rates.

For soft errors:

1. All of the basics for reliability and error recovery in the memory subsystem including full ECC (error correcting code) protection for caches and memory interfaces are included in the design.
2. Using many simpler cores allows fewer sockets to be used and less silicon surface area to achieve the same delivered performance. So that is to say, Green Flash has less exposure to major sources of failure than a conventional high-frequency core design. Therefore, fewer sockets and fewer random bit-flips due to mechanical noise and other stochastic error sources.
3. The core clock frequency of 500 MHz improves Signal to Noise Ratio for on-chip data transfers.
4. Incorporation of a Nonvolatile Random Access Memory (NVRAM) memory controller and channel on each System on Chip (SoC). Each node can copy the image of memory to the NVRAM periodically to do local checkpoints. If there is a soft-error (e.g., an uncorrectable memory error), then the node can initiate a roll-back to the last available checkpoint. For hard failures (e.g., a node does and cannot be revived), the checkpoint image will be copied to neighboring nodes on a periodic basis to facilitate localized state recovery. Both strategies enable much faster roll-back when errors are encountered than the conventional user-space checkpointing approach.

Therefore, the required fault resilience strategies will bear similarity to other systems that employ a similar number of sockets (~120,000), which are not unprecedented. The BlueGene system at Lawrence Livermore National Laboratory contains a comparable number of sockets, and achieves a 7–15 day Mean Time Between Failures (MTBF), which is far longer than systems that contain a fraction the number of processor cores. Therefore, careful application of well-known fault-resilience techniques together with a few

novel “extended fault resilience” mechanisms such as localized NVRAM checkpoints can achieve an acceptable MTBF for extreme-scale implementations of this approach to system design.

Conclusions

Green Flash proposes a radical approach of application-driven computing design to break through the slow pace of incremental changes, and foster a sustainable hardware/software ecosystem with broad-based support across the IT industry. Green Flash has enabled the exploration of practical advanced programming models together with lightweight hardware support mechanisms that allow programmers to utilize massive on-chip concurrency, thereby creating the market demand for massively concurrent components that can also be the building block of midrange and extreme-scale computing systems. New programming models must be part of a new software development ecosystem that spans all scales of systems, from midrange to the extreme-scale to facilitate a viable migration path from development to large-scale production computing systems. The use of the FPGA-based hardware emulation platforms, such as RAMP, to prototype and run hardware prototypes at near-realtime speeds before it is built allow testing of full-fledged application codes and advanced software development to commence many years before the final hardware platform is constructed. These tools have enabled a tightly coupled software/hardware codesign process that can be applied effectively to the complex HPC application space.

Rather than ask “what kind of scientific applications can run on our HPC cluster after it arrives,” the question should be turned around to ask “what kind of system should be built to meet the needs of the most important science problems.” This approach is able to realize its most substantial gains in energy-efficiency by peeling back the complexity of high-frequency microprocessor design point to reduce sources of waste (wasted opcodes, wasted bandwidth, waste caused by orienting architectures toward serial performance). BlueGene and SiCortex have demonstrated the advantages of using the simpler low-power embedded processing elements to create energy-efficient computing platforms. However, the Green Flash codesign approach goes beyond traditional embedded core design point of BlueGene and SiCortex by using explicit message queues and software controlled memories to further optimize

data movement, while still retaining a smaller conventional cache-hierarchy only to support incremental porting to the more energy and bandwidth-efficient design point. Furthermore, simple hardware support for lightweight on-chip interprocessor synchronization and communication make it much simpler and straightforward and efficient to program massive arrays of processors than more exotic programming models such as CUDA and Streaming.

Green Flash has been a valuable research vehicle to understand how the evolution of massively parallel chip architectures can be guided by close-coupled feedback with the design of the application, algorithms, and hardware together. Application-driven design ensures hardware design decisions do not evolve in reaction to hardware constraints, without regard to programmability and delivered application performance. The design study has been driven by a deep dive into the climate application space, but enables explorations that cut across all application areas and have ramifications to the next generation of fully general-purpose architectures. Ultimately, Green Flash should consist of an architecture that can maximally leverage reusable components from the mass market of the embedded space while improving the programmability for the many-core design point. The building blocks of a future HPC system must be the preferred solution in terms of performance and programmability for everything from the smallest high-performance energy-efficient embedded system, to midrange departmental systems, to the largest-scale systems.

Gustafson's Law

JOHN L. GUSTAFSON
Intel Labs, Santa Clara, CA, USA

Synonyms

Gustafson–Barsis Law; Scaled speedup; Weak scaling

Definition

Gustafson's Law says that if you apply P processors to a task that has serial fraction f , scaling the task to take the

same amount of time as before, the speedup is

$$\begin{aligned}\text{Speedup} &= f + P(1 - f) \\ &= P - f(P - 1).\end{aligned}$$

It shows more generally that the serial fraction does not theoretically limit parallel speed enhancement, if the problem or workload scales in its parallel component. It models a different situation from that of Amdahl's Law, which predicts time reduction for a fixed problem size.

Discussion

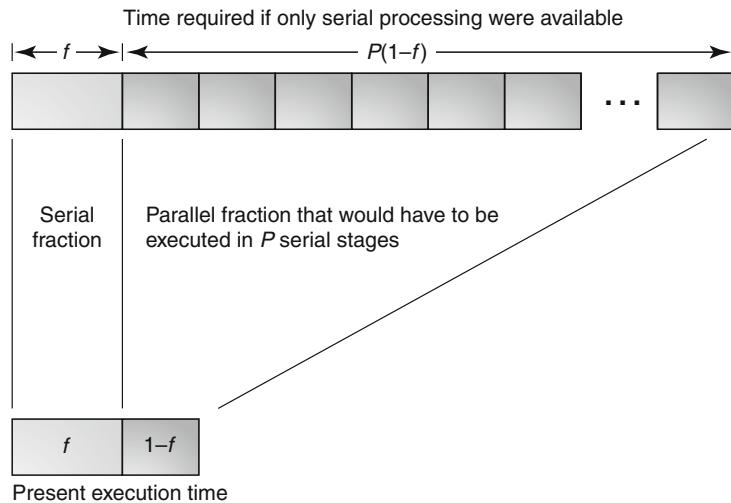

Graphical Explanation

Figure 1 explains the formula in the Definition:

The time the user is willing to wait to solve the workload is unity (lower bar). The part of the work that is observably serial, f , is unaffected by parallelization. The remaining fraction of the work, $1 - f$, parallelizes perfectly so that a serial processor would take P times longer to execute it. The ratio of the top bar to the bottom bar is thus $f + P(1 - f)$. Some prefer to rearrange this algebraically as $P - f(P - 1)$.

The diagram resembles the one used in the explanation of Amdahl's Law (see ►Amdahl's Law) except that Amdahl's Law fixes the *problem size* and answers the question of how parallel processing can reduce the execution time. Gustafson's Law fixes the *run time* and answers the question of how much longer time the present workload would take in the absence of parallelism [5]. In both cases, f is the experimentally observable fraction of the current workload that is serial. The similarity of the diagram to the one that explains Amdahl's Law has led some to "unify" the two laws by a change of variable. It is an easy algebraic exercise to set the upper bar to unit time and express the f of Gustafson's Law in terms of the variables of Amdahl's Law, but this misses the point that the two laws proceed from *different premises*. Every attempt at unification begins by applying the same premise, resulting in a circular argument that the two laws are the same.

The fundamental underlying observation of Gustafson's Law is that more powerful computer systems usually solve larger problems, not the same size problem in less time. Hence, a performance enhancement like parallel processing expands what a user can do with a computing system to match the time the user is willing to wait for the answer. While computing power has increased by many orders of magnitude over the last

Gustafson's Law. Fig. 1 Graphical derivation of Gustafson's Law

half-century (see ▶ [Moore's Law](#)), the execution time for problems of interest has been constant, since that time is tied to human timescales.

History

In a 1967 conference debate over the merits of parallel computing, IBM's Gene Amdahl argued that a considerable fraction of the work of computers was inherently serial, from both algorithmic and architectural sources. He estimated the serial fraction f at about 0.25–0.45. He asserted that this would sharply limit the approach of parallel processing for reducing execution time [1]. Amdahl argued that even the use of two processors was less cost-effective than a serial processor. Furthermore, the use of a large number of processors would never reduce execution time by more than $1/f$, which by his estimate was a factor of about 2–4.

Despite many efforts to find a flaw in Amdahl's argument, "Amdahl's Law" held for over 20 years as justification for the continued use of serial computing hardware and serial programming models.

The Rise of Microprocessor-Based Systems

By the late 1970s, microprocessors and dynamic random-access memory (DRAM) had dropped in price to the point where academic researchers could afford them as components in experimental parallel designs. Work in 1983 by Charles Seitz at Caltech using a message-passing collection of 64 microprocessors [11]

showed excellent absolute performance in terms of floating-point operations per second, and seemed to defy Amdahl's pessimistic prediction. Seitz's success led John Gustafson at FPS to drive development of a massively parallel cluster product with backing from the Defense Advanced Research Projects Agency (DARPA). Although the largest configuration actually sold of that product (the FPS T Series) had only 256 processors, the architecture permitted scaling to 16,384 processors. The large number of processors led many to question: *What about Amdahl's Law?* Gustafson formulated a counterargument in April 1986, which showed that performance is a function of both the problem size and the number of processors, and thus Amdahl's Law need not limit performance. That is, the serial fraction f is not a constant but actually decreases with increased problem size. With no experimental evidence to demonstrate the idea, the counterargument had little impact on the computing community.

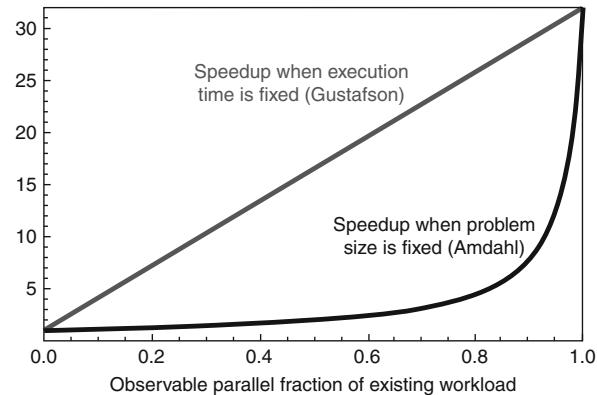

An idea for a source of experimental evidence arose in the form of a challenge that Alan Karp had publicized the year before [8]. Karp had seen announcements of the 65,536-processor CM-1 from Thinking Machines and the 1,024-processor NCUBE10 from nCUBE, and believed Amdahl's Law made it unlikely that such massively parallel computers would achieve a large fraction of their rated performance. He published a skeptical challenge and a financial reward for anyone who could demonstrate a parallel speedup of over 200 times on

three real applications. Karp suggested computational fluid dynamics, structural analysis, and econometric modeling as the three application areas and gave some ground rules to insure that entries focused on honest parallel speedup without tricks or workarounds. For example, one could not cripple the serial version to make it artificially 200 times slower than the parallel system. And the applications, like the three suggested, had to be ones that had interprocessor communication throughout their execution as opposed to “embarrassingly parallel” problems that had communication only at the beginning and end of a run.

By 1987, no one had met Karp’s challenge, so Gordon Bell adopted the same set of rules and suggested applications as the basis for the Gordon Bell Award, softening the goal from 200 times to whatever the best speedup developers could demonstrate. Bell expected the initial entries to achieve about tenfold speedup [2].

The purchase by Sandia National Laboratories of the first 1,024-processor NCUBE 10 system created the opportunity for Gustafson to demonstrate his argument on the experiment outlined by Karp and Bell, so he joined Sandia and worked with researchers Gary Montry and Robert Benner to demonstrate the practicality of high parallel speedup. Sandia had real applications in fluid dynamics and structural mechanics, but none in econometric modeling, so the three researchers substituted a wave propagation application. With a few weeks of tuning and optimization, all three applications were running at over 500-fold speedup with the fixed-size Amdahl restriction, and over 1,000-fold speedup with the scaled model proposed by Gustafson. Gustafson described his model to Sandia Director Edwin Barsis, who suggested explaining scaled speedup using a graph like that shown in Fig. 2.

Barsis also insisted that Gustafson publish this concept, and is probably the first person to refer to it as “Gustafson’s Law.” With the large experimental speedups combined with the alternative model, *Communications of the ACM* published the results in May 1988 [5]. Since Gustafson credited Barsis with the idea of expressing the scaled speedup model as graphed in Fig. 2, some refer to Gustafson’s Law as the Gustafson–Barsis Law. The three Sandia researchers

Gustafson's Law. Fig. 2 Speedup possible with 32 processors, by Gustafson's Law and Amdahl's Law

G

published the detailed explanation of the application parallelizations in a *Society of Industrial and Applied Mathematics* (SIAM) journal [4].

Parallel Computing Watershed

Sandia’s announcement of 1,000-fold parallel speedups created a sensation that went well beyond the computing research community. Alan Karp announced that the Sandia results had met his Challenge, and Gordon Bell gave his first award to the three Sandia researchers. The results received publicity beyond that of the usual technical journals, appearing in *TIME*, *Newsweek*, and the US Congressional Record. Cray, IBM, Intel, and Digital Equipment began work in earnest developing commercial computers with massive amounts of parallelism for the first time.

The Sandia announcement also created considerable controversy in the computing community, partly because some journalists sensationalized it as a proof that Amdahl’s Law was false or had been “broken.” This was never the intent of Gustafson’s observation. He maintained that Amdahl’s Law was the correct answer but to the wrong question: “How much can parallel processing reduce the run time of a current workload?”

Observable Fraction and Scaling Models

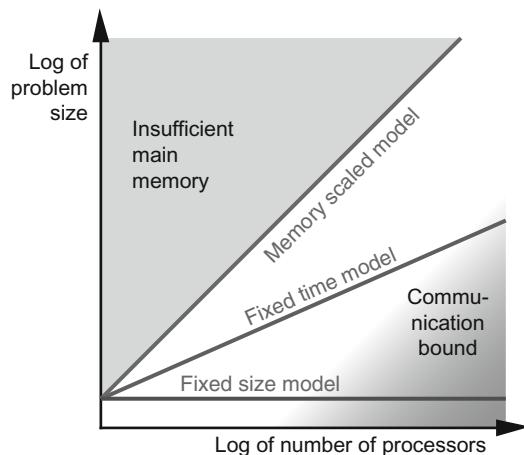

As part of the controversy, many maintained that Amdahl’s Law was still the appropriate model to use in all situations, or that Gustafson’s Law was simply

a corollary to Amdahl's Law. For scaled speedup, the argument went that one simply works backward to determine what the f fraction in Amdahl's Law must have been to yield such performance. This is an example of circular reasoning, since the proof that Amdahl's Law applies begins by assuming it applies.

For many programs, it is possible to instrument and measure the fraction of time f spent in serial execution. One can place timers in the program around serial regions and obtain an estimate of f . This fraction then allows Amdahl's Law estimates of time reduction, or Gustafson's Law estimates of scaled speedup. Neither law takes into account communication costs or intermediate degrees of parallelism. (When communication costs are included in Gustafson's fixed-time model, the speedup is again limited as the number of processors grows, because communication costs rise to the point where there is no way to increase the size of the amount of work without increasing the execution time.)

A more common practice is to measure the parallel speedup as the number of processors is varied, and fit the resulting curve to derive f . This approach confuses serial fraction with communication overhead, load imbalance, changes in the relative use of the memory hierarchy, and so on. Some refer to the requirement to keep the problem size the same yet use more processors as "strong scaling." Still, a common phenomenon that results from "strong scaling" is that it is *easier*, not *harder*, to obtain high amounts of speedup. When spreading a problem across more and more processors, the *memory per processor* goes down to the point where the data fits entirely in cache, resulting in *superlinear speedup* [3]. Sometimes, the superlinear speedup effects and the communication overheads partially cancel out, so what appears to be a low value of f is actually the result of the combination of the two effects. In modern parallel systems, performance analysis with either Amdahl's Law or Gustafson's Law will usually be inaccurate since communication costs and other parallel processing phenomena have large effects on the speedup.

In Fig. 3, Amdahl's Law governs the Fixed-Sized Model line, Gustafson's Law governs the Fixed-Time Model line, and what some call the Sun-Ni Law governs the Memory Scaled Model [12]. The fixed-time model line is an irregular curve in general, because of

Gustafson's Law. Fig. 3 Different scaling types and communication costs

the communication cost effects and because the percentage of the problem that is in each memory tier (mass storage, main RAM, levels of cache) changes with the use of more processors.

Analogy

There are many aspects of technology where an enhancement for time reduction actually turns out to be an enhancement for what one can accomplish in the same time as before. Just as Amdahl's Law is an expression of the more general Law of Diminishing Returns, Gustafson's Law is an expression of the more general observation that technological advances are used to improve what humans accomplish in the length of time they are accustomed to waiting, not to shorten the waiting time.

Commuting Time

As civilization has moved from walking to horses to mechanical transportation, the average speed of getting to and from work every day has gone up dramatically. Yet, people take about half an hour to get to or from work as a tolerable fraction of the day, and this amount of time is probably similar to what it has been for centuries. Cities that have been around for hundreds or thousands of years show a concentric pattern that reflect the increasing distance people could commute for the amount of time they were able to tolerate.

Transportation provides many analogies for Gustafson's Law that expose the fallacy of fixing the size of a problem as the control variable in discussing large performance gains. A commercial jet might be able to travel 500 miles per hour, yet if one asks "How much will it reduce the time it takes me presently to walk to work and back?" the answer would be that it does not help at all. It would be easy to apply an Amdahl-type argument to the time to travel to an airport as the serial fraction, such that the speedup of using a jet only applies to the remaining fraction of the time and thus is not worth doing. However, this does not mean that commercial jets are useless for transportation. It means that faster devices are for larger jobs, which in this case means longer trips.

Here is another transportation example: If one takes a trip at 30 miles per hour and immediately turns around, how fast does one have to go to average 60 miles per hour? This is a trick question that many people incorrectly answer, "90 miles per hour." To average 60 miles per hour, one would have to travel back at infinite speed, that is, return *instantly*. Amdahl's Law applies to this fixed-distance trip. However, suppose the question were posed differently: "If one travels for an hour at 30 miles per hour, how fast does one have to travel in the next hour to average 60 miles per hour?" In that case, the intuitive answer of "90 miles per hour" is the correct one. Gustafson's Law applies to this fixed-time trip.

The US Census

In the early debates about scaled speedup, Heath and Worley [6] provided an example of a fixed-sized problem that they said was not appropriate for Gustafson's Law and for which Amdahl's Law should be applied: the US Census. While counting the number of people in the USA would appear to be a fixed-sized problem, it is actually a perfect example of a fixed-time problem since the Constitution mandates a complete headcount every 10 years. It was in the late nineteenth century, when Hollerith estimated that the population had grown to the point where existing approaches would take longer than 10 years that he developed the card punch tabulation methods that made the process fast enough to fit the fixed-time budget.

With much faster computing methods now available, the Census process has grown to take into

account many more details about people than the simple head count that the Constitution mandates. This illustrates a connection between Gustafson's Law and the jocular Parkinson's Law: "Work expands to fill the available time."

Printer Speed

In the 1960s, when IBM and Xerox were developing the first laser printers that could print an entire page at a time, the goal was to create printers that could print several pages per second so that printer speed could match the performance improvements of computing speed. The computer printouts of that era were all of monospaced font with a small character set of uppercase letters and a few symbols. Although many laser printer designers struggled to produce such simple output with reduced time per page, the product category evolved to produce high quality output for desktop publishing instead of using the improved technology for time reduction. People now wait about as long for a page of printout from a laser printer as they did for a page of printout from the line printers of the 1960s, but the task has been scaled up to full color, high resolution printing encompassing graphics output, and a huge collection of typeset fonts from alphabets in all the world's languages. This is an example of Gustafson's Law applied to printing technology.

Biological Brains

Kevin Howard, of Massively Parallel Technologies Inc., once observed that if Amdahl's Law governed the behavior of biological brains, then a human would have about the same intelligence as a starfish. The human brain has about 100 billion neurons operating in parallel, so for us to avoid passing the point of diminishing returns for all that parallelism, the Amdahl serial fraction f would have to be about 10^{-14} . The fallacy of this seeming paradox is in the underlying assumption that a human brain must do the same task a starfish brain does, but must reduce the execution time to nanoseconds. There is no such requirement, and a human brain accomplishes very little in a few nanoseconds no matter how many neurons it uses at once. Gustafson's Law says that on a time-averaged basis, the human brain will accomplish *vastly more complex tasks* than what a starfish can attempt, and thus avoids the absurd conclusion of the fixed-task model.

Perspective

The concept of scaled speedup had a profound enabling effect on parallel computing, since it showed that simply asking a different question (and perhaps a more realistic one) renders the pessimistic predictions of Amdahl's Law moot. Gustafson's 1988 announcement of 1,000-fold parallel speedup created a turning point in the attitude of computer manufacturers towards massively parallel computing, and now all major vendors provide platforms based on the approach. Most (if not all) of the computer systems in the TOP500 list of the worlds' fastest supercomputers are comprised of many thousands of processors, a degree of parallelism that computer builders regarded as sheer folly prior to the introduction of scaled speedup in 1988.

A common assertion countering Gustafson's Law is that "Amdahl's Law still holds for scaled speedup; it's just that the serial fraction is a lot smaller than had been previously thought." However, this requires inferring the small serial fraction from the measured speedup. This is an example of circular reasoning since it involves choosing a conclusion, then working backward to determine the data that make the conclusion valid. Gustafson's Law is a simple formula that predicts scaled performance from experimentally measurable properties of a workload.

Some have misinterpreted "scaled speedup" as simply increasing the amount of memory for variables, or increasing the fineness of a grid. It is more general than this. It applies to every way in which a calculation can be improved somehow (accuracy, reliability, robustness, etc.) with the addition of more processing power, and then asks *how much longer the enhanced problem would have taken to run without the extra processing power*.

Horst Simon, in his 2005 keynote talk at the International Conference on Supercomputing, "*Progress in Supercomputing: The Top Three Breakthroughs of the Last 20 Years and the Top Three Challenges for the Next 20 Years*," declared the invention of the Gustafson's scaled speedup model as the number one achievement in high-performance computing since 1985.

Bibliographic Entries and Further Reading

Gustafson's 1988 two-page paper in the *Communications of the ACM* [5] outlines his basic idea of fixed-time performance measurement as an alternative to Amdahl's assumptions. It contains the rhetorical question, "How can this be, in light of Amdahl's Law?" that some misinterpreted as a serious plea for the resolution of a paradox. Readers may find a flurry of responses in *Communications* and elsewhere, as well as attempts to "unify" the two laws.

An objective analysis of Gustafson's Law and its relation to Amdahl's Law can be found in many modern textbooks on parallel computing such as [7], [9], or [10]. In much the way some physicists in the early twentieth century refused to accept the concepts of relativity and quantum mechanics, for reasons more intuition-based than scientific, there are computer scientists who refuse to accept the idea of scaled speedup and Gustafson's Law, and who insist that Amdahl's Law suffices for all situations.

Pat Worley analyzed the extent to which one can usefully scale up scientific simulations by increasing their resolution [13]. In related work, Xian-He Sun and Lionel Ni built a more complete mathematical framework for scaled speedup [12] in which they promote the idea of memory-bounded scaling, even though execution time generally increases beyond human patience when the memory used by a problem scales as much as linearly with the number of processors. In a related vein, Vipin Kumar proposed "Isoefficiency" for which the memory increases as much as necessary to keep the efficiency of the processors at a constant level even when communication and other impediments to parallelism are taken into account.

Synonyms

Hierarchical data format

Definition

HDF5 [1] is a data model, software library, and file format for storing and managing data.

Discussion

Introduction

The HDF5 technology suite is designed to organize, store, discover, access, analyze, share, and preserve diverse, complex data in continuously evolving heterogeneous computing and storage environments. It supports an unlimited variety of datatypes, and is designed for flexible and efficient I/O and for high volume and complex data. The HDF5 library and file format are portable and extensible, allowing applications to evolve in their use of HDF5. The HDF5 technology suite also includes tools and applications for managing, manipulating, viewing, and analyzing data in the HDF5 format.

Originally designed within the National Center for Supercomputing Applications at the University of Illinois at Urbana-Champaign [2], HDF5 is now primarily developed and maintained by The HDF Group [3], a nonprofit organization dedicated to ensuring the sustainable development of HDF technologies and the ongoing accessibility of data stored in HDF files. HDF5 builds on lessons learned from other data storage libraries and file formats, such as the original HDF file format (now known as HDF4 [4]), netCDF [5], TIFF [6], and FITS [7], while adding unique features and extending the boundaries of prior data storage models.

Data Model

HDF5 implements a simple but versatile data model, which has two primary components: groups and datasets. Group objects in an HDF5 file contain a collection of named links to other objects in an HDF5 file. Dataset objects in HDF5 files store arrays of arbitrary element types and are the main method for storing application data.

Groups, which are analogous to directories in a traditional file system, can contain an arbitrary number of uniquely named links. A link can connect a group to another object in the same HDF5 file; include a named

path to an object in the HDF5 file, which may not exist currently; or refer to an object in another HDF5 file. Unlike links in a traditional file system, HDF5 links can be used to create fully cyclic directed graph structures. Each group contains one or more B-tree data structures as indices to its collection of links, which are stored in a heap structure within the HDF5 file.

Dataset objects store application data in an HDF5 file as a multidimensional array of elements. Each dataset is primarily defined by the description of how many dimensions its array has and the size of those dimensions, called a “dataspace”; and the description of the type of element to store at each location in the array, called a “datatype”.

An HDF5 dataspace describes the number of dimensions for an array, as well as the current and maximum number of elements in each dimension. The maximum number of elements in an array dimension can be specified as “unlimited,” allowing an array to be extended over time. An HDF5 dataspace can have multiple dimensions that have unlimited maximum dimensions, allowing that array to be extended in any or all of those dimensions.

An HDF5 datatype describes the type of data to store in each element of an array and can be one of the following classes: integer, floating-point, string, bitfield, opaque, compound, reference, enum, variable-length sequence, and array. These classes generally correspond to the analogous computer science concepts, but the reference and variable-length sequence datatypes are unusual. Reference datatypes contain links to HDF5 objects, allowing HDF5 applications to create datasets that act like groups. The former contain references or pointers to HDF5 objects, allowing HDF5 applications to create datasets that can act as lookup tables or indices. Variable-length sequence datatypes allow a dynamic number of elements of a base datatype to be stored as an element and are one mechanism for creating datasets that represent ragged arrays. All of the HDF5 datatypes can be combined in any arbitrary way, allowing for great flexibility in how an application stores its data.

The elements of an HDF5 dataset can be stored in different ways, allowing an application to choose between various I/O access performance trade-offs.

Dataset elements can be stored as a single sequence in the HDF5 file, called “contiguous” storage, which

allows for constant time access to any element in the array and no storage overhead for locating the elements in the dataset. However, contiguous data storage does not allow a dataset to use a dataspace with unlimited dimensions or to compress the dataset elements.

The dataspace for a dataset can also be decomposed into fixed-size sub-arrays of elements, called “chunks,” which are stored individually in the file. This “chunked” data storage requires an index for locating the chunks that store the data elements. Datasets that have a data space with unlimited dimensions must use chunked data storage for storing their elements.

Using chunked data storage allows an application that will be accessing sub-arrays of the dataset to tune the chunk size to its sub-array size, allowing for much faster access to those sub-arrays than would be possible with contiguous data storage. Additionally, the elements of datasets that use chunked data storage can be compressed or have other operations, like checksums, etc., applied to them.

The advantages of chunked data storage are balanced by some limitations, however. Using an index for mapping dataset element coordinates to chunk locations in the file can slow down access to dataset elements if the application’s I/O access pattern does not line up with the chunk’s sub-array decomposition. Furthermore, there is additional storage overhead for storing an index for the dataset, along with extra I/O operations to access the index data structure.

Datasets with very small amounts of element data can store their elements as part of the dataset description in the file, avoiding any extra I/O accesses to retrieve the dataset elements, since the HDF5 library will read them when accessing the dataset description. This “compact” data storage must be very small (less than 64 KB), and may not be used with a dataspace that has unlimited dimensions or when dataset elements are compressed.

Finally, a dataset can store its elements in a different, non-HDF5, file. This “external” data storage method can be used to share dataset elements between an HDF5 application and a non-HDF5 application. As with contiguous data storage, external data storage does not allow a dataset to use a dataspace with unlimited dimensions or compress the dataset elements.

HDF5 also allows application-defined metadata to be stored with any object in an HDF5 file.

These “attributes” are designed to store information about the object they are attached to, such as input parameters to a simulation, the name of an instrument gathering data, etc. Attributes are similar to datasets in that they have a dataspace, a datatype, and elements values. Attributes require a name that is unique among the attributes for an object, similar to link names within groups. Attributes are limited to dataspaces that do not use unlimited maximum dimensions and cannot have their data elements compressed, but can use any datatype for their elements.

Examples of Using HDF5

The following C code example shows how to use the HDF5 library to store a large array. In the example below, the data to be written to the file is a three-dimensional array of single-precision floating-point values, with dimensions of 1024 elements along each axis:

```

1 float data[1024][1024][1024];
2 hid_t file_id, dataspace_id, dataset_id;
3 hsize_t dims[3] = {1024, 1024, 1024};
4
5 <...acquire or assign data values...>
6
7 file_id = H5Fcreate("example.h5",
8 H5F_ACC_TRUNC, H5P_DEFAULT,
9 H5P_DEFAULT);
10
11 dataset_id = H5Dcreate(file_id, "/Float_data",
12 H5T_NATIVE_FLOAT, dataspace_id,
13 H5P_DEFAULT, H5P_DEFAULT, H5P_DEFAULT);
14
15 H5Dwrite(dataset_id, H5T_NATIVE_FLOAT,
16 dataspace_id, dataspace_id, H5P_DEFAULT,
17 data);
18
19 H5Dclose(dataset_id);
20
21 H5Sclose(dataspace_id);
22
23 H5Fclose(file_id);
```

In this example, lines 1–3 declare the variables needed for the example, including the 3-D array of data to store. Line 5 represents the application’s process of filling the data array with information. Lines 7–9 create a new HDF5 file, a new dataspace describing a fixed-size three-dimensional array of dimensions $1024 \times 1024 \times 1024$, and a new dataset using a single-precision floating-point datatype and the dataspace created. Line 11 writes the entire 4 GB array to the file in a single I/O operation, and lines 13–15 close the objects created earlier. Several of the calls use H5P_DEFAULT as a parameter, which is a placeholder for an HDF5 property list object, which can control more complicated properties of objects or operations.

The next C code example creates an identically structured file, but adds the necessary calls to open the file with 8 processes in parallel and to perform a collective write to the dataset created.

1	float data[512][512][512];
2	hid_t file_id, file_dataspace_id, mem_dataspace _id, dataset_id, fa_plist_id, dx_plist_id;
3	hsize_t file_dims[3] = {1024, 1024, 1024};
4	hsize_t mem_dims[3] = {512, 512, 512};
5	
6	<...acquire or assign data values...>
7	
8	fa_plist_id = H5Pcreate(H5P_FILE_ACCESS);
9	H5Pset_fapl_mpio(fa_plist_id, MPI_COMM_WORLD, MPI_INFO_NULL);
10	file_id = H5Fcreate("example.h5", H5F_ACC_ TRUNC, H5P_DEFAULT, fa_plist_id);
11	H5Pclose(fa_plist_id);
12	file_dataspace_id = H5Screate_simple(3, file_dims, NULL);
13	dataset_id = H5Dcreate(file_id, "/Float_data", H5T_NATIVE_FLOAT, file_dataspace_id, H5P_DEFAULT, H5P_DEFAULT, H5P_DEFAULT);
14	
15	mem_dataspace_id = H5Screate_simple(3, mem_dims, NULL);

16	
17	< ...select process's elements in file dataspace... >
18	
19	dx plist_id = H5Pcreate(H5P_DATASET_XFER);
20	H5Pset_dxpl_mpio(dx plist_id, H5FD_MPIO_COLLECTIVE);
21	H5Dwrite(dataset_id, H5T_NATIVE_FLOAT, mem dataspace_id, file dataspace_id, dx plist_id, data);
22	
23	H5Pclose(dx plist_id);
24	H5Dclose(dataset_id);
25	H5Sclose(mem dataspace_id);
26	H5Sclose(file dataspace_id);
27	H5Fclose(file id);

In this updated example, the size of the data array on line 1 has been changed to be only one eighth of the total array size, to allow for each of the eight processes to write a portion of the total array in the file. Lines 8–10 have been updated to create a file access property list, change the file driver for opening the file to use MPI-I/O and collectively open the file with all processes, using the file access property list. Lines 12–13 create the dataset in the file in the same way as the previous example. Line 15 creates a dataspace for each process's portion of the dataset in the file, and line 17 represents a section of code for selecting the part of the file's dataspace that each process will write to (which is omitted due to space constraints). Lines 19–21 create a dataset transfer property list, set the I/O operation to be collective, and perform a collective write operation where each process writes a different portion of the dataset in the file. Finally, lines 23–27 release resources used for the example.

This example shows some ways that property lists can be used to modify the operation of HDF5 API calls, as well as demonstrating a simple example of parallel I/O using HDF5 API calls.

Higher-Level Data Models Built on HDF5

HDF5 provides a set of generic higher-level data models that describe how to store images and tables as

datasets and describe the coordinates of dataspace elements. A scientific user community can also use HDF5 as the basis for exchanging data among its members by creating a standardized domain-specific data model that is relevant to their area of interest. Domain-specific data models specify the names of HDF5 groups, datasets and attributes, the dataspace and datatype for the datasets and attributes, etc. Frequently, a domain's user community also creates a “wrapper library” that calls HDF5 library routines while enforcing the domain's standardized data model.

Library Interface

Software applications create, modify, and delete HDF5 objects through an object-oriented library interface that manipulates the objects in HDF5 files. Applications can use the HDF5 library to operate directly on the base HDF5 objects or use a domain-specific wrapper library that operates at a higher level of abstraction. The core software library for accessing HDF5 files is written in C, but library interfaces for the HDF5 data model have been created for many programming languages, including Fortran, C++, Java, Python, Perl, Ada, and C#.

File Format

Objects in the HDF5 data model created by the library interface are stored in files whose structure is defined by the HDF5 file format. The HDF5 file format has many unique aspects, some of which are: a mechanism for storing non-HDF5 formatted data at the beginning of a file, a method of “micro-versioning” file data structures that makes incremental changes to the format possible, and data structures that enable constant-time lookup of data within the file in situations which previously required a logarithmic number of operations.

The HDF5 file format is designed to be flexible and extensible, allowing for evolution and expansion of the data model in an incremental and structured way. This allows new releases of the HDF5 software library to continue to access all previous versions of the HDF5 file format. This capability empowers application developers to create HDF5 files and access data contained within them over very long periods of time.

Tools

HDF5 is distributed with command-line utilities that can inspect and operate on HDF5 files. Operations provided by command-line utilities include copying HDF5

objects from one file to another, compacting internally fragmented HDF5 files to reduce their size, and comparing two HDF5 files to determine differences in the objects contained within them. The latter differencing utility, called “h5diff”, is also provided as a parallel computing application that uses the MPI programming interface to quickly compare two files using multiple processes.

Many other applications, both commercial and open source, can access data stored in HDF5 files. Some of these applications include MATLAB [8], Mathematica [9], HDFView [10], VisIt [11], and EnSight [12]. Some of these applications provide generic browsing and modification of HDF5 files, while others provide specialized visualization of domain-specific data models stored in HDF5 files.

Parallel File I/O

Applications that use the MPI programming interface [13] can use the HDF5 library to access HDF5 files in parallel from multiple concurrently executing processes. Internally, the HDF5 library uses the MPI interface for coordinating access to the HDF5 file as well as for performing parallel operations on the file. Efficiently accessing an HDF5 file in parallel requires storing the file on a parallel file system designed for access through the MPI interface.

Two methods of accessing an HDF5 file in parallel are possible: “independent” and “collective.” Independent parallel access to an HDF5 file is performed by a process in a parallel application without coordination with or cooperation from the other processes in the application. Collective parallel access to an HDF5 file is performed with all the processes in the parallel application cooperating and possibly communicating with each other.

The following discussion of HDF5 library capabilities describes parallel I/O features in the current release at the time this entry was written, release 1.8.6. The parallel I/O features in the HDF5 library are continually improving and evolving to address the ongoing changes in the landscape of parallel computing. Unless otherwise stated, limitations in the capabilities of the HDF5 library are not inherent to the HDF5 data model or file format and may be addressed in future library releases.

The HDF5 library requires that operations that create, modify, or delete objects in an HDF5 file be performed collectively. However, operations that only open

objects for reading can be performed independently. Requiring collective operations for modifying the file’s structure is currently necessary so that all processes in the parallel application keep a consistent view of the file’s contents.

Reading or writing the elements of a dataset can be performed independently or collectively. Accessing the elements of a dataset with independent or collective operations involves different trade-offs that application developers must balance.

Using independent operations requires a parallel application to create the overall structure of the HDF5 file at the beginning of its execution, or possibly with a nonparallel application prior to the start of the parallel application. The parallel application can then update elements of a dataset without requiring any synchronization or coordination between the processes in the application. However, the application must subdivide the portions of the file accessed from each process to avoid race conditions that would affect the contents of the file. Additionally, accessing a file independently may cause the underlying parallel file system to perform very poorly, due to its lack of a global perspective on the overall access pattern, which prevents the file system from taking advantage of many caching and buffering opportunities available with collective operations.

Accessing HDF5 dataset elements collectively requires that all processes in the parallel application cooperate when performing a read or write operation. Collective operations use the MPI interface within the HDF5 library to describe the region(s) of the file to access from each process, and then use collective MPI I/O operations to access the dataset elements. Collectively accessing HDF5 dataset elements allows the MPI implementation to communicate between processes in the application to determine the best method of accessing the parallel file system, which can greatly improve performance of the I/O operation. However, the communication and synchronization overhead of collective access can also slow down an application’s overall performance.

To get good performance when accessing an HDF5 dataset, it is important to choose a storage method that is compatible with the type of parallel access chosen. For example, compact data storage requires all writes to dataset elements be performed collectively, while external data storage requires all dataset element accesses be performed independently.

Collective and independent element access also involves the MPI and parallel file system layers, and those layers add their own complexities to the equation. HDF5 application developers must carefully balance the trade-offs of collective and independent operations to determine when and how to use them.

High performance access to HDF5 files is a strongly desired feature of application developers, and the HDF5 library has been designed with the goal of providing performance that closely matches the performance possible when an application accesses unformatted data directly. Considerable effort has been devoted to enhancing the HDF5 library's parallel performance, and this effort continues as new parallel I/O developments unfold.

Significant Parallel Applications and Libraries That Use HDF5

Many applications and software libraries that use HDF5 have become significant software assets, either commercially or as open source projects governed by a user community. HDF5's stability, longevity, and breadth of features have attracted many developers to it for storing their data, both for sequential and parallel computing purposes.

The first software library to use HDF5 was developed collaboratively by developers at the US Department of Energy's (DOE) Lawrence Livermore, Los Alamos and Sandia National Laboratories. This effort was called the "Sets and Fields" (SAF) library [14] and was developed to give the parallel applications that dealt with large, complex finite element simulations on the highest performing computers of the time a way to efficiently store their data.

Many large scientific communities worldwide have adopted HDF5 for storing data with parallel applications. Some significant examples include the FLASH software for simulating astrophysical nuclear flashes from the University of Chicago [15], the Chombo package for solving finite difference equations using adaptive mesh refinement from Lawrence Berkeley National Laboratory [16], and the open source NeXus software and data format for interchanging data in the neutron, x-ray, and muon science communities [17].

netCDF, PnetCDF, and HDF5

Another significant software library that uses HDF5 is the netCDF library [5], developed at the Unidata

Program Center for the University Corporation for Atmospheric Research (UCAR). Originally designed for the climate modeling community, netCDF has since been embraced by many other scientific communities. netCDF has adopted HDF5 as its principal storage method, as of version 4.0, in order to take advantage of several features in HDF5 that its previous file format did not provide, including data compression, a wider array of types for storing data elements, hierarchical grouping structures, and more flexible parallel operations.

Created prior to the development of netCDF-4, parallel-netCDF or "PnetCDF" [18] was developed by Argonne National Laboratory. PnetCDF allows parallel applications to access netCDF format files with collective data operations. PnetCDF does not extend the netCDF data model or format beyond allowing larger objects to be stored in netCDF files. Files written by PnetCDF and versions of the netCDF library prior to netCDF-4 do not use the HDF5 file format and instead store data in the "netCDF classic" format [19].

Future Directions

Both the primary development team at The HDF Group and the user community that has formed around the HDF5 project are constantly improving it. HDF5 continues to be ported to new computer systems and architectures and has its performance improved and errors corrected over time. Additionally, the HDF5 data model is expanding to encompass new developments in the field of high performance storage and computing.

Some improvements being designed or implemented as of this entry's writing include: increasing the efficiency of small file I/O operations through advanced caching mechanisms, finding ways to allow parallel applications to create HDF5 objects in a file with independent operations, and implementing new chunked data storage indexing methods to improve collective access performance.

Additionally, HDF5 continues to lead the scientific data storage field in its adoption of asynchronous file I/O for improved performance, journaled file updates for improved resiliency, and methods for improving concurrency by allowing different applications to read and write to the same HDF5 file without using a locking mechanism.

Bibliographic Notes and Further Reading

HDF5 has been under development since 1996, a short history of its development is recorded at The HDF Group web site [20].

Datasets in HDF5 files are analogous to sections of trivial fiber bundles [21], where the HDF5 dataspace corresponds to a fiber bundle's base space, the HDF5 datatype corresponds to the fiber, and the dataset, a variable whose value is the totality of the data elements stored, represents a section through the total space (which is the Cartesian product of the base space and the fiber).

HDF5 datatypes can be very complex and many more details are found in reference [22].

The HDF5 file format is documented in [23].

Many more applications and libraries use HDF5 than are discussed in this entry. A partial list can be found in [24].

Homology to Sequence Alignment, From

WU-CHUN FENG^{1,2}, HESHAN LIN¹

¹Virginia Tech, Blacksburg, VA, USA

²Wake Forest University, Winston-Salem, NC, USA

Discussion

Two sequences are considered to be *homologous* if they share a common ancestor. Sequences are either homologous or nonhomologous, but not in-between [13]. Determining whether two sequences are actually homologous can be a challenging task, as it requires inferences to be made between the sequences. Further complicating this task is the potential that the sequences may *appear* to be related via chance similarity rather than via common ancestry.

One approach toward determining homology entails the use of sequence-alignment algorithms that maximize the similarity between two sequences. For homology modeling, these alignments could be used to obtain the likely amino-acid correspondence between the sequences.

Introduction

Sequence alignment identifies similarities between a pair of biological sequences (i.e., pairwise sequence alignment) or across a set of multiple biological sequences (i.e., multiple sequence alignment). These alignments, in turn, enable the inference of functional, structural, and evolutionary relationships between sequences. For instance, sequence alignment helped biologists identify the similarities between the SARS virus and the more well-studied coronaviruses, thus enhancing the biologists' ability to combat the new virus.

Pairwise Sequence Alignment

There are two types of pairwise alignment: *global alignment* and *local alignment*. Global alignment seeks to align a pair of sequences entirely to each other, i.e., from one end to the other. As such, it is suitable for comparing sequences with roughly the same length, e.g., two closely homologous sequences. Local alignment seeks to identify significant matches between parts of the sequences. It is useful to analyze partially related

sequences, e.g., protein sequences that share a common domain.

Many approaches have been proposed for aligning a pair of sequences. Among them, dynamic programming is a common technique that can find optimal alignments between sequences. Dynamic programming can be used for both local alignment and global alignment. The algorithms in both cases are quite similar. The scoring model of an alignment algorithm is given by a substitution matrix and a gap-penalty function. A substitution matrix stores a matching score for every possible pair of letters. A matching score is typically measured by the frequency that a pair of letters occurs in the known homologous sequences according a certain statistical model. Popular substitution matrices include PAM and BLOSUM, an example of which is shown in Fig. 1. A gap-penalty function defines how gaps in the alignments are weighed in alignment scores. For instance, with a linear gap-penalty function, the penalty score grows linearly with the length of a gap. With an affine gap-penalty function, the penalty factors are differentiated for the opening and the extension of a gap.

The following discussion will focus on the basic algorithm and its parallelization of Smith–Waterman, a popular local-alignment tool based on dynamic programming. (For more advanced techniques to compute pairwise sequence alignment, the reader should consult the “Bibliographic Notes and Further Reading” section at the end of this entry.)

Case Study: Smith–Waterman Algorithm

Given two sequences $S_1 = a_1a_2\cdots a_m$ and $S_2 = b_1b_2\cdots b_n$, the Smith–Waterman algorithm uses an m by n scoring matrix H to calculate and track the alignments. A cell $H_{i,j}$ stores the highest similarity score that can be achieved by any possible alignment ending at a_i and b_j . The Smith–Waterman algorithm has three phases: *initialization*, *matrix filling*, and *traceback*.

The initialization phase simply assigns a value of 0 to each of the matrix cells in the first row and the first column. In the matrix-filling phase, the problem of aligning the two whole sequences is broken into smaller subproblems, i.e., aligning partial sequences. Accordingly, a cell $H_{i,j}$ is updated based on the values of its preceding neighbors. For the sake of illustration, the rest of the discussion assumes a linear gap-penalty function

H

Homology to Sequence Alignment, From: Fig. 1 BLOSUM62 substitution matrix

where the penalty of a gap is equal to a constant factor g (typically negative) times the length of the gap.

There are three possible alignment scenarios where $H_{i,j}$ is derived from its neighbors: (1) a_i and b_j are associated, (2) there is a gap in sequence S_1 , and (3) there is a gap in sequence S_2 . As such, the scoring matrix can be filled according to (1). The first three terms in (1) correspond to the three scenarios; the zero value ensures that there are no negative scores. $S(a_i, b_j)$ is the matching score derived by looking up the substitution matrix.

$$H_{i,j} = \max \begin{cases} H_{i-1,j-1} + S(a_i, b_j) \\ H_{i-1,j} + g \\ H_{i,j-1} + g \\ 0 \end{cases} \quad (1)$$

When a cell is updated, the direction from which the maximum score is derived also needs to be stored (e.g., in a separate matrix). After the matrix is filled, a traceback process is used to recover the path of the best alignment. It starts from the cell with the highest score in the matrix and ends at a cell with a value of 0, following the direction information recorded earlier.

The majority of execution time is spent on the matrix-filling phase in Smith-Waterman. Algorithm 1 shows a straightforward implementation of the matrix

Algorithm 1 Matrix Filling in Smith–Waterman

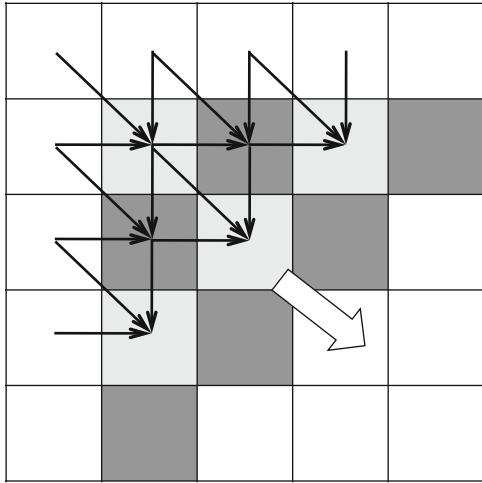

```

for  $i = 1$  to  $m$  do
  for  $j = 1$  to  $n$  do
     $max = H_{i-1,j-1} + S(a_i, b_j) > H_{i-1,j} + g ? H_{i-1,j-1} +$ 
     $S(a_i, b_j) : H_{i-1,j} + g$ 
    if  $H_{i,j-1} + g > max$  then
       $H_{i,j} = H_{i,j-1} + g$ 
    else

    end if
  end for
end for

```

filling. In the inner loop of the algorithm, the cell calculated in one iteration depends on the value updated in the previous iteration, resulting in a “read-after-write” hazard (see [14] for details), which can reduce the instruction-level parallelism that can be exploited by pipelining, and hence, adversely impact performance. In addition, this algorithm is difficult to directly parallelize because of the data dependency between iterations in the inner loop.

As depicted in Fig. 2, the calculation of a particular cell depends on its west, northwest, and north neighbors. However, the updates of individual cells along an anti-diagonal are independent. This observation

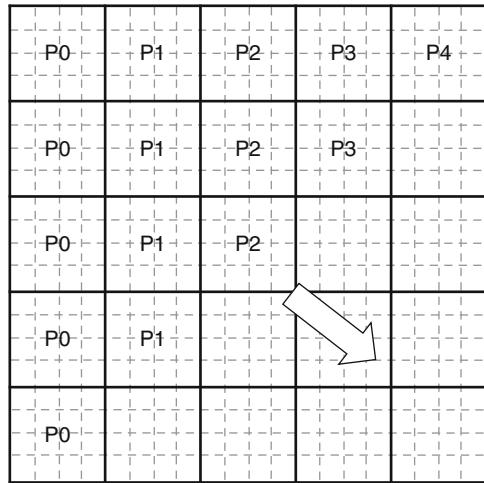

Homology to Sequence Alignment, From. Fig. 2 Data dependency of matrix filling

motivates a waveform-filling algorithm [11], where the matrix cells on an anti-diagonal can be updated simultaneously. That is, because there is no dependency between two adjacent cells along an anti-diagonal, this algorithm greatly reduces read-after-write hazards, and in turn, increases the execution efficiency and ease of parallelization. For example, in a shared-memory environment, individual threads can compute a subset of cells along an anti-diagonal. However, synchronization between threads must occur after computing each anti-diagonal.

Since a scoring matrix is typically stored in “row major” order, as shown in Algorithm 1, the above waveform algorithm may have a large memory footprint when computing an anti-diagonal, thus limiting the benefits of processor caches. One improvement entails partitioning the matrix into tiles and having each parallel processing unit fill a subset of the tiles, as shown in Fig. 3. By carefully choosing the tile size, data processed by a thread can fit in the processor cache. Furthermore, when parallelized in distributed environments, the tiled approach can effectively reduce internode communication, as compared to the fine-grained waveform approach, because only elements at the borders of individual tiles need to be exchanged between different compute nodes.

With the waveform approach, the initial amount of parallelism in the algorithm is low. It gradually increases

Homology to Sequence Alignment, From. Fig. 3 Tiled implementation

along each successive anti-diagonal until reaching the maximum parallelism along the longest anti-diagonal, and then monotonically decreases thereafter. A trade-off needs to be made in choosing the tile size. If the tile size is too large, there is not sufficient parallelism to exploit at the beginning of the waveform computation, which results in idle resources in systems with a large number processing units. On the other hand, too small a tile size will incur much more synchronization and communication overhead. Nonetheless, the waveform approach may generate imbalanced workloads on different processors, especially at the beginning and end of the computation. It is worth noting that there is an alternative parallel algorithm that uses prefix-sum to compute the scoring matrix row by row (or column by column) [4], which can generate uniform task distribution among all processors.

The above discussion assumes a simple linear gap-penalty function. In practice, the Smith-Waterman algorithm uses an affine gap-penalty scheme, which requires maintaining three scoring matrices in order to track the gap opening and extension. Consequently, both the time and space usages increase by a factor of three in implementation using affine gap penalties.

Sequence Database Search

With the proliferation of public sequence data, sequence database search has become an important task in sequence analysis. For example, newly discovered

sequences are typically searched against a database of sequences with known genes and known functions in order to help predict the functions of the newly discovered sequences. A sequence database-search tool compares a set of query sequences against all sequences in a database with a pairwise alignment algorithm and reports the matches that are statistically significant. Although dynamic-programming algorithms can be used for sequence database search, the algorithms are too computationally demanding to keep up with the database growth. Consequently, heuristic-based algorithms, such as BLAST [2, 3] and FASTA [21], have been developed for rapidly identifying similarities in sequence databases.

BLAST is the most widely used sequence database-search tool. It reduces the complexity of alignment computation by filtering potential matches with common words, called k -mers. Specifically, there are four stages in comparing a query sequence and a database sequence.

- Stage 1: The query and the database sequences are parsed into words of length k (k is 3 for protein sequences and 11 for DNA sequences by default). The algorithm then matches words between the query sequence and the database sequence and calculates an alignment score for each matched word, based on a substitution matrix (e.g., BLOSUM62). Only matched words with alignment scores higher than a threshold are kept for the next stage.
- Stage 2: For a high-scoring matched word, ungapped alignment is performed by extending the matched word in both directions. An alignment score will be calculated along the extension. The extension stops when the alignment score stops increasing and slightly drops off from the maximum alignment score (controlled by another threshold).
- Stage 3: Ungapped alignments with scores larger than a given threshold obtained from stage 2 are chosen as seed alignments. Gapped alignments are then performed on the seed alignments using a dynamic-programming algorithm, following both forward and backward directions.
- Stage 4: Traceback is performed to recover the paths of gapped alignments.

BLAST calculates the significance of result alignments using Karlin-Altschul statistics. The Karlin-Altschul

theory uses a statistic called the e-value (E) to measure the likelihood that an alignment is resulted from matches by chance (i.e., matches between random sequences) as compared to true homologous relationships. The e-value can be calculated according to (2):

$$E = Kmn \cdot e^{-\lambda S} \quad (2)$$

where K and λ are the Karlin-Altschul parameters, m and n are the query length and the total length of all database sequences, and S is the alignment score. The e-value indicates how many alignments with a score higher than S can be found by chance in the search space, i.e., the multiple of the query sequence length and the database length. The lower the e-value, the more significant is an alignment. The alignment results of a query sequence are sorted in the order of e-value.

A sequence database-search job needs to compute $M \times N$ pairwise sequence alignments, where M and N are the numbers of the query and database sequences, respectively. This computation can be parallelized with a coarse-grained approach, where the alignments of individual pairs of sequences are assigned to different processing units.

Early parallel sequence-search software adopted a *query segmentation* approach, where a sequence-search job is parallelized by having individual compute nodes concurrently search disjoint subsets of query sequences against the whole sequence database. Since the searches of individual query sequences are independent, this *embarrassingly parallel* approach is easy to implement and scales well. However, the size of sequence databases is growing much faster than the memory size of a typical single computer. When the database cannot fit in memory, data will be frequently swapped in and out of the memory when searching multiple queries, thus causing significant performance degradation, because disk I/O is several orders of magnitude slower than memory access. Query segmentation can improve the search throughput, but it does not reduce the response time taken to search a single query sequence.

Database segmentation is an alternative parallelization approach, where large databases are partitioned and cached in the aggregate memory of a group of compute nodes. By doing so, the repeated I/O overhead of searching large databases is avoided. Database segmentation also improves the search response time since a

compute node searches only a portion of the database. However, database segmentation introduces computational dependencies between individual nodes because the distributed results generated at different nodes need to be merged and sorted to produce the final output. The parallel overhead of merging and sorting increases as the system size grows.

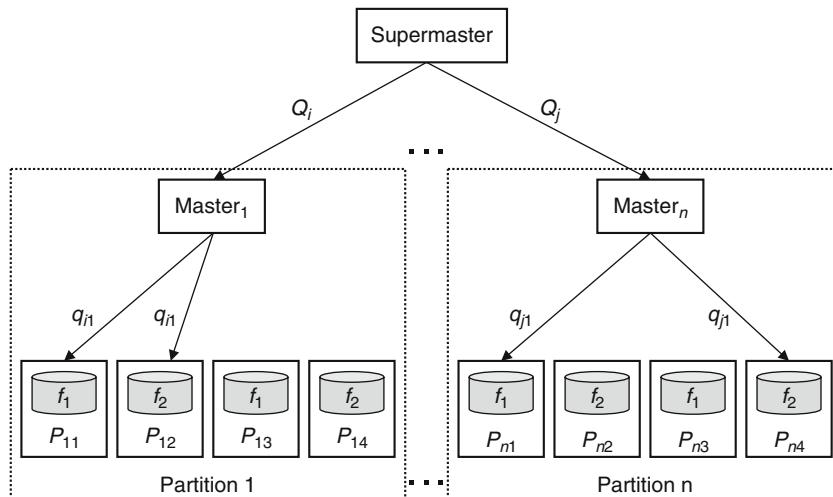

With the astronomical growth of sequence databases, today's large-scale sequence search jobs can be very resource demanding. For instance, BLAST searching in a metagenomics project can consume several millions of processor hours. Massively parallel sequence-search tools, such as mpiBLAST [6, 19, 20] and ScalaBLAST [33], have been developed to accelerate large-scale sequence search jobs on state-of-the-art supercomputers. These tools use a combination of query segmentation and database segmentation to offer massive parallelism needed to scale on a large number of processors.

Case Study: mpiBLAST

mpiBLAST is an open-source parallelization of NCBI BLAST that has been designed for petascale deployment. Adopting a scalable, hierarchical design, mpiBLAST parallelizes a search job via a combination of query segmentation and database segmentation. As shown in Fig. 4, processors in the system are organized into

equal-sized *partitions*, which are supervised by a dedicated *supermaster* process. The supermaster is responsible for assigning tasks to different partitions and handling inter-partition load balancing. Within each partition, there is one *master* process and many *worker* processes. The master is responsible for coordinating both computation and I/O scheduling in a partition. The master periodically fetches a subset of query sequences from the supermaster and assigns them to workers, and it coordinates output processing of queries that have been processed in the partition. The sequence database is partitioned into fragments and replicated to workers in the system. This hierarchical design avoids creating scheduling bottlenecks in large systems by distributing scheduling workloads to multiple masters.

Large-scale sequence searches can be highly data-intensive, and as such, the efficiency of data management is critical to the program scalability. For the input data, having thousands of processors simultaneously load database fragments from shared storage may overwhelm the I/O subsystem. To address this, mpiBLAST designates a set of compute nodes as I/O proxies, which read database fragments from the file system in parallel and replicate them to other workers using the broadcasting mechanism in MPI [28, 29] libraries. In addition, mpiBLAST allows workers to cache

Homology to Sequence Alignment, From. Fig. 4 mpiBLAST hierarchical design. Q_i and Q_j are query batches fetched from the supermaster to masters, and q_{i1} and q_{j1} are query sequences that are assigned by masters to their workers. In this example, the database is segmented into two fragments f_1 and f_2 and replicated twice within each partition

assigned database fragments in the memory or local storage, and it uses a task-scheduling algorithm that takes into account data locality to minimize repeated loading of database fragments.

With database segmentation, result alignments of different database fragments are usually interleaved in the global output because those alignments need to be sorted by e-values. Consequently, the output data generated at each worker is noncontiguous in the output file. Straightforward noncontiguous I/O with many seek-and-write operations is slow on most file systems. This type of I/O can be optimized with collective I/O [27, 44, 46], which is available in parallel I/O libraries such as ROMIO [45]. Collective I/O uses a two-phase process. In the first phase, involved processes exchange data with each other to form large trunks of contiguous data, which are stored as memory buffers in individual processes. In the second phase, the buffered data is written to the actual file system. Collective I/O improves I/O performance because continuous data accesses are much more efficient than noncontiguous ones. Traditional collective I/O implementations require synchronization between all involved processes for each I/O operation. This synchronization overhead will adversely impact sequence-search performance when computation is

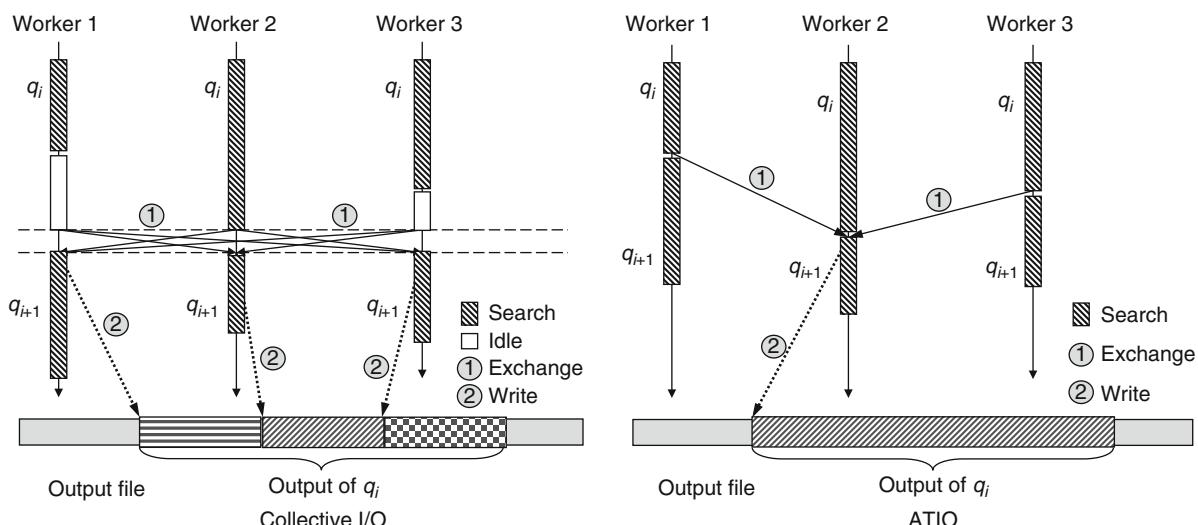

imbalanced across different processes. To address this issue, mpiBLAST introduces a parallel I/O technique called asynchronous, two-phase I/O (ATIO), which allows worker processes to rearrange I/O data without synchronizing with each other. Specifically, mpiBLAST appoints a worker as the write leader for each query sequence. The write leader aggregates output data from other workers via nonblocking MPI communication and carries out the write operation to the file system. ATIO overlaps I/O reorganization and sequence-search computation, thus improving the overall application performance. Figure 5 shows the difference between collective I/O and ATIO within the context of mpiBLAST.

H

Multiple Sequence Alignment

Multiple sequence alignment (MSA) identifies similarities among three or more sequences. It can be used to analyze a family of related sequences to reveal phylogenetic relationships. Other usages of multiple sequence alignment include detection of conserved biological features and genome sequencing. Multiple sequence alignment can also be global or local.

Like pairwise sequence alignment, multiple sequence alignment can be computed using *dynamic*

Homology to Sequence Alignment, From. Fig. 5 Collective I/O and ATIO. Collective I/O requires synchronization and introduces idle waiting in worker processes. ATIO uses a write leader to aggregate noncontiguous data from other workers in an asynchronous manner

programming algorithms. Although these algorithms can find optimal alignments, the required resources for these algorithms grow exponentially as the number of sequences increases. Suppose there are N sequences and the average sequence length is L , the time and space complexities are both $O(L^N)$. Thus, it is computationally impractical to use dynamic programming to align a large number of sequences.

Many heuristic approaches have been proposed to reduce the computational complexity of multiple sequence alignment. *Progressive alignment methods* [8, 12, 32, 35, 47] use guided pairwise sequence alignment to rapidly construct MSA for a large number of sequences. These methods first build a phylogenetic tree based on all-to-all pairwise sequence alignments using neighbor joining [40] or UPGMA [43] techniques. Guided by the phylogenetic tree, the most similar sequences are first aligned, the less similar sequences are then progressively added to the initial MSA. One problem with progressive methods is that errors that occur in early aligning stages are propagated to the final alignment results. *Iterative alignment methods* [10, 49] address this problem by introducing “correction” mechanisms during the MSA construction process. These methods incrementally align sequences as progressive methods, but continuously adjust the structure of the phylogenetic tree and previously computed alignments according to a certain objective function.

Case Study: ClustalW

ClustalW [47] is a widely used MSA program based on progressive methods. The ClustalW algorithm includes three stages: (1) distance matrix computation, (2) guided tree construction, and (3) progressive alignment. Due to the popularity of ClustalW, its parallelization has been well studied on clusters [9, 17] and multiprocessor systems [5, 30].

In the first stage, ClustalW computes a distance matrix by performing all-to-all pairwise alignment over input sequences. This requires a total of $\frac{N(N-1)}{2}$ comparison for N sequences since the alignment of a pair of sequences is symmetric. ClustalW allows users to choose between two alignment algorithms: a faster k -mer matching algorithm and a slower but more accurate dynamic programming algorithm. This stage of the algorithm is embarrassingly parallel. Alignments of individual pairs of sequences can be statically assigned

or dynamically assigned with a greedy algorithm to different processing units. Additional parallelism can be exploited by parallelizing the alignment of a single pair of sequences, similar to the Smith–Waterman algorithm.

In the second stage, a guided tree is constructed using a neighbor-joining algorithm based on the alignment scores in the distance matrix. Initially all sequences are leaf nodes of a star-like tree. The algorithm iteratively selects a pair of nodes and joins them into a new internal node until there are no nodes left to join, at which point a bifurcated tree is created. Algorithm 2 gives the pseudocode of this process. Suppose there are a total of M nodes at an iteration, there are $\frac{n(n-1)}{2}$ possible pairs of nodes. The pair of nodes that results in the smallest length of branches will be selected to join. An example of neighbor-joining process with four sequences is given in Fig. 6.

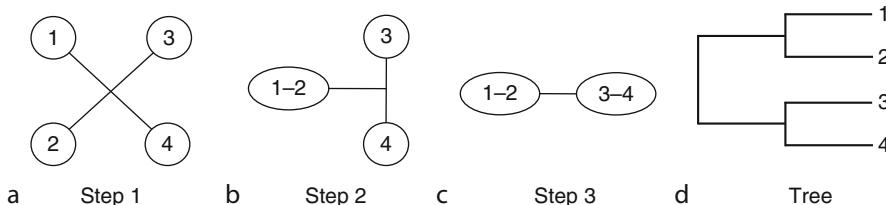

In Algorithm 2, the outermost loop cannot be parallelized because one iteration of neighbor joining is dependent on the previous one. However, within an iteration of neighbor joining, the calculation of branch lengths of all pairs of nodes can be performed in parallel. Since the number of available nodes reduces after each joining operation, the parallelism level decreases as the iteration advances in the outermost loop.

Algorithm 2 Construction of Guided Tree

```

while there are nodes to join do
    Let  $n$  be the number of current available nodes
    Let  $D$  be the current distance matrix
    Let  $L_{min}$  be the smallest length of the tree branches
    for  $i = 2$  to  $n$  do
        for  $j = 1$  to  $i - 1$  do
             $L(i,j) = (n - 2)D_{i,j} - \sum_{k=1}^n D_{i,k} - \sum_{k=1}^n D_{j,k}$ 
            if  $L(i,j) < L_{min}$  then
                 $L_{min} = L(i,j)$ 
            end if
        end for
    end for
    Combine nodes  $i, j$  that result in  $L_{min}$  into a new node
    Update distance matrix with the new node
end while

```

Homology to Sequence Alignment, From. Fig. 6 Neighbor-joining example

In the third stage, the sequence is progressively aligned according to the guided tree. For instance, in the tree shown in Fig. 6(d), sequences 1 and 2 are aligned first, followed by 3 and 4. Finally, the alignment results of $<1-2>$ and $<3-4>$ are aligned. Note that the alignment on a node can only be performed after both of its children are aligned, but the alignments at the same level of the tree can be performed simultaneously. The level of parallelism of the algorithm depends heavily on the tree structure. In the best case, the guided tree is a balanced tree. At the beginning, all the leaves can be aligned in parallel. The number of concurrent alignments decreases by a half at each higher level toward the root of the tree.

Case Study: T-Coffee

T-Coffee [32] is another popular progressive alignment algorithm. Compared to other typical progressive alignment tools, T-Coffee improves the alignment accuracy by adopting a consistency-based scoring function, which uses similarity information among all input sequences to guide the alignment progress. T-Coffee consists of two main steps: *library generation* and *progressive alignment*. The first step constructs a library that contains a mixture of global and local alignments between *every pair* of input sequences. In the library, an alignment is represented as a list of pairwise constraints. Each constraint stores a pair of matched residues along with an alignment weight, which is essentially a three-tuple $<S_{xi}, S_{yj}, w>$, where S_{xi} is the i th residue of sequence S_x and w is the weight. T-Coffee incorporates pairwise global alignments generated by ClustalW as well as top ten nonintersecting local alignments reported by Lalign from the FASTA package [21]. T-Coffee can also take alignment information from other MSA software. The pairwise constraints of a same pair of matched residues from various sources (e.g., global and local alignments) will be combined to

remove duplication. Constructing the library requires $\frac{N(N-1)}{2}$ global and local alignments and thus is highly compute-intensive.

After all pairwise alignments are incorporated in the library, T-Coffee performs *library extension*, a procedure that incorporates transitive alignment information to the weighing of pairwise constraints. Basically, for a pair of sequences x and y , if there is a sequence z that aligns to both x and y , then constraints between x and y will be reweighed by combining the weights of the corresponding constraints between x and z as well as y and z . Suppose the average sequence length is L , since for each pair of sequences, the extension algorithm needs to scan the rest of $N - 2$ sequences, and there are at most L constraints between a pair of sequences, the worst computation complexity of library extension is $O(N^3L^2)$.

In the second step, T-Coffee performs progressive alignment guided by a phylogenetic tree built with the neighbor-joining method, similar to the ClustalW algorithm. However, T-Coffee uses the weights in the extended library to align residues when grouping sequences/alignments. Since those weights bear complete alignment information from all input sequences, the progressive alignment in T-Coffee can reduce errors caused by the greediness of classic progressive methods.

Parallel T-Coffee (PTC) is a parallel implementation of T-Coffee in cluster environments [53]. PTC adopts a master-worker architecture and uses MPI to communicate between different processes. As mentioned earlier, the library generation in T-Coffee needs to compute all-to-all global and local alignments. The computation tasks of these alignments are independent of each other. PTC uses guided self-scheduling (GSS) [36] to distribute alignment tasks to different worker nodes. GSS first assigns a portion of the tasks to the workers. Each worker monitors its performance when processing the initial assignments; this performance information is

then sent to the master and used for dynamic scheduling for subsequent assignments.

After pairwise alignments are finished, duplicated constraints generated on distributed workers need to be combined. PTC implements this with parallel sorting. Each constraint is assigned to a bucket resident at a worker. Each worker can then concurrently combine duplicated constraints within its own bucket. The constraints in the library are then transformed into a three-dimensional lookup table, with rows and columns indexed by sequences and residues, respectively. Each element in the lookup table stores all constraints for a residue of a sequence. The lookup table will be accessed by all processors during the progressive alignment. PTC evenly distributes the lookup table by rows to all processors and allows table entries to be accessed by other processors through one-sided remote memory access. An efficient caching mechanism is also implemented to improve lookup performance.

During the progressive alignment, PTC schedules tree nodes to a processor according to their readiness; a tree node that has a fewer number of unprocessed child nodes has a higher scheduling priority. For tree nodes that have all child nodes processed, PTC gives higher priority to the ones with shorter estimated execution time. Similar to ClustalW, the parallelism of progress alignment in PTC can be limited if the guided tree is unbalanced. To address this issue, Orobital et al. proposed a heuristic approach that can construct a more balanced guided tree by allowing a pair of nodes to be grouped if their similarity value is smaller than the average similarity value between all sequences in the distance matrix [34].

Bibliographic Notes and Further Reading

As discussed in the case study of Smith-Waterman, typical sequence-alignment algorithms require $O(mn)$ space and time, where m and n are the lengths of compared sequences. Such a space requirement can be impractical for computing alignments of large sequences (e.g., those with a length of multiple

megabytes) on commodity machines. To address this issue, Mayers and Miller introduced a space-efficient alignment algorithm [31] adapted from the Hirschberg technique [15], which was originally developed for finding the longest common subsequence between two strings. By recursively dividing the alignment problem into subproblems at a “midpoint” along the *middle column* of the scoring matrix, Mayers and Miller’s approach can find the optimal alignment within $O(m + n)$ space but still $O(mn)$ time. Huang showed that a straightforward parallelization of the Hirschberg algorithm would require more than linear aggregate space [16], i.e., each processor needed to store more than $O\left(\frac{m+n}{p}\right)$ data, where p is the number of concurrent processors. In turn, Huang proposed an improved algorithm that recursively divides the alignment problem at the midpoint along the *middle anti-diagonal* of the scoring matrix. By doing so, Huang’s algorithm required only $O\left(\frac{mn}{p}\right)$ space per processor but with an increased time complexity of $O\left(\frac{(m+n)^2}{p}\right)$. Aluru et al. presented an alternative space-efficient parallel algorithm [4] that is more time efficient ($O\left(\frac{mn}{p}\right)$) but also consumes more space ($O\left(m + \frac{n}{p}\right), m \leq n$) than Huang’s approach. In their approach, an $O(mn)$ algorithm is first used to partition the scoring matrix into p vertical slices, and the last column of each slice as well as its intersection with the optimal alignment is stored. Each processor then takes a slice and uses a Hirschberg-based algorithm to compute the optimal alignment within the slice. In a subsequent study, Aluru et al. proposed an improved parallel algorithm [37] that requires $O\left(\frac{mn}{p}\right)$ time and $O\left(\frac{m+n}{p}\right)$ space, when $p = O\left(\frac{n}{\log n}\right)$ processors are used. In other words, such a parallel algorithm achieves “optimal” time and space complexities because this algorithm delivers a linear speedup with respect to the best known sequential algorithm.

The computational intensity of sequence-alignment algorithms has motivated studies in parallelizing these algorithms on accelerators. Various algorithms have been accelerated using the SIMD instruction extensions of commodity processors [38, 51], field-programmable gate array (FPGA) [18, 26], Cell Broadband Engine [1, 39, 42], and graphics processing units (GPUs) [22–24, 41, 48, 51, 52]. Developing and optimizing applications on traditional accelerators is much more

difficult than on CPUs, which may partially explain why accelerator-based solutions have not been widely adopted even if these solutions have demonstrated very promising performance results. However, the continuing improvement of software environments on commodity GPUs has made them increasingly popular for accelerating sequent alignments. To cope with the astronomical growth of sequence data, cloud-based solutions [7, 25] have also been developed to enable users to tackle large-scale problems with elastic compute resources from public clouds such as Amazon EC2.

HPC Challenge Benchmark

JACK DONGARRA, PIOTR LUSZCZEK
University of Tennessee, Knoxville, TN, USA

Definition

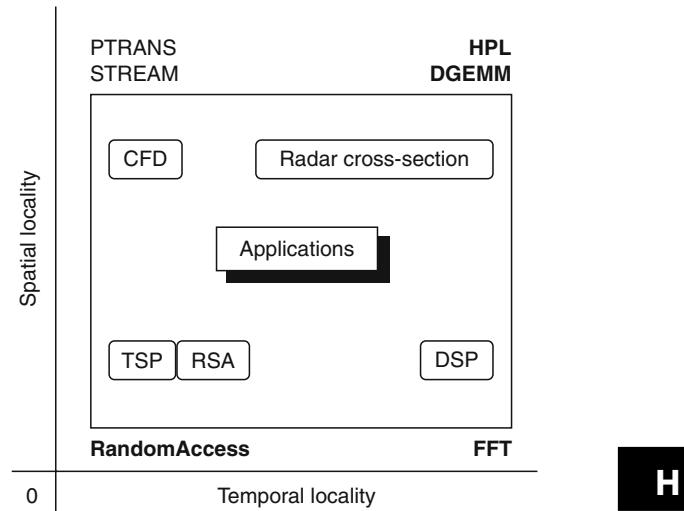

HPC Challenge (HPCC) is a benchmark that measures computer performance on various computational kernels that span the memory access locality space. HPCC includes tests that are able to take advantage of nearly all available floating point performance: High Performance LINPACK and matrix-matrix multiply allow for data reuse that is only bound by the size of large register file and fast cache. The twofold benefit from these tests is the ability to answer the question how well the hardware is able to work around the

“memory wall” and how today’s machines compare to the systems of the past as they are cataloged by the LINPACK Benchmark Report [3] and TOP500. HPCC also includes other tests, STREAM, PTRANS, FFT, RandomAccess – when they are combined together they span the memory access locality space. They are able to reveal the growing inefficiencies of the memory subsystem and how they are addressed in the new computer infrastructures. HPCC also offers scientific rigor to the benchmarking effort. The tests stress double precision floating point accuracy: the absolute prerequisite in the scientific world. In addition, the tests include careful verification of the outputs – undoubtedly an important fault-detection feature at extreme computing scales.

Discussion

The HPC Challenge benchmark suite was initially developed for the DARPA HPCS program [6] to provide a set of standardized hardware probes based on commonly occurring computational software kernels. The HPCS program involves a fundamental reassessment of how to define and measure performance, programmability, portability, robustness and, ultimately, productivity across the entire high-end domain. Consequently, the HPCC suite aimed both to give conceptual expression to the underlying computations used in this domain, and to be applicable to a broad spectrum of computational science fields. Clearly, a number of compromises needed to be embodied in the current form of the suite, given such a broad scope of design requirements. HPCC was designed to provide approximate bounds on computations that can be characterized by either high or low spatial and temporal locality (see Fig. 1, which gives the conceptual design space for the HPCC component tests). In addition, because the HPCC tests consist of simple mathematical operations, HPCC provides a unique opportunity to look at language and parallel programming model issues. As such, the benchmark is designed to serve both the system user and designer communities.

Figure 2 shows a generic memory subsystem in the leftmost column and how each level of the hierarchy is tested by the HPCC software (the second column from the left), along with the design goals for the future

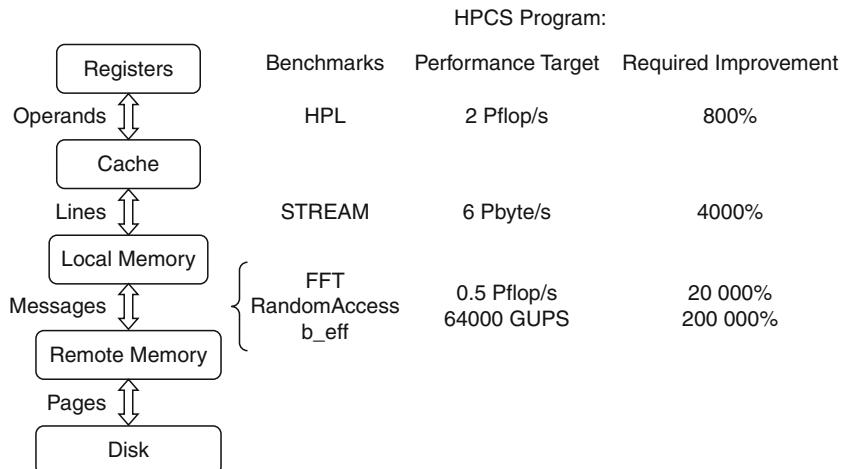

HPC Challenge Benchmark. Fig. 1 The application areas targeted by the HPCS Program are bound by the HPCC tests in the memory access locality space

systems that originated in the HPCS program (the third column from the right). In other words, these are the projected target performance numbers that are to come out of the winning HPCS vendor designs. The last column shows the relative improvement in performance that needs to be achieved in order to meet the goals.

The TOP500 Influence

The most commonly known ranking of supercomputer installations around the world is the TOP500 list [14]. It uses the equally well-known LINPACK benchmark [4] as a single figure of merit to rank 500 of the world’s most powerful supercomputers. The often-raised question about the relation between the TOP500 list and HPCC can be addressed by recognizing the positive aspects of the former. In particular, the longevity of the TOP500 list gives an unprecedented view of the high-end arena across the turbulent era of Moore’s law [10] rule and the emergence of today’s prevalent computing paradigms. The predictive power of the TOP500 list is likely to have a lasting influence in the future, as it has had in the past. HPCC extends the TOP500 list’s concept of exploiting a commonly used kernel and, in the context of the HPCS goals, incorporates a larger, growing suite of computational kernels. HPCC has already

HPC Challenge Benchmark. Fig. 2 HPCS program benchmarks and performance targets

HPC Challenge Benchmark. Table 1 All of the top 10 entries of the 27th TOP500 list that have results in the HPCC database

Rank	Name	Rmax	HPL	PTRANS	STREAM	FFT	RandomAccess	Lat.	B/w
1	BG/L	280.6	259.2	4665.9	160	2,311	35.47	5.92	0.16
2	BG W	91.3	83.9	171.5	50	1,235	21.61	4.70	0.16
3	ASC purple	75.8	57.9	553.0	44	842	1.03	5.11	3.22

9	Red storm	36.2	33.0	1813.1	44	1,118	1.02	7.97	1.15

begun to serve as a valuable tool for performance analysis. Table 1 shows an example of how the data from the HPCC database can augment the TOP500 results (for the current version of the table please visit the HPCC website).

Short History of the Benchmark

The first reference implementation of the HPCC suite of codes was released to the public in 2003. The first optimized submission came in April 2004 from Cray, using the then-recent X1 installation at Oak Ridge National Lab. Ever since, Cray has championed the list of optimized HPCC submissions. By the time of the first HPCC birds-of-a-feather session at the Supercomputing conference in 2004 in Pittsburgh, the public database of results already featured major

supercomputer makers – a sign that vendors were participating in the new benchmark initiative. At the same time, behind the scenes, the code was also being tried out by government and private institutions for procurement and marketing purposes. A 2005 milestone was the announcement of the HPCC Awards contest. The two complementary categories of the competition emphasized performance and productivity – the same goals as the sponsoring HPCS program. The performance-emphasizing Class 1 award drew the attention of many of the biggest players in the supercomputing industry, which resulted in populating the HPCC database with most of the top 10 entries of the TOP500 list (some exceeding their performances reported on the TOP500 – a tribute to HPCC's continuous results update policy). The contestants competed to achieve the highest raw performance in one of the four

	HPL	Compute x from the system of linear equations $Ax = b$.
	DGEMM	Compute update to matrix C with a product of matrices A and B .
	STREAM	Perform simple operations on vectors a , b , and c .
	PTRANS	Compute update to matrix A with a sum of its transpose and another matrix B .
	RandomAccess	Perform integer update of random vector T locations using pseudo-random sequence.
	FFT	Compute vector z to be the Fast Fourier Transform (FFT) of vector x .
	b.eff	Perform ping-pong and various communication ring exchanges.

HPC Challenge Benchmark. Fig. 3 Detail description of the HPCC component tests (A, B, C – matrices, a, b, c, x, z – vectors, α , β – scalars, T – array of 64-bit integers)

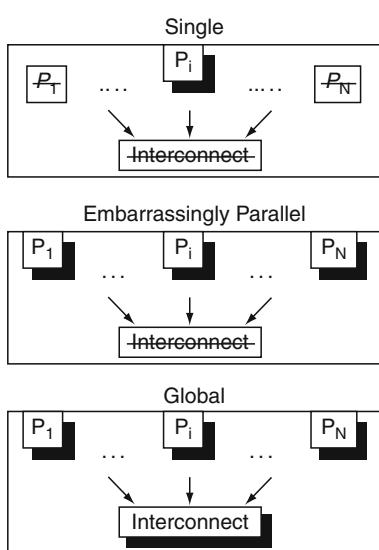

tests: HPL, STREAM, RANDA, and FFT. At the SC09 conference in Portland, Oregon, HPCC listed its first Pflop/s machine – Cray XT 5 called Jaguar from Oak Ridge National Laboratory. The Class 2 award, by solely focusing on productivity, introduced a subjectivity factor into the judging and also into the submission criteria, regarding what was appropriate for the contest. As a result, a wide range of solutions were submitted, spanning various programming languages (interpreted and compiled) and paradigms (with explicit and implicit parallelism). The Class 2 contest featured openly available as well as proprietary technologies, some of which were arguably confined to niche markets and some were

widely used. The financial incentives for entering turned out to be all but needless, as the HPCC seemed to have gained enough recognition within the high-end community to elicit entries even without the monetary assistance. (HPCwire provided both press coverage and cash rewards for the four winning contestants in Class 1 and the single winner in Class 2.) At the HPCC's second birds-of-a-feather session during the SC07 conference in Seattle, the former class was dominated by IBM's BlueGene/L at Lawrence Livermore National Lab, while the latter class was split among MTA pragmatically decorated C and UPC codes from Cray and IBM, respectively.

The Benchmark Tests' Details

Extensive discussion and various implementations of the HPCC tests are available elsewhere [5, 8, 15]. However, for the sake of completeness, this section provides the most important facts pertaining to the HPCC tests' definitions.

All calculations use double precision floating-point numbers as described by the IEEE 754 standard [1], and no mixed precision calculations [9] are allowed. All the tests are designed so that they will run on an arbitrary number of processors (usually denoted as p). Figure 3 shows a more detailed definition of each of the seven tests included in HPCC. In addition, it is possible to run the tests in one of three testing scenarios to stress various hardware components of the system. The scenarios are shown in Fig. 4. In the “Single” scenario, only one process is chosen to run the test. Accordingly, the remaining processes remain idle and so does the interconnect (shown with strike-out font in the Figure). In the “Embarrassingly Parallel” scenario, all processes run the tests simultaneously but they do not communicate with each other. And finally, in the “Global” scenario, all components of the system work together on all tests.

HPC Challenge Benchmark. Fig. 4 Testing scenarios of the HPCC components

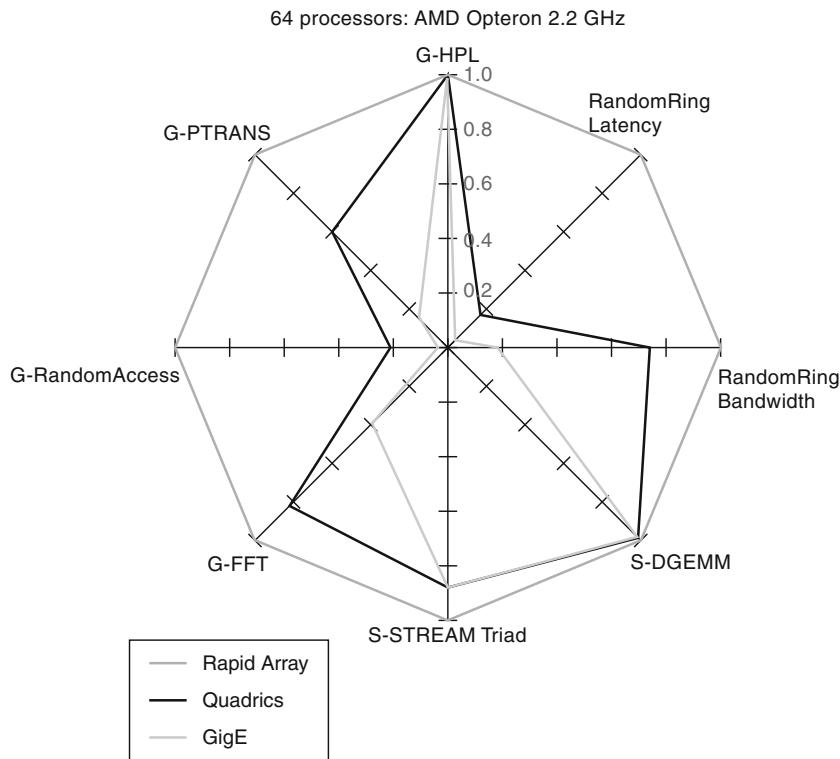

Benchmark Submission Procedures and Results

The reference implementation of the benchmark may be obtained free of charge at the benchmark's web site (<http://icl.cs.utk.edu/hpcc/>). The reference implementation should be used for the base run: it is written in a portable subset of ANSI C [7] using a hybrid programming model that mixes OpenMP [2, 16] threading with MPI [11–13] messaging. The installation of the software requires creating a script file for Unix's make(1) utility. The distribution archive comes with script files for many common computer architectures. Usually, a few changes to any of these files will produce the script file for a given platform. The HPCC rules allow only standard system compilers and libraries to be used through their supported and documented interface, and the build procedure should be described at submission time. This ensures repeatability of the results and serves as an educational tool for end users who wish to use a similar build process for their applications.

After a successful compilation, the benchmark is ready to run. However, it is recommended that changes be made to the benchmark's input file that describes the sizes of data to use during the run. The sizes should reflect the available memory on the system and the number of processors available for computations.

There must be one baseline run submitted for each computer system entered in the archive. An optimized run for each computer system may also be submitted. The baseline run should use the reference implementation of HPCC, and in a sense it represents the scenario when an application requires use of legacy code – a code that cannot be changed. The optimized run allows the submitter to perform more aggressive optimizations and use system-specific programming techniques (languages, messaging libraries, etc.), but at the same time still includes the verification process enjoyed by the base run.

All of the submitted results are publicly available after they have been confirmed by email. In addition to the various displays of results and exportable raw data, the HPCC website also offers a kiviat chart display to visually compare systems using multiple performance numbers at once. A sample chart that uses actual HPCC results data is shown in Fig. 5.

HPF (High Performance Fortran)

High Performance Fortran (HPF) is an extension of Fortran 90 for parallel programming. In HPF programs, parallelism is represented as data parallel operations in a single thread of execution. HPF extensions included statements to specify data distribution, data alignment, and processor topology, which were used for the translation of HPF codes onto an SPMD message-passing form.

HPS Microarchitecture

YALE N. PATT

The University of Texas at Austin, Austin, TX, USA

Synonyms

The high performance substrate

Definition

The microarchitecture specified by Yale Patt, Wen-mei Hwu, Stephen Melvin, and Michael Shebanow in 1984 for implementing high-performance microprocessors.

It achieves high performance via aggressive branch prediction, speculative execution, wide issue, and out-of-order execution, while retaining the ability to handle precise exceptions via in-order retirement.

Discussion

The High Performance Substrate (HPS) was the name given to the microarchitecture conceived by Professor Yale Patt and his three PhD students, Wen-mei Hwu, Michael Shebanow, and Stephen Melvin, at the University of California, Berkeley in 1984 and first published in Micro 18 in October, 1985 [1, 2]. Its goal was high-performance processing of single-instruction streams by combining aggressive branch prediction, speculative execution, wide issue, dynamic scheduling (out-of-order execution), and retirement of instructions in program order (i.e., in-order).

Out-of-order execution had appeared in previous machines from Control Data [3] and IBM [4], but had pretty much been dismissed as a nonviable mechanism due to its lack of in-order retirement, which prevented the processor from implementing precise exceptions. The checkpoint retirement mechanisms of HPS removed that problem [5, 6]. It should also be noted that solutions to the precise exception problem were also being developed simultaneously and independently by James Smith and Andrew Plezskun [7].

HPS was first targeted for the VAX instruction set architecture and demonstrated that an HPS implementation of the VAX could process instruction streams at a rate of three cycles per instruction (CPI), as compared to the VAX-11/780, which processed at the rate of 10.5 CPI [8].

Instructions are processed as follows: Using an aggressive branch predictor and wide-issue fetch/decode mechanism, multiple instructions are fetched each cycle, decoded into data flow graphs (one per instruction), and merged into a global data flow graph containing all instructions in process. Instructions are scheduled for execution when their flow dependencies (RAW hazards) have been satisfied and executed speculatively and out-of-order with respect to the program order of the program. Results produced by these

instructions are stored temporarily in a results buffer (aka re-order buffer) until they can be retired in-order. The essence of the paradigm is that the global data graph consists of nodes corresponding to micro-operations and edges corresponding to linkages between micro-ops that produce operands and micro-ops that source them. The edges of the data flow graph produced as a result of decode correspond to internal linkages within an instruction. Edges created as a result of merging an individual instruction's data flow graph into the global data flow graph correspond to linkages between live-outs of one instruction and live-ins of a subsequent instruction. A Register Alias Table was conceived to maintain correct linkages between live-outs and live-ins. A node, corresponding to a micro-op, is available for execution when all its flow dependencies are resolved.

The HPS research group refers to the paradigm as Restricted Data Flow (RDF) since at no time does the data flow graph for the entire program exist. Rather, the size of the global data flow graph is increased every cycle as a result of new instructions being decoded and merged, and decreased every cycle as a result of old instructions retiring. At every point in time, only those instructions in the active window – the set of instructions that have been fetched but not yet retired – are present in the data flow graph. The set of instructions in the active window are often referred to as “in-flight” instructions. The number of in-flight instructions is orders of magnitude smaller than the size of a data flow graph for the entire program. The result is data flow processing of a program without incurring any of the problems of classical data flow.

Since 1985, the HPS microarchitecture has seen continual development and improvement by many research groups at many universities and industrial labs. The basic paradigm has been adopted for most cutting-edge high-performance microprocessors, starting with Intel on its Pentium Pro microprocessor in the late 1990s [9].

Hybrid Programming With SIMPLE

GUOJING CONG¹, DAVID A. BADER²

¹IBM, Yorktown Heights, NY, USA

²Georgia Institute of Technology, Atlanta, GA, USA

Definition

Most high performance computing systems are clusters of shared-memory nodes. Hybrid parallel programming handles distributed-memory parallelization across the nodes and shared-memory parallelization within a node.

SIMPLE refers to the joining of the **SMP** and **MPI**-like message passing paradigms [7] and the *simple* programming approach. It provides a methodology of programming cluster of SMP nodes. It advocates a hybrid methodology which maps directly to underlying architectural aspects. SIMPLE combines shared memory programming on shared memory nodes with message passing communication between these nodes. SIMPLE provides (1) a complexity model and set of efficient communication primitives for SMP nodes and clusters; (2) a programming methodology for clusters of SMPs which is both efficient and portable; and (3) high performance algorithms for sorting integers, constraint-satisfied searching, and computing the two-dimensional FFT.

The SIMPLE Computational Model

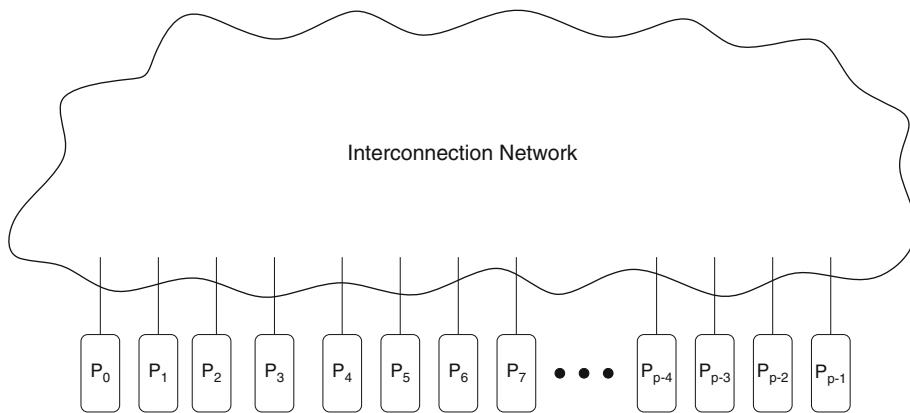

A simple paradigm is used in SIMPLE for designing efficient and portable parallel algorithms. The architecture consists of a collection of SMP nodes interconnected by a communication network (as shown in Fig. 1) that can be modeled as a complete graph on which communication is subject to the restrictions imposed by the latency and the bandwidth properties of the network. Each SMP node contains several identical processors, each typically with its own on-chip cache and a larger off-chip cache, which have uniform access to a shared memory and other resources such as the network interface.

Parameter r is used to represent the number symmetric processors per node (see Fig. 2 for a diagram of a typical node). Notice that each CPU typically has its own on-chip cache (L1) and a larger off-chip level

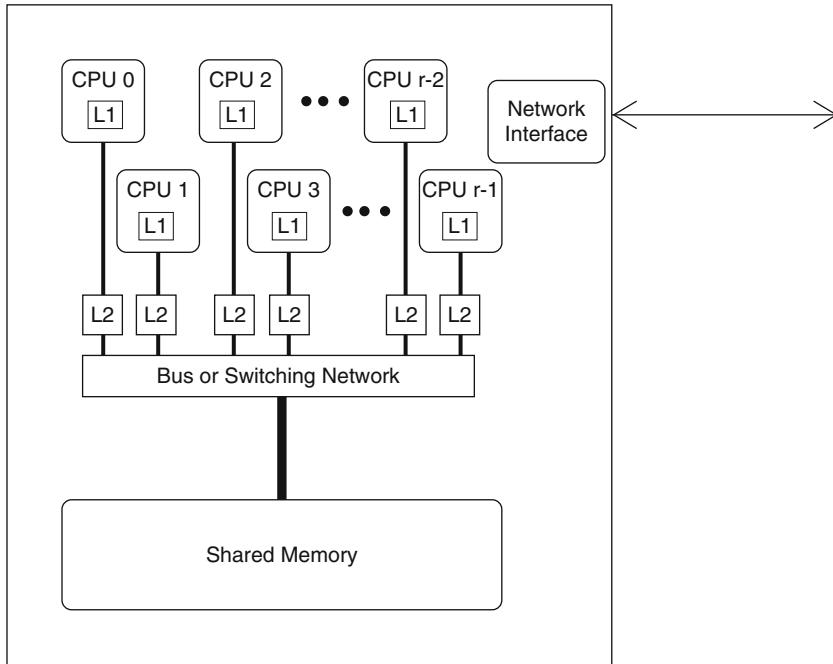

two cache (L2), which can be tightly integrated into the memory system to provide fast memory accesses and cache coherence. The shared memory programming of each SMP node is based on threads which communicate via coordinated accesses to shared memory. SIMPLE provides several primitives that synchronize the threads at a barrier, enable one thread to broadcast data to the other threads, or calculate reductions across the threads. In SIMPLE, only the CPUs from a certain node have access to that node's configuration. In this manner, there is no restriction that all nodes must be identical, and certainly configuration can be constructed from SMP nodes of different sizes. Thus, the number of threads on a specific remote node is not globally available. Because of this, SIMPLE supports only node-oriented communication, meaning that communication is restricted such that, given any source node s and destination node d , with $s \neq d$, only one thread on node s can send (receive) a message to (from) node d at any given time.

Complexity Model

In the SIMPLE complexity model, each SMP is viewed as a two-level hierarchy for which good performance requires both good load distribution and the minimization of secondary memory access. The cluster is viewed as a collection of powerful processors connected by a communication network. Maximizing performance on the cluster requires both efficient load balancing and regular, balanced communication. Hence, our performance model combines two separate but complimentary models.

Hybrid Programming With SIMPLE. Fig. 1 Cluster of processing elements

H

Hybrid Programming With SIMPLE. Fig. 2 A typical symmetric multiprocessing (SMP) node used in a cluster. L1 is on-chip level-one cache, and L2 is off-chip level-two cache

The SIMPLE model recognizes that efficient algorithm design requires the efficient decomposition of the problem among the available processors, and so, unlike some other models for hierarchical memory, the cost of computation is included in the complexity. The cost model also encourages the exploitations of temporal and spatial locality. Specifically, memory at each SMP is seen as consisting of two levels: cache and main memory. A block of m contiguous words can be read from or written to main memory in $(\epsilon + \frac{mr}{\alpha})$ time, where ϵ is the latency of the bus, r is the number of processors competing for access to the bus, and α is the bandwidth. By contrast, the transfer of m noncontiguous words would require $m(\epsilon + \frac{r}{\alpha})$ time.

A parallel algorithm is viewed as a sequence of local SMP computations interleaved with communication steps, where computation and communication is allowed to overlap. Assuming no congestion, the transfer of a block consisting of m words between two nodes takes $(\tau + \frac{m}{\beta})$ time, where τ is the latency of the network, and β is the bandwidth per node. SIMPLE assumes that the bisection bandwidth is sufficiently high to support block permutation routings among the p nodes at the rate of $\frac{1}{\beta}$. In particular, for any subset

of q nodes, a block permutation among the q nodes takes $(\tau + \frac{m}{\beta})$ time, where m is the size of the largest block. Using this cost model, the communication time $T_{comm}(n, p)$ of an algorithm can be viewed as a function of the input size n , the number of nodes p , and the parameters τ and β . The overall complexity of algorithm for the cluster $T(n, p)$ is given by the sum of T_{smp} and $T_{comm}(n, p)$.

Communication Primitives

The communication primitives are grouped into three modules: Internode Communication Library (ICL), **SMP Node**, and SIMPLE. ICL communication primitives handle internode communication, **SMP Node** primitives aid shared-memory node algorithms, and SIMPLE primitives combine **SMP Node** with ICL on SMP clusters.

The ICL communication library services internode communication and can use any of the vendor-supplied or freely available thread-safe implementation of MPI. The ICL libraries are based upon a reliable, application-layer send and receive primitive, as well as a send-and-receive primitive which handles the exchanging of messages between

sets of nodes where each participating node is the source and destination of one message. The library also provides a barrier operation based upon the send and receive which halts the execution at each node until all nodes check into the barrier, at which time, the nodes may continue execution. In addition, ICL includes collective communication primitives, for example, scan, reduce, broadcast, allreduce, alldtoall, alldtoallv, gather, and scatter. See [1].

SMP Node

The **SMP Node** Library contains important primitives for an SMP node: barrier, replicate, broadcast, scan, reduce, and allreduce, whereby on a single node, barrier synchronizes the threads, broadcast ensures that each thread has the most recent copy of a shared memory location, scan (reduce) performs a prefix (reduction) operation with a binary associative operator (e.g., addition, multiplication, maximum, minimum, bitwise-AND, and bitwise-OR) with one datum per thread, and allreduce replicates the result from reduce.

Each of these collective SMP primitives can be implemented using a *fan-out* or *fan-in* tree constructed as follows. A logical k -ary balanced tree is built for an SMP node with r processors, which serves as both a fan-out and fan-in communication pattern. In a k -ary tree, level 0 has one processor, level 1 has k processors, level 2 has k^2 processors, and so forth, with level j containing k^j processors, for $0 \leq j \leq L - 1$, where there are L levels in the tree. If $\log_k r$ is not an integer, then the last level ($L - 1$) will hold less than k^{L-1} processors. Thus, the number of processors r is bounded by

$$\sum_{j=0}^{L-2} k^j < r \leq \sum_{j=0}^{L-1} k^j. \quad (1)$$

Solving for the number of levels L , it is easy to see that

$$L = \lceil \log_k(r(k-1) + 1) \rceil \quad (2)$$

where the ceiling function $\lceil x \rceil$ returns the smallest integer greater than or equal to x .

An efficient algorithm for replicating a data buffer B such that each processor i , ($0 \leq i \leq r - 1$), receives a unique copy B_i of B makes use of the fan-out tree, with the source processor situated as the root node of the k -ary tree. During step j of the algorithm,

for ($0 \leq j \leq L - 2$), each of k^j processors writes k unique copies of the data for its k children. The time complexity of this SMP replication algorithm given an m -word buffer is

$$\begin{aligned} T_{smp} &= \sum_{j=0}^{L-2} k \left(\epsilon + \frac{k^j m}{\alpha} \right) \\ &= k(L-1)\epsilon + \frac{m}{\alpha}(r-1) \\ &\leq k(\log_k(r(k-1) + 1) - 1)\epsilon + \frac{m}{\alpha}(r-1) \\ &\leq k(\log_k(r + 1/k))\epsilon + \frac{m}{\alpha}(r-1) \\ &= O((\log r)\epsilon + \frac{mr}{\alpha}). \end{aligned} \quad (3)$$

The best choice of k , ($2 \leq k \leq r - 1$), depends on SMP size r and machine parameters ϵ and α , but can be chosen to minimize Eq. 3.

An algorithm which barrier synchronizes r SMP processors can use a fan-in tree followed by a fan-out tree, with a unit message size m , taking twice the replication time, namely, $O((\log r)\epsilon + r/\alpha)$.

For certain SMP algorithms, it may not be necessary to replicate data, but to share a read-only buffer for a given step. A broadcast SMP primitive supplies each processor with the address of the shared buffer by replicating the memory address in $T_{smp} = O((\log r)\epsilon + r/\alpha)$.

A reduce primitive, which performs a reduction with a given binary associative operator, uses a fan-in tree, combining partial sums during each step. For initial data arrays of size m per processor, this takes $O((\log r)\epsilon + mr/\alpha)$. The allreduce primitive performs a reduction followed by replicate so that each processor receives a copy of the result with a cost of $O((\log r)\epsilon + \frac{mr}{\alpha})$.

Scans (also called prefix-sums) are defined as follows. Each processor i , ($0 \leq i \leq r - 1$), initially holds an element a_i , and at the conclusion of this primitive, holds the prefix-sum $b_i = a_0 * a_1 * \dots * a_i$, where $*$ is any binary associative operator. An SMP algorithm similar to the PRAM algorithm (e.g., [5]) is employed which uses a binary tree for finding the prefix-sums. Given an array of elements A of size $r = 2^d$ where d is a nonnegative integer, the output is array C such that $C(0, i)$ is the i th prefix-sum, for ($0 \leq i \leq r - 1$).

In fact, arrays A , B , and C in the SMP prefix-sum algorithm (Alg. 1) can be the same array. The analysis is as follows. The first for loop takes $\sum_{h=1}^{\log r} 3(\epsilon + \frac{r}{2^h} \frac{m}{\alpha})$,

and the second **for** loop takes $\sum_{h=0}^{\log r} \binom{3+2}{2} (\epsilon + \frac{r}{2^h} \frac{m}{\alpha})$ for a total complexity of $T_{smp} \leq 8\epsilon \log r + 3\frac{mr}{\alpha} = O((\log r)\epsilon + \frac{mr}{\alpha})$.

Simple

Finally, the SIMPLE communication library, built on top of ICL and **SMP Node**, includes the primitives for the SIMPLE model: barrier, scan, reduce, broadcast, allreduce, alltoall, alltoallv, gather, and scatter. These hierarchical layers of our communication libraries are pictured in Fig. 3.

The **SMP Node**, ICL, and SIMPLE libraries are implemented at a high level, completely in user space

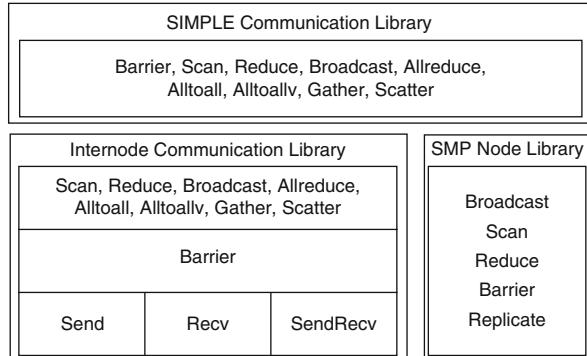

Algorithm 1 SMP scan algorithm for processor i , ($0 \leq i \leq r - 1$) and binary associative operator $*$

```

set  $B(0, i) = A(i)$ .

for  $h = 1$  to  $\log r$  do
  if  $1 \leq i \leq r/2^h$  then
    set  $B(h, i) = B(h - 1, 2i - 1) * B(h - 1, 2i)$ .

for  $h = \log r$  downto 0 do
  if  $1 \leq i \leq r/2^h$  then
    {
      If  $i$  even, Set  $C(h, i) = C(h + 1, i/2)$ ;
      If  $i = 1$ , Set  $C(h, 1) = B(h, 1)$ ;
      If  $i$  odd, Set  $C(h, i) = C(h + 1, (i - 1)/2) * B(h, i)$ .
    }
  
```

Hybrid Programming With SIMPLE. Fig. 3 Hierarchy of SMP, message passing, and SIMPLE communication libraries

(see Fig. 4). Because no kernel modification is required, these libraries easily port to new platforms.

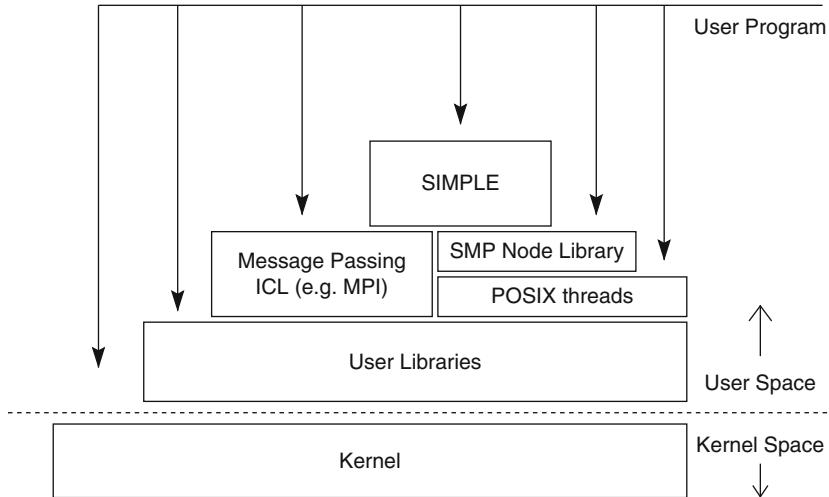

As mentioned previously, the number of threads per node can vary, along with machine size. Thus, each thread has a small set of context information which holds such parameters as the number of threads on the given node, the number of nodes in the machine, the rank of that node in the machine, and the rank of the thread both (1) on the node and (2) across the machine. Table 1 describes these parameters in detail.

Because the design of the communication libraries is modular, it is easy to experiment with different implementations. For example, the ICL module can make use of any of the freely available or vendor-supplied thread-safe implementations of MPI, or a small communication kernel which provides the necessary message passing primitives. Similarly, the **SMP Node** primitives can be replaced by vendor-supplied SMP implementations.

The Alltoall Primitive

One of the most important collective communication events is the alltoall (or transpose) primitive which transmits regular sized blocks of data between each pair of nodes. More formally, given a collection of p nodes each with an m element sending buffer, where p divides m , the alltoall operation consists of each node i sending its j th block of $\frac{m}{p}$ data elements to node j , where node j stores the data from i in the i th block of its receiving buffer, for all $(0 \leq i, j \leq p - 1)$. An efficient message passing implementation of alltoall would be as follows. The notation “ var_i ” refers to memory location “ $var + (\frac{m}{p} * i)$,” and src and dst point to the source and destination arrays, respectively.

To implement this algorithm (Alg. 2), multiple threads ($r \leq p$) per node are used. The local memory copy trivially can be performed concurrently by one thread while the remaining threads handle the internode communication as follows. The $p - 1$ iterations of the loop are partitioned in a straightforward manner to the remaining threads. Each thread has the information necessary to calculate its subset of loop indices, and thus, this loop partitioning step requires no synchronization overheads. The complexity of this primitive is twice $(\epsilon + \frac{m}{r} \frac{r}{\alpha})$ for the local memory read

Hybrid Programming With SIMPLE. Fig. 4 User code can access SIMPLE, SMP, message passing, and standard user libraries. Note that SIMPLE operates completely in user space

Hybrid Programming With SIMPLE. Table 1 The local context parameters available to each SIMPLE thread

Parameter	Description
NODES = p	Total number of nodes in the cluster
MYNODE	My node rank, from 0 to NODES – 1
THREADS = r	Total number of threads on my node
MYTHREAD	The rank of my thread on this node, from 0 to THREADS – 1
TID	Total number of threads in the cluster
ID	My thread rank, with respect to the cluster, from 0 to TID – 1

Algorithm 2 SIMPLE Alltoall primitive

copy the appropriate $\frac{m}{p}$ elements from src_{MYNODE} to dst_{MYNODE} .

```
for i = 1 to NODES – 1 do
    set k = MYNODE  $\oplus$  i;
    send  $\frac{m}{p}$  elements from  $src_k$  to node k, and
    receive  $\frac{m}{p}$  elements from node k to  $dst_k$ .
```

Computation Primitives

SIMPLE computation primitives do not communicate data but affect a thread's execution through (1) loop parallelization, (2) restriction, or (3) shared memory management. Basic support for data parallelism, that is, “parallel do” concurrent execution of loops across processors on one or more nodes, is provided.

Data Parallel

The SIMPLE methodology contains several basic “pardo” directives for executing loops concurrently on one or more SMP nodes, provided that no dependencies exist in the loop. Typically, this is useful when an independent operation is to be applied to every location in an array, for example, in the element-wise addition of two arrays. Pardo implicitly partitions the loop to the threads without the need for coordinating overheads such as synchronization or communication between processors. By default, pardo uses block partitioning of the loop assignment values to the threads, which typically results in better cache utilization due to the array locations on left-hand side of the assignment being owned by local caches more often than not. However, SIMPLE explicitly provides both block and cyclic partitioning interfaces for the pardo directive.

Similar mechanisms exist for parallelizing loops across nodes. The `all_pardo_cyclic (i, a, b)` directive will cyclically assign each iteration of the loop

and writes, and $(\tau + \frac{m}{\beta})$ for internode communication, for a total cost of $O(\tau + \frac{m}{\beta} + \epsilon + \frac{m}{\alpha})$.

across the entire collection of processors. For example, $i = a$ will be executed on the first processor of the first node, $i = a + 1$ on the second processor of the first node, and so on, with $i = a + r - 1$ on the last processor of the first node. The iteration with $i = a + r$ is executed by the first processor on the second node. After $r \cdot p$ iterations are assigned, the next index will again be assigned to the first processor on the first node. A similar directive called `all_pardo_block`, which accepts the same arguments, assigns the iterations in a block fashion to the processors; thus, the first $\frac{b-a}{rp}$ iterations are assigned to the first processor, the next block of iterations are assigned to the second processor, and so forth. With either of these SIMPLE directives, each processor will execute at most $\lceil \frac{n}{rp} \rceil$ iterations for a loop of size n .

Control

The second category of SIMPLE computation primitives control which threads can participate in the context by using restrictions.

[Table 2](#) defines each control primitive and gives the largest number of threads able to execute the portion of the algorithm restricted by this statement. For example, if only one thread per node needs to execute a command, it can be preceded with the `on_one_thread` directive. Suppose data has been gathered to a single node. Work on this data can be accomplished on that node by preceding the statement with `on_one_node`. The combination of these two primitives restricts execution to exactly one thread, and can be shortcut with the `on_one` directive.

Memory Management

Finally, shared memory allocations are the third category of SIMPLE computation primitives. Two directives are used:

1. `node_malloc` for dynamically allocating a shared structure
2. `node_free` for releasing this memory back to the heap

The `node_malloc` primitive is called by all threads on a given node, and takes as a parameter the number of bytes to be allocated dynamically from the heap. The primitive returns to each thread a valid pointer to the shared memory location. In addition, a thread may allow others to access local data by broadcasting the corresponding memory address. When this shared memory is no longer required, the `node_free` primitive releases it back to the heap.

H

SIMPLE Algorithmic Design

Programming Model

The user writes an algorithm for an arbitrary cluster size p and SMP size r (where each node can assign possibly different values to r at runtime), using the parameters from [Table 1](#). SIMPLE expects a standard main function (called `SIMPLE_main()`) that, to the user's view, is immediately up and running on each thread. Thus, the user does not need to make any special calls to initialize the libraries or communication channels. SIMPLE makes available the rank of each thread on its node or across the cluster, and algorithms can use these ranks in a straightforward fashion to break symmetries and

Hybrid Programming With SIMPLE. [Table 2](#) Subset of SIMPLE control primitives

Control Primitives				
Primitive	Definition	Max number of participating threads	MYNODE restriction	MYTHREAD restriction
<code>on_one_thread</code>	only one thread per node	p		0
<code>on_one_node</code>	all threads on a single node	r	0	
<code>on_one</code>	only one thread on a single node	1	0	0
<code>on_thread(i)</code>	one thread (i) per node	p		i
<code>on_node(j)</code>	all threads on node j	r	j	

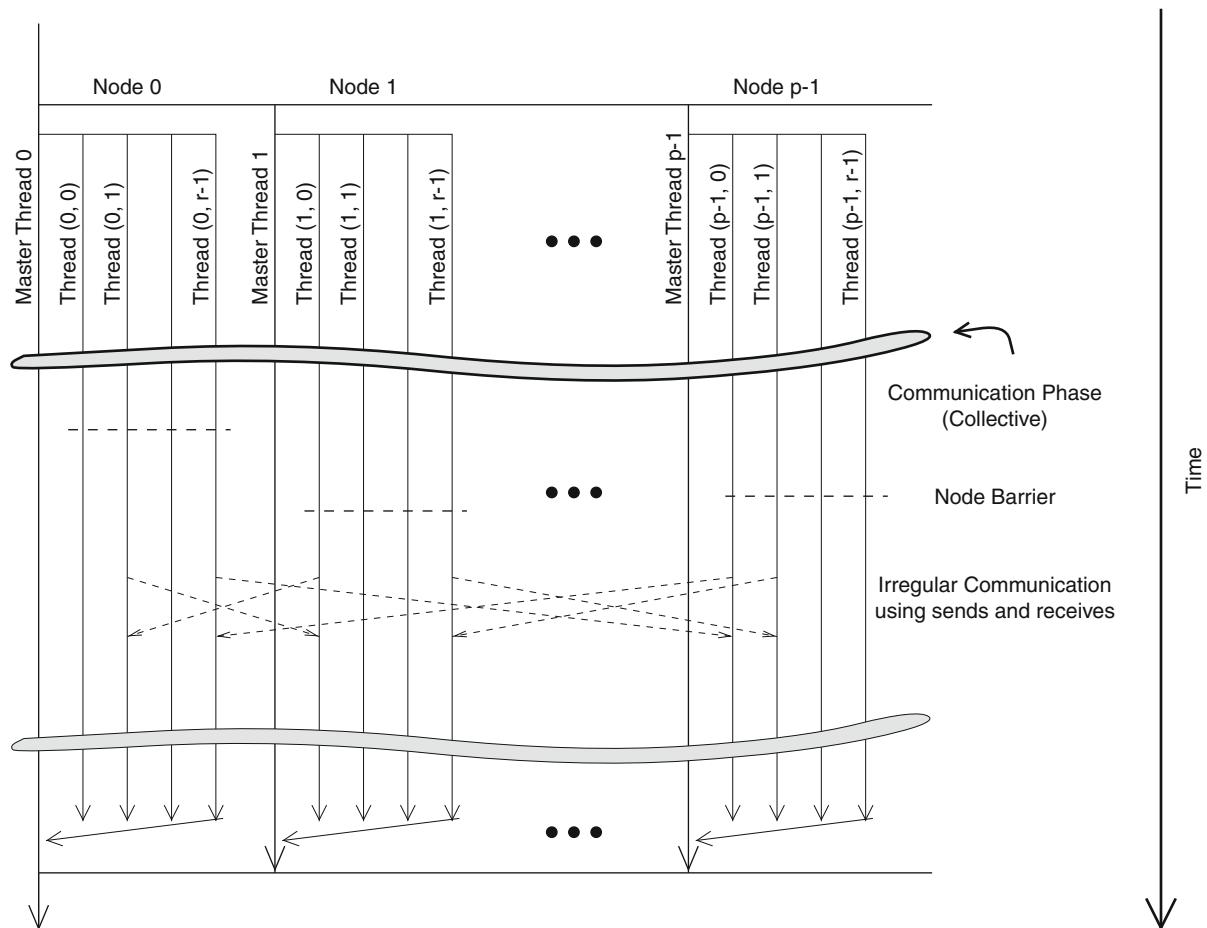

partition work. The only argument of SIMPLE_main() is “**THREADED**,” a macro pointing to a private data structure which holds local thread information. If the user’s main function needs to call subroutines which make use of the SIMPLE library, this information is easily passed via another macro “**TH**” in the calling arguments. After all threads exit from the main function, the SIMPLE code performs a shut down process.

Runtime Support

When a SIMPLE algorithm first begins its execution, the SIMPLE runtime support has already initialized parallel mechanisms such as barriers and established the network-based internode communication channels which remain open for the life of the program. The various libraries described in Sect. “The SIMPLE

Computational Model” have runtime initializations which take place as follows.

The runtime start-up routines for a SIMPLE algorithm are performed in two steps. First, the ICL initialization expands computation across the nodes in a cluster by launching a master thread on each of the p nodes and establishing communication channels between each pair of nodes. Second, each master thread launches r user threads, where each node is at least an r -way SMP. (A rule of thumb in practice is to use r threads on an $r + 1$ -way SMP node, which allows operating system tasks to fully utilize at least one CPU.) It is assumed that the r CPUs concurrently execute the r threads. The thread flow of an example SIMPLE algorithm is shown in Fig. 5. As mentioned previously, our methodology supports

Hybrid Programming With SIMPLE. Fig. 5 Example of a SIMPLE algorithm flow of master and compute-based user threads. Note that the only responsibility of each master thread is only to launch and later join user threads, but never to participate in computation or communication

only node-oriented communication, that is, given any source node s and destination node d , with $s \neq d$, only one thread on node s can send (receive) a message to (from) node d during a communication step. Also note that the master thread does not participate in any computation, but sits idle until the completion of the user code, at which time it coordinates the joining of threads and exiting of processes.

The programming model is simply implemented using a portable thread package called POSIX threads (**pthreads**).

A Possible Approach

The latency for message passing is an order of magnitude higher than accessing local memory. Thus, the most costly operation in a SIMPLE algorithm is internode communication, and algorithmic design must attempt to minimize the communication costs between the nodes.

Given an efficient message passing algorithm, an incremental process can be used to design an efficient SIMPLE algorithm. The computational work assigned to each node is mapped into an efficient SMP algorithm. For example, independent operations such as those arising in *functional parallelism* (e.g., independent I/O and computational tasks, or the local memory copy in the SIMPLE `alltoall` primitive presented in the previous section) or *loop parallelism* typically can be *threaded*. For functional parallelism, this means that each thread acts as a functional process for that task, and for loop parallelism, each thread computes its portion of the computation concurrently. Loop transformations may be applied to reduce data dependencies between the threads. Thread synchronization is a costly operation when implemented in software and, when possible, should be avoided.

Example: Radix Sort

Consider the problem of sorting n integers spread evenly across a cluster of p shared-memory r -way SMP nodes, where $n \geq p^2$. Fast integer sorting is crucial for solving problems in many domains, and as such, is used as a kernel in several parallel benchmarks such as NAS (Note that the NAS IS benchmark requires that the integers be ranked and not necessarily placed in sorted order.) [4] and SPLASH [8].

Consider the problem of sorting n integer keys in the range $[0, M - 1]$ that are distributed equally in the

shared memories of a p -node cluster of r -way SMPs. **Radix Sort** decomposes each key into groups of ρ -bit digits, for a suitably chosen ρ , and sorts the keys by applying a counting sort routine on each of the ρ -bit digits beginning with the digit containing the least significant bit positions [6]. Let $R = 2^\rho \geq p$. Assume (w.l.o.g.) that the number of nodes is a power of two, say $p = 2^k$, and hence $\frac{R}{p}$ is an integer $= 2^{\rho-k} \geq 1$.

SIMPLE Counting Sort Algorithm

Counting Sort algorithm sorts n integers in the range $[0, R - 1]$ by using R counters to accumulate the number of keys equal to the value i in bucket B_i , for $0 \leq i \leq R - 1$, followed by determining the rank of each key. Once the rank of each key is known, each key can be moved into its correct position using a permutation ($\frac{n}{p}$ -relation) routing [2, 3], whereby no node is the source or destination of more than $\frac{n}{p}$ keys. Counting Sort is a **stable** sorting routine, that is, if two keys are identical, their relative order in the final sort remains the same as their initial order.

Algorithm 3 SIMPLE Counting Sort Algorithm

Step (1): For each node i , $(0 \leq i \leq p - 1)$, count the frequency of its $\frac{n}{p}$ keys; that is, compute $H_{i[k]}$, the number of keys equal to k , for $(0 \leq k \leq R - 1)$.

Step (2): Apply the `alltoall` primitive to the H arrays using the block size $\frac{R}{p}$. Hence, at the end of this step, each node will hold $\frac{R}{p}$ consecutive rows of H .

Step (3): Each node locally computes the prefix-sums of its rows of the array H .

Step (4): Apply the (inverse) `alltoall` primitive to the R corresponding prefix-sums augmented by the total count for each bin. The block size of the `alltoall` primitive is $2\frac{R}{p}$.

Step (5): On each node, compute the ranks of the $\frac{n}{p}$ local elements using the arrays generated in **Steps (1)** and **(4)**.

Step (6): Perform a personalized communication of keys to rank location using an $\frac{n}{p}$ -relation algorithm.

The pseudocode for our Counting Sort algorithm (Alg. 3) uses six major steps and can be described as follows.

In **Step (1)**, the computation can be divided evenly among the threads. Thus, on each node, each of r threads (**A**) histograms $\frac{1}{r}$ of the input concurrently, and (**B**) merges these r histograms into a single array for node i . For the prefix-sum calculations on each node in **Step (3)**, since the rows are independent, each of r threads can compute the prefix-sum calculations for $\frac{R}{rp}$ rows concurrently. Also, the computation of ranks on each node in **Step (5)** can be handled by r threads, where each thread calculates $\frac{n}{rp}$ ranks of the node's local elements. Communication can also be improved by replacing the message passing `alltoall` primitive used in **Steps (2)** and **(4)** with the appropriate SIMPLE primitive.

The h -relation used in the final step of Counting Sort is a permutation routing since $h = \frac{n}{p}$, and was given in the previous section.

Histogramming in **Step (1A)** costs $O\left(\epsilon + \frac{n}{p} \frac{1}{\alpha}\right)$ to read the input and $O\left(\epsilon + R \frac{r}{\alpha}\right)$ for each processor to write its histogram into main memory. Merging in **Step (1B)** uses an SMP reduce with cost $O\left((\log r)\epsilon + R \frac{r}{\alpha}\right)$. SIMPLE `alltoall` in **Step (2)** and the inverse `alltoall` in **Step (4)** take $O\left(\tau + \frac{R}{\beta} + \epsilon + \frac{R}{\alpha}\right)$ time. Computing local prefix-sums in **Step (3)** costs $O\left(\epsilon + \frac{R}{pr} p \frac{r}{\alpha}\right)$. Ranking each element in **Step (5)** takes $O\left(\epsilon + \frac{n}{p} \frac{1}{\alpha}\right)$ time. Finally, the SIMPLE permutation with $h = \frac{n}{p}$ costs $O\left(\tau + \frac{n}{p} \left(\frac{1}{\beta} + \frac{1}{\alpha} + \frac{\epsilon}{r} \right)\right)$, for $\frac{n}{p} \geq r \cdot \max(p, \log r)$. Thus, the total complexity for Counting Sort, assuming that $n \geq p \cdot \max(R, r \cdot \max(p, \log r))$ is

$$O\left(\tau + \frac{n}{p} \left(\frac{1}{\beta} + \frac{r}{\alpha} + \frac{\epsilon}{r} \right)\right). \quad (4)$$

SIMPLE Radix Sort Algorithm

The message passing **Radix Sort** algorithm makes several passes of the previous message passing Counting Sort in order to completely sort integer keys. Counting Sort can be used as the intermediate sorting routine because it provides a stable sort. Let the n integer keys fall in the range $[0, M - 1]$, and $M = 2^b$. Then $\frac{b}{\rho}$ passes of Counting Sort is needed; each pass

works on ρ -bit digits of the input keys, starting from the least significant digit of ρ bits to the most significant digit. Radix Sort easily can be adapted for clusters of SMPs by using the SIMPLE Counting Sort routine. Thus, the total complexity for Radix Sort, assuming that $n \geq p \cdot \max(R, r \cdot \max(p, \log r))$ is

$$O\left(\frac{b}{\rho} \left(\tau + \frac{n}{p} \left(\frac{1}{\beta} + \frac{r}{\alpha} + \frac{\epsilon}{r} \right) \right)\right). \quad (5)$$

Hypercubes and Meshes

THOMAS M. STRICKER
Zürich, Switzerland

Synonyms

Distributed computer; Distributed memory computers; Generalized meshes and tori; Hypercube; Interconnection network; k-ary n-cube; Mesh; Multicomputers; Multi-processor networks

Definition

In the specific context of computer architecture, a *hypercube* refers to a parallel computer with a common regular interconnect topology that specifies the layout of processing elements and the wiring in between them. The etymology of the term suggests that a hypercube is an unbounded, higher dimensional cube alike geometric structure, that is scaled beyond (greek “hyper”) the three dimensions of a platonic cube (greek “kubos”). In its broader meaning, the term is also commonly used to denote a genre of supercomputer-prototypes and supercomputer-products, that were designed and built in the time period of 1980–1995, including the *Cosmic Cube*, the *Intel iPSC* hypercube, the *FPS T-Series*, and a similar machine manufactured by *nCUBE* corporation. A mesh-connected parallel computer is using a regular interconnect topology with an array of multiple processing elements in one, two, or three dimensions. In a generalization from hypercubes and meshes to the broader class of *k-ary n-cubes*, the concept extends to many more distributed-memory multi-computers with highly regular, direct networks.

Discussion

Introduction and Technical Background

In a *distributed memory multicomputer* with a *direct network*, the processing elements also serve as switching nodes in the network of wires connecting them. For a mathematical abstraction, the arrangement of processors and wires in a parallel machine is commonly expressed as a graph of nodes of processing elements

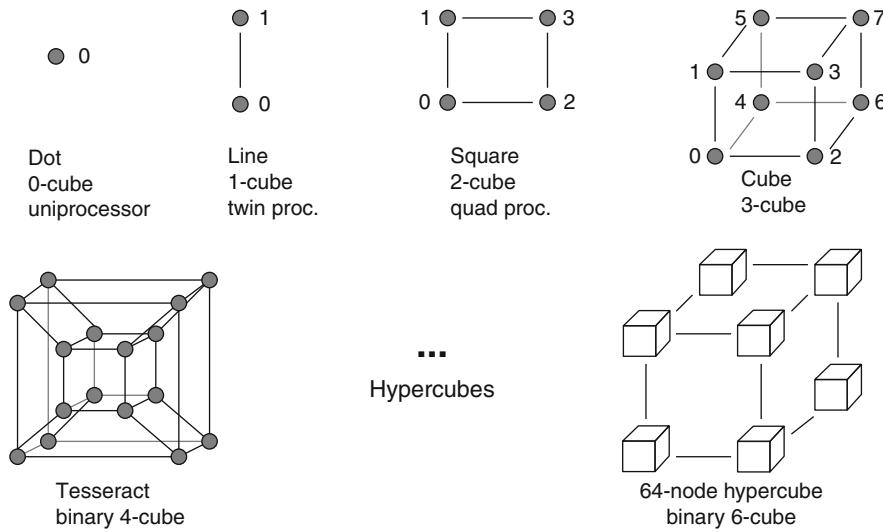

(vertices) and interconnect wires (edges) that are connecting the processors. Since high-speed data transfers normally require an unidirectional point-to-point connection, the resulting interconnection graphs are directed. In addition to the abstract connectivity graph, the optimal layout of processing elements and wires in physical space must be studied. In reference to the branch of mathematics dealing with invariant geometric properties in relation to different spaces, this specification is called the *topology* of a parallel computer system.

In geometry, the classical term *cube* refers to the regular convex hexahedron as one of the five platonic solids in three-dimensional space. Cube alike structures, beneath and beyond the three dimensions of a physical cube can be listed as follows and are drawn in Fig. 1.

- *Zero dimensional*: A dot in geometry or a non-connected uniprocessor in parallel computing.
- *One dimensional*: A geometric line segment or a twin processor system, connected with two unidirectional wires.
- *Two dimensional*: A geometric square or a four processor array, connected with four unidirectional wires in the horizontal and four wires in the vertical direction.
- *Three dimensional*: A geometric cube (hexahedron) or eight processors connected with 24 wires.
- *Four dimensional*: A tesseract in geometry or sixteen processors, arranged as two cubes with the eight corresponding vertices linked by two unidirectional wires each.
- *n-dimensional*: A hypercube as an abstract geometric figure, that becomes increasingly difficult to draw on paper or the arrangement of 2^n processor with each processor having n wires to its n immediate neighbors in all n dimensions.

History

With the evolution of supercomputers from a single vector processor toward a collection of high performance microprocessors during the mid-1980s, a large amount of research work focused on the best possible topology for massively parallel machines. In that time period the majority of parallel systems were built from a large

Hypercubes and Meshes. Fig. 1 Graphical rendering of dot (0 dimensional), line (1D), square (2D), cube (3D), and hypercubes (>3D)

number of identical processing elements, each comprising a standard microprocessor, a dedicated semiconductor random access memory, a network interface and – in some cases – even a dedicated local storage disk in every node. All processing elements also served as switching points in the interconnect fabric. This evolution of technology in highly parallel computers resulted in the class of *distributed memory parallel computers* or *multi-computers*.

The extensive research activity goes back to a special focus on geometry in the theory of parallel algorithms pre-dating the development of the first practical parallel systems. This led to a widespread belief, that the physical topology of parallel computing architectures had to reflect the communication pattern of the most common parallel algorithms known at the time. The obvious mathematical treatment of the question through graph theory resulted in countless theoretical papers that established many new topologies, mappings, emulations, and entire equivalence classes of topologies including meshes, hypercubes, and fat trees. The suggestions for a physical layout to connect the nodes of a parallel multicomputer range from simple one-dimensional arrays of processors to some fully interconnected graphs with direct wires from every node to every other node in the system. Hierarchical rings and busses were also considered. The many results

of the effort are compiled into a comprehensive text book [1].

During the golden age of the practical hypercubes (roughly during the years of 1985–1995), it was assumed that the topology of high-dimensional binary hypercubes would result in the best network for the direct mapping of many well-known parallel algorithms. In a binary hypercube each dimension is populated with just two processing nodes as shown in Fig. 1. The wiring of $P * \log_2 P$ unidirectional wires to connect P processors in hypercube topology seemed to be an optimal compromise between the minimal interconnect of just P wires for P processors in a ring and the complete interconnect with $P * (P-1)$ wires in a fully connected graph (clique).

In a hypercube or a mesh layout for a parallel system, the processors can only communicate data directly to a subset of neighboring processors and therefore require a mechanism for indirect communication through data forwarding at the intermediate processing nodes. Indirect communication can take place along pre-configured virtual channels or through the use of forwarded messages. Accordingly the practical hypercube and mesh systems are primarily designed for *message passing* as their programming model. However, most stream-based programming models can be supported efficiently with channel virtualization. Shared

memory programming models are often supported on top of a low level message passing software layer or by hardware mechanisms like directory-based caches that rely on messages for communication.

Binary hypercube parallel computers like the *Cosmic Cube* [7], the *iPSC* [8, 9] the *FPS T Series* [10] or *NCube* [11] were succeeded around 1992 by a series of distributed memory multi-computers with a two- or three-dimensional mesh/torus topology, such as the *Ametek Warp/iWarp*, *MassPar*, *J-Machine*, the Intel *Paragon*, Intel *ASCI Red*, *Cray T3D*, *T3E*, *Red Storm*, and *XT4/Seastar*. Scaling to larger machines, the early binary hypercubes were at a severe disadvantage, because they required a high number of dimensions resulting in an unbounded number of ports for the switches at every node (due to the *unbounded in/out degree* of the hypercube topology). Something all the hypercubes and the more advanced mesh/torus architectures have in common is that they rely heavily on the message routing technologies developed for the early hypercubes. They are classified as *generalized hypercubes (k -ary n -cubes)* in the literature and therefore included in this discussion. By the turn of the century the concept of hypercubes was definitely superseded by the *network of workstations* (NOWs) and by the *cluster of personal computers* (COPs) that used a more or less irregular interconnect fabric built with dedicated network switches that are readily available from the global working technology of the Internet.

Significance of Parallel Algorithms and Their Communication Patterns

A valid statement about the optimal interconnect layout in a parallel system can only be made under the assumption that there is a best suitable mapping between the M data elements of a large simulation problem and the P processing elements in a parallel computer. For simple, linear mappings (e.g., M/P elements on every processor in block or block/cyclic distribution) the communication patterns of operations between data elements translate into roughly the same communication pattern of messages between the processors in the parallel machine. For simplicity, we also assume $M \gg P$ and that M and P are powers of two. In an algorithm with

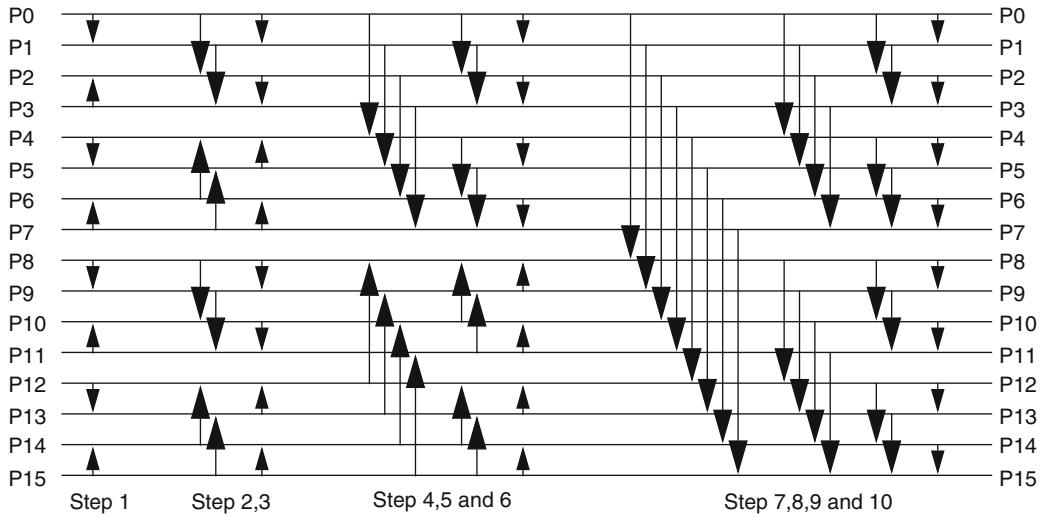

a hypercube communication pattern all communication activities take place between nodes that are direct neighbors in the layout of a hypercube. For the common number scheme of nodes this is between node pairs that differ by exactly one bit in their number. Every communication in a hypercube pattern therefore crosses just one wire in the hypercube machine.

Algorithms with Pure Hypercube Communication Patterns

Several well-known and important algorithms do require a sequence of inter-node communication steps that follow a pure hypercube communication pattern. In most of these algorithms, the communication happens in steps along increasing or decreasing dimensions, e.g., the first communication step between neighbors whose number differs in the least significant bit followed by a next step until a last step with communication to neighbors differing in the most significant bit. Most parallel computers cannot use more than one or two links for communication at the same time due to bandwidth constraints within the processor node. Therefore, a true pipeline with more than one or two overlapping hypercube communication steps is rarely encountered in practical programs.

One of the earliest and best-known algorithms with a pure hypercube communication pattern is the *bitonic sorting algorithm* that goes back to a generalized merge sort algorithm for parallel computers published in 1968 [3]. The communication graph in Fig. 2 shows all the hypercube communication steps that are required to merge locally sorted subsequences into a globally sorted sequence on 16 processors.

The most significant and most popular algorithm communicating between nodes in a pure hypercube pattern is the classic calculation of a *Fast Fourier Transform (FFT)* over an one-dimensional array, with its data distributed among P processors in a simple block partitioning. During the Fourier transformation of a large distributed array a certain number of butterfly calculations can be carried out in local memory up to the point when the distance between the elements in the butterfly becomes large enough that processor boundaries are crossed and some inter-processor communication over

Hypercubes and Meshes. Fig. 2 Batcher bitonic parallel sorting algorithm. A series of hypercube communication steps will merge 16 locally sorted subsequences into one globally sorted array. The arrows indicate the direction of the merge, i.e., one processor gets the upper and the other processor gets the lower half of the merged sequence

the hypercube links is required. The distance of butterfly operations is always a power of two and therefore it maps directly to a hypercube.

In the more advanced and multi-dimensional FFT library routines the communication operations between elements at the larger distances might eventually be reduced by dynamically rearranging the distribution of array elements during the calculation. Such a redistribution is typically performed by global data transpose operation that requires an *all-to-all personalized communication* (AAPC), i.e., individual and distinct data blocks are exchanged among all P processors. In general, fully efficient and scalable AAPC does require a scalable bandwidth interconnect, like the binary hypercube. In practice a talented programmer can optimize such collective communication primitives to run at maximal link speed for sufficiently large mesh- and torus-connected multi-computers (i.e., Cray T3D/T3E tori with up to 512 nodes) [5].

Algorithms with Next Neighbor Communication Pattern

Most simulations in computational physics, chemistry, and biology are calculating some physical interactions (forces) between a large number of model nodes (i.e., particles or grid points) in three-dimensional physical space. Therefore, they only require a limited amount

of communication between the model nodes in at most three dimensions because the longer range forces can be summarized or omitted. Consequently the communication in the parallel code of an equation solver, based on relaxation techniques is also limited to nearby processor in two or three dimensions.

Many calculations in natural science do not require communication in dimensions that are higher than three and there is no need to arrange processing elements of a parallel computer in hypercube topologies. Users in the field of scientific computing have recently introduced some optimizations that require increased connectivity. Modern physical simulations are carried out on *irregular meshes*, that are modeling the physical space more accurately by adapting the density of meshing points to some physical key parameter like the density of the material, the electric field, or a current flow. Irregular meshes grid points and sparse matrices are more difficult to partition into regular parallel machines. Advanced simulation methods also involve the summation of certain particle interactions and forces in Fourier and Laplace spaces to achieve a better accuracy in fewer simulation steps (e.g., the particle-mesh Ewald summation in molecular dynamics). Both improvements result in denser communication patterns that require higher connectivity. In the end it remains fairly hard to judge for the systems architect, whether

these codes alone can justify the more complex wiring of a high-dimensional hypercube within the range of the machine sizes, that are actually purchased by the customers.

Meshes as a Generalization of Binary Hypercubes into k -ary n -Cubes

In the original form of a binary hypercube, the wires connect only two processing nodes in every dimension. In linear arrays and rings a larger number of processors can be connected in every dimension. The combination of multiple dimensions and multiple processors connected along a line in one dimension leads to a natural generalization of the hypercube concept that includes the popular 1D, 2D, and 3D arrays of processing elements. In computer architecture, the term “mesh” is used for a two- or higher-dimensional processor array. A linear array of processing nodes can be wired into a ring by a wrap-around link. A two or higher dimensional mesh, that is equipped with wrap-around links is called a torus.

The generalized form of hypercubes and meshes is characterized by two parameters, the maximal number of elements found along one dimension, k , and the total number of dimensions used, n . The binary hypercubes described in the introduction are classified as a **2-ary n -cubes**. A $k \times k$, two-dimensional torus can be classified as a **k -ary 2-cube**.

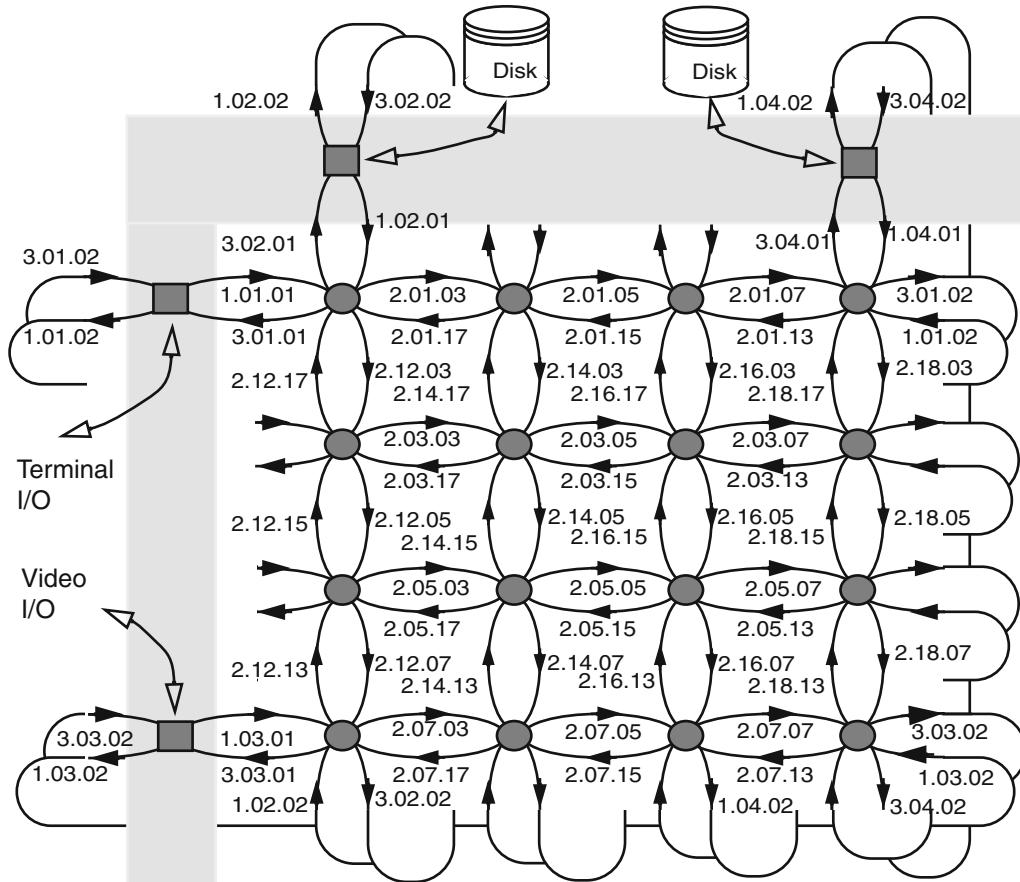

With the popularity of the hypercube topology in the beginning of distributed memory computing, many key technologies for message forwarding and routing were developed in the early hypercube machines. These ideas extend quite easily to the generalized k -ary n -cubes and were incorporated quickly into meshes and tori. In hypercubes, meshes and tori alike, the messages traveling between arbitrary processing nodes have to traverse multiple links to reach their destination. They have to be forwarded in a number of intermediate nodes, raising the important issues of *message forwarding policies* and *deadlock avoidance*.

In a general setting it would be very hard to establish a global guarantee that every message can travel right through without any delay along a given route. Therefore, some low level flow control mechanisms are used to stop and hold the messages, if another message is already occupying a channel along the path. The most

common strategies for forwarding the messages in a hypercube network are *wormhole* or *cut-through routing*. If not done carefully, blocking and delaying messages along the path can lead to tricky deadlock situations, in particular when the messages are indefinitely blocking each other within an interconnect fabric. During the era of the first hypercube multicomputers two key technologies for deadlock avoidance were described [7] and applied to the construction of prototypes and products:

- *Dimension order routing*: In binary hypercubes routes between two nodes must be chosen in a way that the distance in the highest dimension is traveled first, before any distance of a lesser dimension is traveled. Therefore messages can only be stopped due to a busy channel in a dimension lower than the one that they are traveling. The channels in the lowest dimension always lead to a final destination. The messages occupying these channels can make progress immediately and free the resource for other messages blocked at the same and higher dimensions. This is sufficient to prevent a routing deadlock.
- *Dateline-based torus routing*: With the wrap-around link of rings and tori, the case of messages blocking each other in a single dimension around the back-loops has to be addressed. This is done by replicating the physical wires into some parallel virtual channels forming a higher and a lower virtual ring. A dateline is established at a particular position in the ring. The dateline can only be crossed if the message switches from the higher to the lower ring at that position. With this simple trick, all connections along the ring remain possible, but the messages in the ring can no longer block each other in a circular deadlock.

Both *deadlock avoiding* techniques are normally combined to permit deadlock-free routing in the generalized k -ary n -cube topologies. Extending the well-known dimension-order and dateline routing strategies to slightly irregular network topologies is an additional challenge. The two abstract rules for legal message routes can be translated into a simple channel numbering scheme providing a total order of all channels within an interconnect, including all irregular nodes. A simple

Hypercubes and Meshes. Fig. 3 Generalized hypercubes. Channel numbering based on the original hypercube routing rules for the validation of a deadlock-free router in a slightly irregular two-dimensional torus with several IO nodes (an iWarp system)

rule that channels must be followed in a strictly increasing/decreasing order to form a legal route is sufficient to prevent deadlock. With the technique, illustrated in Fig. 3, it becomes possible to code and validate the router code for any k -ary 2-cube configuration that was offered as part of the Intel/CMU *iWarp* product line, including the service nodes that are arbitrarily inserted into the otherwise regular torus network [6].

Mapping Hypercube Algorithms into Meshes and Tori

By design the binary hypercube topology provides a fully scalable *worst case bisection bandwidth*. Regardless of how the machine is scaled or partitioned, the algorithm can count on the same amount of bandwidth per processor for the communication between the two

halves. In meshes and tori the total bisection bandwidth does not scale up linearly with the number of nodes. The global operations, that are usually communication bound, become increasingly costly in larger machines. The concept of the scalable bisection bandwidth was thought to be a key advantage of the hypercube designs that is not present in meshes for a long time.

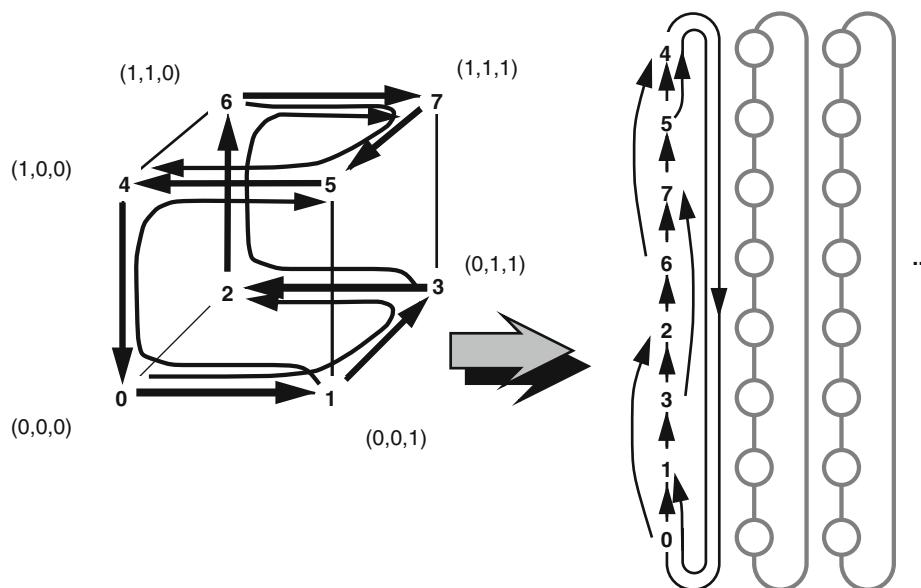

In the theory of parallel algorithms the asymptotic lower bounds on communication in binary hypercubes usually differ from the bounds holding for communication in an one-, two- or three-dimensional mesh/torus. The lower bound on the number of steps (i.e., the time complexity) is determined by the amount of data that has to be moved between the processing elements and by the number of wires that are available for this task (i.e., the bisection bandwidth). The upper bound is

usually determined by the sophistication of the algorithm. One of the most studied algorithms is *parallel sorting* in a 1-1 comparison based model [2, 3]. Similar considerations can be made for *matrix transposes* or *redistributions of block/cyclic arrays* distributed across the nodes of a parallel machine.

In the practice of parallel computing, a mesh-connected machine must be fairly large until an algorithmic limitation due to bisection bandwidth is encountered and a slowdown over a properly hypercube connected machine can be observed [5]. As an example, the bandwidth of an 8-node ring, a 64-node two-dimensional torus or a 512-node three-dimensional torus is sufficient to permit arbitrary array transpose operations without any slowdown over a hypercube of the same size. The comparison assumes that the processing nodes of both machines can transfer data from and to the network at about the speed of a bidirectional link – as this is the case for most parallel machines. Therefore, a few simple mapping techniques are used in practice to implement higher dimensional binary hypercubes on k-ary meshes or tori. A three-dimensional binary hypercube can be mapped into an eight node ring with a small performance penalty using a *Gray code mapping* as illustrated in Fig. 4.

In this simple mapping some links have to be shared or multiplexed by a factor of two and next-neighbor communication is extended to a distance of up to three hops. The mapping of larger virtual hypercube networks comes at the cost of an increasing dilation (increase in link distance) and congestion (a multiplexing factor of each link) for higher dimensions. The congestion factor can be derived using the calculations of bisection bandwidth for both topologies. A binary 6-cube can be mapped into a 2D torus and the 9-cube into a 3D torus by extending the linear scheme to multiple dimensions.

In their VLSI implementation, a two- or three-dimensional mesh/torus-machine is much easier to lay out in an integrated circuit than an eight- or ten-dimensional hypercube with its complicated wiring structure. Therefore its simple next-neighbor links can be built with faster wires and wider channels for multiple wires. The resulting advantage for the implementation is known to offset the congestion and dilation factors in practice. It is therefore highly interesting to study these technology trade-offs in practical machines. For 1-1 sorting, the algorithmic complexity and the measured execution times on a virtual hypercube mapped to mesh match the known complexities and

Hypercubes and Meshes. Fig. 4 Gray code mapping of a binary three-cube into an eight node ring. Virtual network channels were used to implement virtual hypercube network in machines that are actually wired as meshes or tori

running times of the algorithm for direct execution on a mesh fairly closely [2, 4].

Limitations of the Hypercube Machines

The ideal topology of a binary hypercube comes at the high cost of significant disadvantages and restrictions regarding their practical implementation in the VLSI circuits of a parallel computer. Therefore, a number of alternative options to build multicomputers were developed beyond hypercubes, meshes, and their superclass of the k -ary n -cubes.

Among the alternatives studied are: *hierarchical rings*, that differ slightly from multi-dimensional tori, *cube-connected cycles*, that successfully combine the scalable bisection bandwidth of hypercubes with the bounded in/out degrees of lower - dimensional meshes and finally *fat trees* that are provably optimal in their layout of wiring for VLSI. Those interconnect structures have in common, that they are still fairly regular and can leverage of the same practical technical solutions for message forwarding, routing and link level flow control, the way the traditional hypercubes do. None of these regular interconnects requires a spanning routing protocol or TCP/IP connections to function properly.

Towards the end of the golden age of hypercubes, the regular, direct networks were facing an increasing competition by new types of networks built either from physical links with different strength (i.e., different link bandwidths implemented by a multiplication of wires or in a different technology). In 1991, the Thinking Machines Corporation announced the Connection Machine CM5 using a fat tree topology and this announcement contributed to end of the hypercube age. After the year 2000, the physical network topologies became less and less important in supercomputer architecture. The detailed structure of the networks became hidden and de-emphasized due to many higher-level abstractions of parallelizing compilers and message passing libraries available to the programmers.

The availability of high performance commodity networking switches for use in the highly irregular topology of the global Internet accelerated this trend. In most newer designs, a fairly large multistage network of switches (e.g., a Clos network) has replaced the older direct networks of hypercubes and meshes. At this time only a small fraction of PC Clusters is still including

the luxury of a low latency, high performance interconnect. Despite all trends to abstraction and de-emphasis of network structure, the key figures of *message forwarding latency* and the *bisection bandwidth* remain the most important measure of scalability in a parallel computer architecture.

Hypercube Machine Prototypes and Products

One of the earliest practical computer systems using a hypercube topology is the *Cosmic Cube* prototype designed by the Group of C. Seitz at the California Institute of Technology [7]. The system was developed in the first half of the 1980s using the VLSI integration technologies newly available at the time. The first version of the system comprised 64 nodes with an Intel 8086/8087 microprocessor/floating point coprocessors combination running at 5 MHz and using 128 kB of memory in each node. The nodes were connected with point-to-point links running at 2 Mbit/s nominal speed. The original system of 64 nodes was allegedly planned as a $4 \times 4 \times 4$ three-dimensional torus with bidirectional links – but this particular topology is fully equivalent to a binary six-dimensional hypercube under a gray code mapping and became therefore known as a first *hypercube multicomputer*, rather than as a first three-dimensional torus. Subsequently a small number of commercial machines were built in a collaboration with a division of AMETEK Corporation [15].

The Caltech prototypes lead to the development of iPSC at the Intel Supercomputer Systems Division, a commercial product series based on hypercube topology [8, 9]. An example of the typical technical specifications is the iPSC/2 system as released in 1987: 64 nodes, Intel 80386/387 processor/floating point coprocessor running at 16 MHz, 4–16 MB of main memory in each node, the nodes connected with links running 22 Mbit/s. iPSC systems were programmed using the NX message passing library, similar in the functionality, but pre-dating the popular portable message passing systems like PVM or MPI. The development of the product line was strongly supported by (D)ARPA, the Advanced Research Project Agency of the US Dept. of Defense.

During roughly the same time period a hypercube machine was also offered by NCube Corporation, a super-computing vendor that was fully dedicated to the development of hypercube systems at the time. The

NCube 6,400 model, available to Nasa AMES in 1991 was a 64-node system with a 20 MHz full custom 64 bit CPU/FPU with up to 64 MB main memory in every node and 20 Mbit/s interconnects. The largest configuration commercially offered was a binary 10-cube with 1,024 processing nodes [11, 12].

The *FPS (Floating Point Systems)* T Series Parallel Vector Supercomputer was also made of multiple processing nodes interconnected as a binary n-cube. Each node is implemented on a single printed circuit board, contains 1 MB of data storage memory, and has a peak vector computational speed of 12 MFLOPS. Eight vector nodes are grouped around a system support node and a disk storage system to form a module. The module is the basic building block for larger system configurations in hypercube topology. The T series was named after the tesseract, a geometric cube in four-dimensional space [10].

The *Thinking Machine* CM2 also included a hypercube communication facility for data exchanges between the nodes as well as a mesh (called NEWS grid) [13]. As an SIMD machine with a large number of bit slice processors, its architecture differed significantly from the classical hypercube multicomputer. In its successor, the *Thinking Machine* CM5, the direct networks were given up in favor of a fat tree using a variable number of (typically N-1) of additional switches to form a network in fat tree topology. A similar trend was followed in the machines of *Meiko/Quadrics*. The delay of the T9000 transputer chips with processing and communication capabilities on a single chip forced the designers of the CS2 system to build their communication system with a multi-stage fabric of switches instead of a hypercube interconnect. The multicomputer line by IBM, the IBM SP1 and its follow-on products also used a multi-stage switch fabric. Therefore, these architectures do no longer qualify as generalized hypercubes with direct networks.

It is worth mentioning that the first *Beowulf* clusters of commodity PCs were equipped with three to five network interfaces that could be wired directly in hypercube topology. Routing of messages between the links was achieved by system software in the ethernet drivers of the LINUX operating system. The communication benchmark presented in the first beowulf paper were measured on an 8-node system, wired as 2^3 cube [14]. The author also remembers encountering a

Beowulf system on display at the Supercomputing trade show wired as a 32-node binary 5-cube using multiple 100BaseT network interface cards and simple CAT5 crossover cables.

But as mentioned before, the designs of processors with their own communication hardware on board and direct networks were quickly replaced by commodity switches manufactured by a large number of network equipment vendors in the Internet world. So the topology of the parallel system suddenly became a secondary issue. A large variety of different network configurations rapidly succeeded the regular Beowulf systems in the growing market for clusters of commodity PCs.

H

Research Conferences on Hypercubes

The popularity of hypercube architectures in the second half of the 1980s led to several instances of a computer architecture conference dedicated solely to distributed memory multicomputers with hypercube and mesh topologies. The locations and dates of the conferences are as remembered or collected from citations in subsequent papers:

- First Hypercube Conference in Knoxville, August 26–27, 1985, with proceedings published by SIAM after the conference.
- Second Conference on Hypercube Multiprocessors, Knoxville, TN, September 29–October 1, 1986, with proceedings published by SIAM after the conference.
- Third Conference on Hypercube Concurrent Computers and Applications, Pasadena, CA, January 19–20, 1988 with proceedings published by the ACM, New York.
- Fourth Conference on Hypercube Concurrent Computers and Applications, Monterrey, CA, March 6–9, 1989, proceedings publisher unknown.

and later giving in to the trend that the architecture as distributed memory computer is more important than the hypercube layout:

- Fifth Distributed Memory Computing Conference, Charleston, SC, April 8–12, 1990 with proceedings published by IEEE Computer Society Press.
- Sixth Distributed Memory Computing Conference, Portland, OR, April 29–May 1, 1991 with proceedings published by IEEE Computer Society Press.

- First European Distributed Memory Computing, EDMCC, held in Rennes, France.
- Second European Distributed Memory Computing, EDMCC2, Munich, FRG, April 22–24, 1991 with Proceedings by Springer, Lecture Notes in Computer Science.

After these rather successful meetings of computer architects and application programmers, the conference series on hypercubes and distributed memory parallel systems lost its momentum and in 1992, the specialized venues were unfortunately discontinued.

Bibliographic Notes and Further Reading

A most detailed description of the algorithms optimally suited for hypercubes, the classes of hypercube equivalent networks, and the emulation of different topologies with respect to algorithmic models is given in an 835 page textbook by F.T. Leighton that appeared in 1991 [1]. A detailed description of the network topologies and the technical data of all practical hypercube prototypes built and machines commercially sold between 1985 and 1995 can be found through Google Scholar in the numerous papers written by the architects working for the computer manufacturers or by researches at the

different US national labs evaluating and benchmarking these distributed memory multicomputers. The most interesting study dedicated entirely to binary hypercubes appeared in 1991 in Parallel Computing [12]. The visit to the trade show of “Supercomputing” during the “hypercube” years was a memorable experience, because countless new distributed memory system vendors surprised the audience with a new parallel computer architecture every year. Most of them contained some important innovation and can still be admired in the permanent collections of the computer museums in Boston (MA), Mountain View (CA), and Paderborn (Germany).

Formal Definition of Hypergraph Partitioning

A hypergraph $\mathcal{H} = (\mathcal{V}, \mathcal{N})$ is defined as a set of vertices (cells) \mathcal{V} and a set of nets (hyperedges) \mathcal{N} among those vertices. Every net $n \in \mathcal{N}$ is a subset of vertices, that is, $n \subseteq \mathcal{V}$. The vertices in a net n are called its *pins*. The size of a net is equal to the number of pins. The *degree* of a vertex is equal to the number of nets it is connected to. Graph is a special instance of hypergraph such that each net has exactly two pins. Vertices can be associated with weights, denoted with $w[\cdot]$, and nets can be associated with costs, denoted with $c[\cdot]$.

$\Pi = \{\mathcal{V}_1, \mathcal{V}_2, \dots, \mathcal{V}_K\}$ is a *K-way partition* of \mathcal{H} if the following conditions hold:

- Each part \mathcal{V}_k is a nonempty subset of \mathcal{V} , that is, $\mathcal{V}_k \subseteq \mathcal{V}$ and $\mathcal{V}_k \neq \emptyset$ for $1 \leq k \leq K$
- Parts are pairwise disjoint, that is, $\mathcal{V}_k \cap \mathcal{V}_\ell = \emptyset$ for all $1 \leq k < \ell \leq K$
- Union of K parts is equal to \mathcal{V} , i.e., $\bigcup_{k=1}^K \mathcal{V}_k = \mathcal{V}$

In a partition Π of \mathcal{H} , a net that has at least one pin (vertex) in a part is said to *connect* that part. *Connectivity* λ_n of a net n denotes the number of parts connected by n . A net n is said to be *cut (external)* if it connects more than one part (i.e., $\lambda_n > 1$), and *uncut (internal)* otherwise (i.e., $\lambda_n = 1$). A partition is said to be balanced if each part \mathcal{V}_k satisfies the *balance criterion*:

$$W_k \leq W_{avg}(1 + \varepsilon), \quad \text{for } k = 1, 2, \dots, K. \quad (1)$$

In (1), weight W_k of a part \mathcal{V}_k is defined as the sum of the weights of the vertices in that part (i.e., $W_k = \sum_{v \in \mathcal{V}_k} w[v]$), W_{avg} denotes the weight of each part under the perfect load balance condition (i.e., $W_{avg} = (\sum_{v \in \mathcal{V}} w[v])/K$), and ε represents the predetermined maximum imbalance ratio allowed.

The set of external nets of a partition Π is denoted as \mathcal{N}_E . There are various [20] *cutsizes* definitions for representing the cost $\chi(\Pi)$ of a partition Π . Two relevant definitions are:

$$\chi(\Pi) = \sum_{n \in \mathcal{N}_E} c[n] \quad (2)$$

$$\chi(\Pi) = \sum_{n \in \mathcal{N}_E} c[n](\lambda_n - 1). \quad (3)$$

In (2), the cutsize is equal to the sum of the costs of the cut nets. In (3), each cut net n contributes $c[n](\lambda_n - 1)$ to the cutsize. The cutsize metrics given in (2) and (3)

Definition

Hypergraphs are generalization of graphs where each edge (hyperedge) can connect more than two vertices. In simple terms, the hypergraph partitioning problem can be defined as the task of dividing a hypergraph into two or more roughly equal-sized parts such that a cost function on the hyperedges connecting vertices in different parts is minimized.

Discussion

Introduction

During the last decade, hypergraph-based models gained wide acceptance in the parallel computing community for modeling various problems. By providing natural way to represent multiway interactions and unsymmetric dependencies, hypergraph can be used to elegantly model complex computational structures in parallel computing. Here, some concrete applications will be presented to show how hypergraph models can be used to cast a suitable scientific problem as an hypergraph partitioning problem. Some insights and general guidelines for using hypergraph partitioning methods in some general classes of problems are also given.

will be referred to here as *cut-net* and *connectivity* metrics, respectively. The hypergraph partitioning problem can be defined as the task of dividing a hypergraph into two or more parts such that the cutsize is minimized, while a given balance criterion (1) among part weights is maintained.

A recent variant of the above problem is the *multi-constraint hypergraph* partitioning [9, 18] in which each vertex has a vector of weights associated with it. The partitioning objective is the same as above, and the partitioning constraint is to satisfy a balancing constraint associated with each weight. Here, $w[v, i]$ denotes the C weights of a vertex v for $i = 1, \dots, C$. Hence, the balance criterion (1) can be rewritten as

$$W_{k,i} \leq W_{avg,i} (1 + \varepsilon) \text{ for } k = 1, \dots, K \text{ and } i = 1, \dots, C, \quad (4)$$

where the i th weight $W_{k,i}$ of a part \mathcal{V}_k is defined as the sum of the i th weights of the vertices in that part (i.e., $W_{k,i} = \sum_{v \in \mathcal{V}_k} w[v, i]$), and $W_{avg,i}$ is the average part weight for the i th weight (i.e., $W_{avg,i} = (\sum_{v \in \mathcal{V}} w[v, i]) / K$), and ε again represents the allowed imbalance ratio.

Another variant is the *hypergraph partitioning with fixed vertices*, in which some of the vertices are fixed in some parts before partitioning. In other words, in this problem, a *fixed-part* function is provided as an input to the problem. A vertex is said to be *free* if it is allowed to be in any part in the final partition, and it is said to be *fixed* in part k if it is required to be in \mathcal{V}_k in the final partition Π .

Yet another variant is *multi-objective hypergraph partitioning* in which there are several objectives to be minimized [1, 21]. Specifically, a given net contributes different costs to different objectives.

Sparse Matrix Partitioning

One of the most elaborated applications of hypergraph partitioning (HP) method in the parallel scientific computing domain is the parallelization of sparse matrix-vector multiply (SpMxV) operation. Repeated matrix-vector and matrix-transpose-vector multiplies that involve the same large, sparse matrix are the kernel operations in various iterative algorithms involving sparse linear systems. Such iterative algorithms include solvers for linear systems, eigenvalues, and linear programs. The pervasive use of such solvers motivates the

development of HP models and methods for efficient parallelization of SpMxV operations.

Before discussing the HP models and methods for parallelizing SpMxV operations, it is favorable to discuss parallel algorithms for SpMxV. Consider the matrix-vector multiply of the form $y \leftarrow Ax$, where the nonzeros of the sparse matrix A as well as the entries of the input and output vectors x and y are partitioned arbitrarily among the processors. Let $map(\cdot)$ denote the nonzero-to-processor and vector-entry-to-processor assignments induced by this partitioning. A parallel algorithm would execute the following steps at each processor P_k .

1. Send the local input-vector entries x_j , for all j with $map(x_j) = P_k$, to those processors that have at least one nonzero in column j .
2. Compute the scalar products $a_{ij}x_j$ for the local nonzeros, that is, the nonzeros for which $map(a_{ij}) = P_k$ and accumulate the results y_i^k for the same row index i .
3. Send local nonzero partial results y_i^k to the processor $map(y_i) \neq P_k$, for all nonzero y_i^k .
4. Add the partial y_i^k results received to compute the final results $y_i = \sum y_i^k$ for each i with $map(y_i) = P_k$.

As seen in the algorithm, it is necessary to have partitions on the matrix A and the input- and output-vectors x and y of the matrix-vector multiply operation. Finding a partition on the vectors x and y is referred to as the vector partitioning operation, and it can be performed in three different ways: by decoding the partition given on A ; in a post-processing step using the partition on the matrix; or explicitly partitioning the vectors during partitioning the matrix. In any of these cases, the vector partitioning for matrix-vector operations is called *symmetric* if x and y have the same partition, and *non-symmetric* otherwise. A vector partitioning is said to be *consistent*, if each vector entry is assigned to a processor that has at least one nonzero in the respective row or column of the matrix. The consistency is easy to achieve for the nonsymmetric vector partitioning; x_j can be assigned to any of the processors that has a nonzero in the column j , and y_i can be assigned to any of the processors that has a nonzero in the row i . If a symmetric vector partitioning is sought, then special care must be taken to assign a pair of matching input- and output-vector entries, e.g., x_i and

y_i , to a processor having nonzeros in both row and column i . In order to have such a processor for all vector entry pairs, the sparsity pattern of the matrix \mathbf{A} can be modified to have a zero-free diagonal. In such cases, a consistent vector partition is guaranteed to exist, because the processors that own the diagonal entries can also own the corresponding input- and output-vector entries; x_i and y_i can be assigned to the processor that holds the diagonal entry a_{ii} .

In order to achieve an efficient parallelism, the processors should have balanced computational load and the inter-processor communication cost should have been minimized. In order to have balanced computational load, it suffices to have almost equal number of nonzeros per processor so that each processor will perform almost equal number of scalar products, for example, $a_{ij}x_j$, in any given parallel system. The communication cost, however, has many components (the total volume of messages, the total number of messages, maximum volume/number of messages in a single processor, either in terms of sends or receives or both) each of which can be of utmost importance for a given matrix in a given parallel system. Although there are alternatives and more elaborate proposals, the most common communication cost metric addressed in hypergraph partitioning-based methods is the total volume of communication.

Loosely speaking, hypergraph partitioning-based methods for efficient parallelization of SpMxV model the data of the SpMxV (i.e., matrix and vector entries) with the vertices of a hypergraph. A partition on the vertices of the hypergraph is then interpreted in such a way that the data corresponding to a set of vertices in a part are assigned to a single processor. More accurately, there are two classes of hypergraph partitioning-based methods to parallelizing SpMxV. The methods in the first class build a hypergraph model representing the data and invoke a partitioning heuristic on the so-built hypergraph. The methods in this class can be said to be models rather than being algorithms. There are currently three main hypergraph models for representing sparse matrices, and hence there are three methods in this first class. These three main models are described below in the next section. Essential property of these models is that the cutsizes (3) of any given partition is equal to the total communication volume to be incurred under a consistent vector partitioning when the matrix

elements are distributed according to the vertex partition. The methods in the second class follow a mix-and-match approach and use the three main models, perhaps, along with multi-constraint and fixed-vertex variations in an algorithmic form. There are a number of methods in this second class, and one can develop many others according to application needs and matrix characteristics. Three common methods belonging to this class are described later, after the three main models. The main property of these algorithms is that the sum of the cutsizes of each application of hypergraph partitioning amounts to the total communication volume to be incurred under a consistent vector partitioning (currently these methods compute a vector partitioning after having found a matrix partitioning) when the matrix elements are distributed according to the vertex partitions found at the end.

Three Main Models for Matrix Partitioning

In the *column-net hypergraph model* [11] used for 1D rowwise partitioning, an $M \times N$ matrix \mathbf{A} with Z nonzeros is represented as a unit-cost hypergraph $\mathcal{H}_{\mathcal{R}} = (\mathcal{V}_{\mathcal{R}}, \mathcal{N}_{\mathcal{C}})$ with $|\mathcal{V}_{\mathcal{R}}| = M$ vertices, $|\mathcal{N}_{\mathcal{C}}| = N$ nets, and Z pins. In $\mathcal{H}_{\mathcal{R}}$, there exists one vertex $v_i \in \mathcal{V}_{\mathcal{R}}$ for each row i of matrix \mathbf{A} . Weight $w[v_i]$ of a vertex v_i is equal to the number of nonzeros in row i . The name of the model comes from the fact that columns are represented as nets. That is, there exists one unit-cost net $n_j \in \mathcal{N}_{\mathcal{C}}$ for each column j of matrix \mathbf{A} . Net n_j connects the vertices corresponding to the rows that have a nonzero in column j . That is, $v_i \in n_j$ if and only if $a_{ij} \neq 0$.

In the *row-net hypergraph model* [11] used for 1D columnwise partitioning, an $M \times N$ matrix \mathbf{A} with Z nonzeros is represented as a unit-cost hypergraph $\mathcal{H}_{\mathcal{C}} = (\mathcal{V}_{\mathcal{C}}, \mathcal{N}_{\mathcal{R}})$ with $|\mathcal{V}_{\mathcal{C}}| = N$ vertices, $|\mathcal{N}_{\mathcal{R}}| = M$ nets, and Z pins. In $\mathcal{H}_{\mathcal{C}}$, there exists one vertex $v_j \in \mathcal{V}_{\mathcal{C}}$ for each column j of matrix \mathbf{A} . Weight $w[v_j]$ of a vertex $v_j \in \mathcal{V}_{\mathcal{R}}$ is equal to the number of nonzeros in column j . The name of the model comes from the fact that rows are represented as nets. That is, there exists one unit-cost net $n_i \in \mathcal{N}_{\mathcal{R}}$ for each row i of matrix \mathbf{A} . Net n_i connects the vertices corresponding to the columns that have a nonzero in row i . That is, $v_j \in n_i$ if and only if $a_{ij} \neq 0$.

In the *column-row-net hypergraph model*, otherwise known as the *fine-grain model* [13], used for 2D

nonzero-based fine-grain partitioning, an $M \times N$ matrix \mathbf{A} with Z nonzeros is represented as a unit-weight and unit-cost hypergraph $\mathcal{H}_{\mathcal{Z}} = (\mathcal{V}_{\mathcal{Z}}, \mathcal{N}_{\mathcal{RC}})$ with $|\mathcal{V}_{\mathcal{Z}}| = Z$ vertices, $|\mathcal{N}_{\mathcal{RC}}| = M + N$ nets and $2Z$ pins. In $\mathcal{V}_{\mathcal{Z}}$, there exists one unit-weight vertex v_{ij} for each nonzero a_{ij} of matrix \mathbf{A} . The name of the model comes from the fact that both rows and columns are represented as nets. That is, in $\mathcal{N}_{\mathcal{RC}}$, there exist one unit-cost row-net r_i for each row i of matrix \mathbf{A} and one unit-cost column-net c_j for each column j of matrix \mathbf{A} . The row-net r_i connects the vertices corresponding to the nonzeros in row i of matrix \mathbf{A} , and the column-net c_j connects the vertices corresponding to the nonzeros in column j of matrix \mathbf{A} . That is, $v_{ij} \in r_i$ and $v_{ij} \in c_j$ if and only if $a_{ij} \neq 0$. Note that each vertex v_{ij} is in exactly two nets.

Some Other Methods for Matrix Partitioning

The *jagged-like partitioning method* [16] uses the row-net and column-net hypergraph models. It is an algorithm with two steps, in which each step models either the *expand phase* (the 1st line) or the *fold phase* (the 3rd line) of the parallel SpMxV algorithm given above. Therefore, there are two alternative schemes for this partitioning method. The one which models the expands in the first step and the folds in the second step is described below.

Given an $M \times N$ matrix \mathbf{A} and the number K of processors organized as a $P \times Q$ mesh, the jagged-like partitioning model proceeds as shown in Fig. 1. The algorithm has two main steps. First, \mathbf{A} is partitioned rowwise into P parts using the column-net hypergraph model $\mathcal{H}_{\mathcal{R}}$ (lines 1 and 2 of Fig. 1). Consider a P -way partition $\Pi_{\mathcal{R}}$ of $\mathcal{H}_{\mathcal{R}}$. From the partition $\Pi_{\mathcal{R}}$, one obtains P submatrices \mathbf{A}_p , for $p = 1, \dots, P$ each having roughly equal number of nonzeros. For each p , the rows of the submatrix \mathbf{A}_p correspond to the vertices in \mathcal{R}_p (lines 6 and 7 of Fig. 1). The submatrix \mathbf{A}_p is assigned to the p th row of the processor mesh. Second, each submatrix \mathbf{A}_p for $1 \leq p \leq P$ is independently partitioned columnwise into Q parts using the row-net hypergraph \mathcal{H}_p (lines 8 and 9 of Fig. 1). The nonzeros in the i th row of \mathbf{A} are partitioned among the Q processors in a row of the processor mesh. In particular, if $v_i \in \mathcal{R}_p$ at the end of line 2 of the algorithm, then the nonzeros in the i th row of \mathbf{A} are partitioned among the processors in the p th row of the processor mesh. After partitioning the submatrix \mathbf{A}_p columnwise, the *map* array contains the partition information for the nonzeros residing in \mathbf{A}_p .

For each i , the volume of communication required to fold the vector entry y_i is accurately represented as a part of “*foldVolume*” in the algorithm. For each j , the volume of communication regarding the vector entry x_j

JAGGED-LIKE-PARTITIONING ($\mathbf{A}, K = P \times Q, \varepsilon_1, \varepsilon_2$)

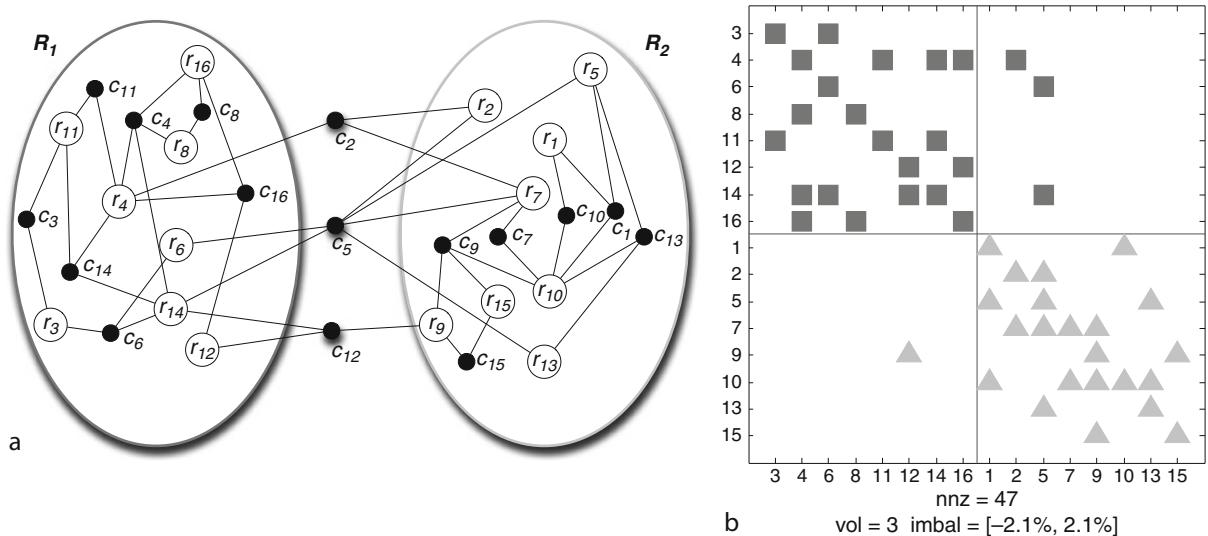

Input : a matrix \mathbf{A} , the number of processors $K = P \times Q$, and the imbalance ratios $\varepsilon_1, \varepsilon_2$.

Output: $map(a_{ij})$ for all $a_{ij} \neq 0$ and total Volume.

**Hypergraph Partitioning.** Fig. 2 First step of four-way jagged-like partitioning of a matrix; (a) two-way partitioning  $\Pi_R$  of column-net hypergraph representation  $\mathcal{H}_R$  of  $\mathbf{A}$ , (b) two-way rowwise partitioning of matrix  $\mathbf{A}^\Pi$  obtained by permuting  $\mathbf{A}$  according to the partitioning induced by  $\Pi$ ; the nonzeros in the same partition are shown with the same shape and color; the deviation of the minimum and maximum numbers of nonzeros of a part from the average are displayed as an interval  $\text{imbal}$ ;  $\text{vol}$  denotes the number of nonzeros and the total communication volume

is accurately represented as a part of “expandVolume” in the algorithm.

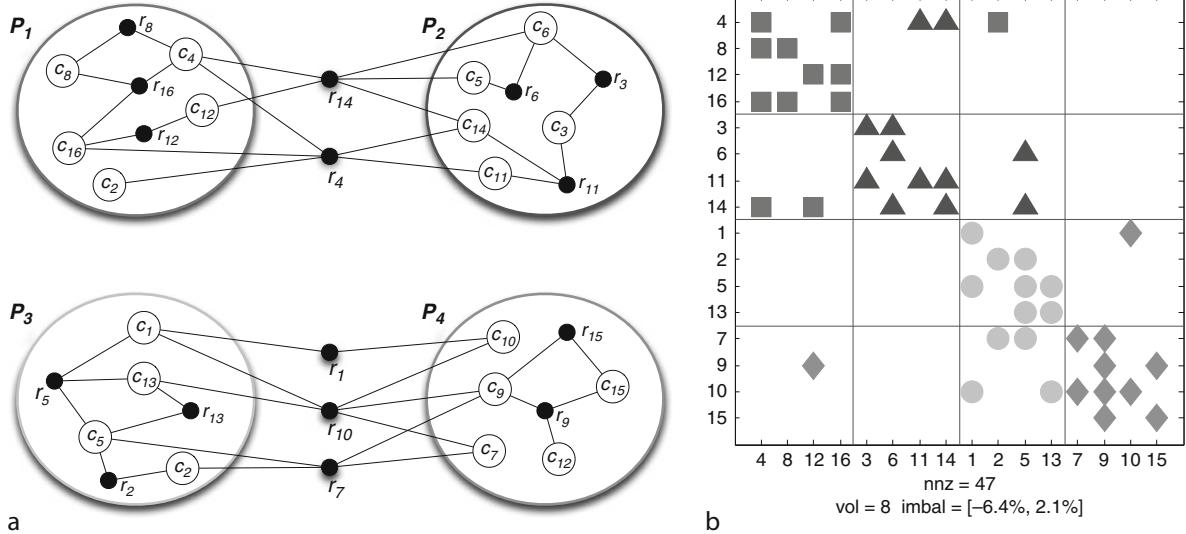

Figure 2a illustrates the column-net representation of a sample matrix to be partitioned among the processors of a  $2 \times 2$  mesh. For simplicity of the presentation, the vertices and the nets of the hypergraphs are labeled with letters “r” and “c” to denote the rows and columns of the matrix. The matrix is first partitioned rowwise into two parts, and each part is assigned to a row of the processor mesh, namely to processors  $\{P_1, P_2\}$  and  $\{P_3, P_4\}$ . The resulting permuted matrix is displayed in Fig. 2b. Figure 3a displays the two row-net hypergraphs corresponding to each submatrix  $\mathbf{A}_p$  for  $p = 1, 2$ . Each hypergraph is partitioned independently; sample partitions of these hypergraphs are also presented in this figure. As seen in the final symmetric permutation in Fig. 3b, the nonzeros of columns 2 and 5 are assigned to different parts, resulting  $P_3$  to communicate with both  $P_1$  and  $P_2$  in the expand phase.

The *checkerboard partitioning method* [14] is also a two-step method, in which each step models either the expand phase or the fold phase of the parallel SpMxV. Similar to jagged-like partitioning, there are two alternative schemes for this partitioning method. The one

which models the expands in the first step and the folds in the second step is presented below.

Given an  $M \times N$  matrix  $\mathbf{A}$  and the number  $K$  of processors organized as a  $P \times Q$  mesh, the checkerboard partitioning method proceeds as shown in Fig. 4. First,  $\mathbf{A}$  is partitioned rowwise into  $P$  parts using the column-net model (lines 1 and 2 of Fig. 4), producing  $\Pi_R = \{\mathcal{R}_1, \dots, \mathcal{R}_P\}$ . Note that this first step is exactly the same as that of the jagged-like partitioning. In the second step, the matrix  $\mathbf{A}$  is partitioned columnwise into  $Q$  parts by using the multi-constraint partitioning to obtain  $\Pi_C = \{\mathcal{C}_1, \dots, \mathcal{C}_Q\}$ . In comparison to the jagged-like method, in this second step the whole matrix  $\mathbf{A}$  is partitioned (lines 4 and 8 of Fig. 4), not the submatrices defined by  $\Pi_R$ . The rowwise and columnwise partitions  $\Pi_R$  and  $\Pi_C$  together define a 2D partition on the matrix  $\mathbf{A}$ , where  $\text{map}(a_{ij}) = P_{p,q} \Leftrightarrow r_i \in \mathcal{R}_p$  and  $c_j \in \mathcal{C}_q$ .

In order to achieve a load balance among processors, a multi-constraint partitioning formulation is used (line 8 of the algorithm). Each vertex  $v_i$  of  $\mathcal{H}_C$  is assigned  $P$  weights:  $w[i, p]$ , for  $p = 1, \dots, P$ . Here,  $w[i, p]$  is equal to the number of nonzeros of column  $c_i$  in rows  $\mathcal{R}_p$  (line 7 of Fig. 4). Consider a  $Q$ -way partitioning of  $\mathcal{H}_C$  with  $P$  constraints using the vertex weight definition

**Hypergraph Partitioning.** Fig. 3 Second step of four-way jagged-like partitioning: (a) Row-net representations of submatrices of  $\mathbf{A}$  and two-way partitionings, (b) Final permuted matrix; the nonzeros in the same partition are shown with the same shape and color; the deviation of the minimum and maximum numbers of nonzeros of a part from the average are displayed as an interval  $\text{imbal}$ ;  $\text{nnz}$  and  $\text{vol}$  denote, respectively, the number of nonzeros and the total communication volume

CHECKERBOARD-PARTITIONING( $\mathbf{A}$ ,  $K = P \times Q$ ,  $\varepsilon_1, \varepsilon_2$ )

Input: a matrix  $\mathbf{A}$ , the number of processors  $K = P \times Q$ , and the imbalance ratios  $\varepsilon_1, \varepsilon_2$ .

Output:  $\text{map}(a_{ij})$  for all  $a_{ij} \neq 0$  and  $\text{totalVolume}$ .

```

1: $\mathcal{H}_{\mathcal{R}} = (\mathcal{V}_{\mathcal{R}}, \mathcal{N}_{\mathcal{C}}) \leftarrow \text{columnNet}(\mathbf{A})$
2: $\Pi_{\mathcal{R}} = \{\mathcal{R}_1, \dots, \mathcal{R}_P\} \leftarrow \text{partition}(\mathcal{H}_{\mathcal{R}}, P, \varepsilon_1)$ \triangleright rowwise partitioning of \mathbf{A}
3: $\text{expandVolume} \leftarrow \text{cutsize}(\Pi_{\mathcal{R}})$
4: $\mathcal{H}_{\mathcal{C}} = (\mathcal{V}_{\mathcal{C}}, \mathcal{N}_{\mathcal{C}}) \leftarrow \text{rowNet}(\mathbf{A})$
5: for $j = 1$ to $|\mathcal{V}_{\mathcal{C}}|$ do
6: for $p = 1$ to P do
7: $w_{j,p} = |\{n_j \cap \mathcal{R}_p\}|$
8: $\Pi_{\mathcal{C}} = \{\mathcal{C}_1, \dots, \mathcal{C}_Q\} \leftarrow \text{MCPartition}(\mathcal{H}_{\mathcal{C}}, Q, \varepsilon_2)$ \triangleright columnwise partitioning of \mathbf{A}
9: $\text{foldVolume} \leftarrow \text{cutsize}(\Pi_{\mathcal{C}})$
10: for all $a_{ij} \neq 0$ of \mathbf{A} do
11: $\text{map}(a_{ij}) = P_{p,q} \Leftrightarrow r_i \in \mathcal{R}_p$ and $c_j \in \mathcal{C}_q$
12: $\text{totalVolume} \leftarrow \text{expandVolume} + \text{foldVolume}$
```

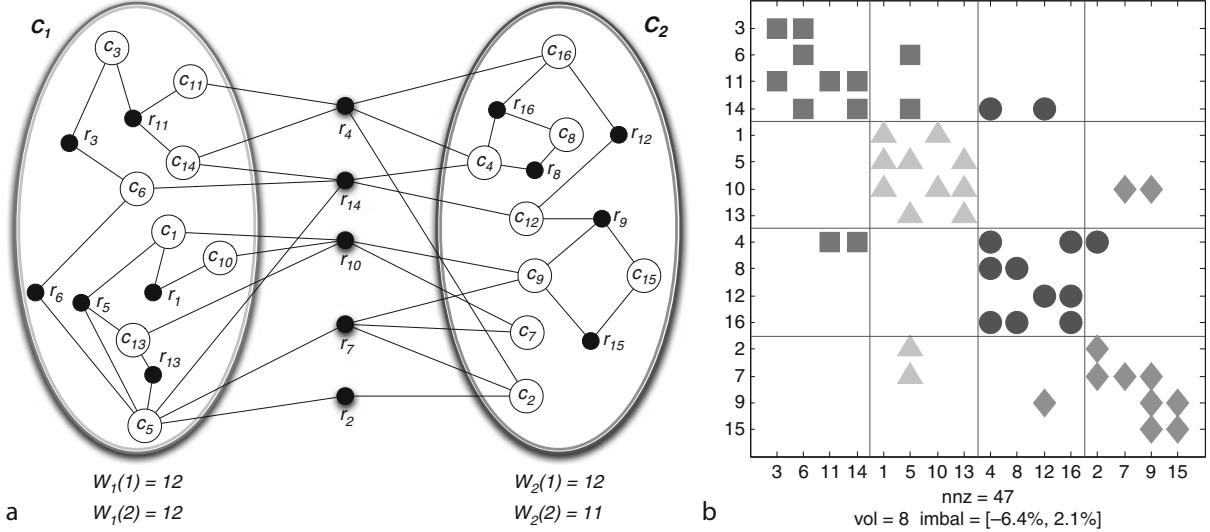

---

**Hypergraph Partitioning.** Fig. 4 Checkerboard partitioning

above. Maintaining the  $P$  balance constraints (4) corresponds to maintaining computational load balance on the processors of each row of the processor mesh.

Establishing the equivalence between the total communication volume and the sum of the cutsizes of the

two partitions is fairly straightforward. The volume of communication for the fold operations corresponds exactly to the  $\text{cutsize}(\Pi_{\mathcal{C}})$ . The volume of communication for the expand operations corresponds exactly to the  $\text{cutsize}(\Pi_{\mathcal{R}})$ .

**Hypergraph Partitioning, Fig. 5** Second step of four-way checkerboard partitioning: **(a)** two-way multi-constraint partitioning  $\Pi_C$  of row-net hypergraph representation  $\mathcal{H}_C$  of  $\mathbf{A}$ , **(b)** Final checkerboard partitioning of  $\mathbf{A}$  induced by  $(\Pi_R, \Pi_C)$ ; the nonzeros in the same partition are shown with the same shape and color; the deviation of the minimum and maximum numbers of nonzeros of a part from the average are displayed as an interval `imbal`; `nnz` and `vol` denote, respectively, the number of nonzeros and the total communication volume

**Figure 5b** displays the  $2 \times 2$  checkerboard partition induced by  $(\Pi_{\mathcal{R}}, \Pi_{\mathcal{C}})$ . Here,  $\Pi_{\mathcal{R}}$  is a rowwise two-way partition giving the same figure as shown in [Fig. 2](#), and  $\Pi_{\mathcal{C}}$  is a two-way multi-constraint partition  $\Pi_{\mathcal{C}}$  of the row-net hypergraph model  $\mathcal{H}_{\mathcal{C}}$  of  $\mathbf{A}$  shown in [Fig. 5a](#). In [Fig. 5a](#),  $w[9, 1] = 0$  and  $w[9, 2] = 4$  for internal column  $c_9$  of row stripe  $\mathcal{R}_2$ , whereas  $w[5, 1] = 2$  and  $w[5, 2] = 4$  for external column  $c_5$ .

Another common method of matrix partitioning is the *orthogonal recursive bisection* (ORB) [27]. In this approach, the matrix is first partitioned rowwise into two submatrices using the column-net hypergraph model, and then each part is further partitioned columnwise into two parts using the row-net hypergraph model. The process is continued recursively until the desired number of parts is obtained. The algorithm is shown in Fig. 6. In this algorithm,  $\text{dim}$  represents either rowwise or columnwise partitioning, where  $-\text{dim}$  switches the partitioning dimension.

In the ORB method shown above, the step *bisect* ( $A, dim, \epsilon$ ) corresponds to partitioning the given matrix either along the rows or columns with, respectively, the column-net or the row-net hypergraph models into two. The total sum of the cutsizes (3) of each bisection

step corresponds to the total communication volume. It is possible to dynamically adjust the  $\epsilon$  at each recursive call by allowing larger imbalance ratio for the recursive call on the submatrix  $A_1$  or  $A_2$ .

## Some Other Applications of Hypergraph Partitioning

As said before, the initial motivations for hypergraph models were accurate modeling of the nonzero structure of unsymmetric and rectangular sparse matrices to minimize the communication volume for iterative solvers. There are other applications that can make use of hypergraph partitioning formulation. Here, a brief overview of general classes of applications is given along with the names of some specific problems. Further application classes are given in bibliographic notes.

*Parallel reduction* or aggregation operations form a significant class of such applications, including the MapReduce model. The reduction operation consists of computing  $M$  output elements from  $N$  input elements. An output element may depend on multiple input elements, and an input element may contribute to multiple output elements. Assume that the operation on which

---

ORB-PARTITIONING( $\mathbf{A}$ ,  $dim$ ,  $K_{min}$ ,  $K_{max}$ ,  $\epsilon$ )

Input: a matrix  $\mathbf{A}$ , the part numbers  $K_{min}$  (at initial call, it is equal to 1) and  $K_{max}$  (at initial call it is equal to  $K$ , the desired number of parts), and the imbalance ratio  $\epsilon$ .

Output:  $map(a_{ij})$  for all  $a_{ij} \neq 0$ .

```

1: if $K_{max} - K_{min} > 0$ then
2: $mid \leftarrow (K_{max} - K_{min} + 1)/2$
3: $\Pi = \langle \mathbf{A}_1, \mathbf{A}_2 \rangle \leftarrow \text{bisect}(\mathbf{A}, dim, \epsilon)$ ▷ Partition \mathbf{A} along dim into two, producing two submatrices
4: $\text{totalVolume} \leftarrow \text{totalVolume} + \text{cutsizes}(\Pi)$
 ▷ Recursively partition each submatrix along the orthogonal direction
5: $map1(\mathbf{A}_1) \leftarrow \text{ORB-PARTITIONING}(\mathbf{A}_1, -dim, K_{min}, K_{min} + mid - 1, \epsilon)$
6: $map2(\mathbf{A}_2) \leftarrow \text{ORB-PARTITIONING}(\mathbf{A}_2, -dim, K_{min} + mid, K_{max}, \epsilon)$
7: $map(\mathbf{A}) \leftarrow map1(\mathbf{A}_1) \cup map2(\mathbf{A}_2)$
8: else
9: $map(\mathbf{A}) \leftarrow K_{min}$
```

---

**Hypergraph Partitioning. Fig. 6** Orthogonal recursive bisection (ORB)

reduction is performed is commutative and associative. Then, the inherent computational structure can be represented with an  $M \times N$  dependency matrix, where each row and column of the matrix represents an output element and an input element, respectively. For an input element  $x_j$  and an output element  $y_i$ , if  $y_i$  depends on  $x_j$ ,  $a_{ij}$  is set to 1 (otherwise zero). Using this representation, the problem of partitioning the workload for the reduction operation is equivalent to the problem of partitioning the dependency matrix for efficient SpMxV.

In some other reduction problems, the input and output elements may be preassigned to parts. The proposed hypergraph model can be accommodated to those problems by adding  $K$  part vertices and connecting those vertices to the nets which correspond to the preassigned input and output elements. Obviously, those part vertices must be fixed to the corresponding parts during the partitioning. Since the required property is already included in the existing hypergraph partitioners [6, 12, 19], this does not add extra complexity to the partitioning methods.

*Iterative methods for solving linear systems* usually employ *preconditioning* techniques. Roughly speaking, preconditioning techniques modify the given linear system to accelerate convergence. Applications of explicit preconditioners in the form of approximate inverses or factored approximate inverses are amenable to parallelization. Because, these techniques require SpMxV operations with the approximate inverse or factors of the approximate inverse at each step. In

other words, preconditioned iterative methods perform SpMxV operations with both coefficient and preconditioner matrices in a step. Therefore, parallelizing a full step of these methods requires the coefficient and preconditioner matrices to be well partitioned, for example, processors' loads are balanced and communication costs are low in both multiply operations. To meet this requirement, the coefficient and preconditioner matrices should be partitioned simultaneously. One can accomplish such a simultaneous partitioning by building a single hypergraph and then partitioning that hypergraph. Roughly speaking, one follows a four-step approach: (i) build a hypergraph for each matrix, (ii) determine which vertices of the two hypergraphs need to be in the same part (according to the computations forming the iterative method), (iii) amalgamate those vertices coming from different hypergraphs, (iv) if the computations represented by the two hypergraphs of the first step are separated by synchronization points then assign multiple weights to vertices (the weights of the vertices of the hypergraphs of the first step are kept), otherwise assign a single weight to vertices (the weights of the vertices of the hypergraphs of the first step are summed up for each amalgamation).

The computational structure of the preconditioned iterative methods is similar to that of a more general class of scientific computations including multiphase, multiphysics, and multi-mesh simulations.

In *multiphase simulations*, there are a number of computational phases separated by global synchronization points. The existence of the global synchronizations

necessitates each phase to be load balanced individually. Multi-constraint formulation of hypergraph partitioning can be used to achieve this goal.

In *multi-physics simulations*, a variety of materials and processes are analyzed using different physics procedures. In these types of simulations, computational as well as the memory requirements are not uniform across the mesh. For scalability issues, processor loads should be balanced in terms of these two components. The multi-constraint partitioning framework also addresses these problems.

In *multi-mesh simulations*, a number of grids with different discretization schemes and with arbitrary overlaps are used. The existence of overlapping grid points necessitates a simultaneous partitioning of the grids. Such a simultaneous partitioning scheme should balance the computational loads of the processors and minimize the communication cost due to interactions within a grid as well as the interactions among different grids. With a particular transformation (the vertex amalgamation operation, also mentioned above), hypergraphs can be used to model the interactions between different grids. With the use of multi-constraint formulation, the partitioning problem in the multi-mesh computations can also be formulated as a hypergraph partitioning problem.

In obtaining partitions for two or more computation phases interleaved with synchronization points, the hypergraph models lead to the minimization of the overall sum of the total volume of communication in all phases (assuming that a single hypergraph is built as suggested in the previous paragraphs). In some sophisticated simulations, the magnitude of the interactions in one phase may be different than that of the interactions in another one. In such settings, minimizing the total volume of communication in each phase separately may be advantageous. This problem can be formulated as a multi-objective hypergraph partitioning problem on the so-built hypergraphs.

There are certain limitations in applying hypergraph partitioning to the multiphase, multiphysics, and multi-mesh-like computations. The dependencies must remain the same throughout the computations, otherwise the cutsize may not represent the communication volume requirements as precisely as before. The weights assigned to the vertices, for load balancing issues, should be static and available prior to the

partitioning; the hypergraph models cannot be used as naturally for applications whose computational requirements vary drastically in time. If, however, the computational requirements change gradually in time, then the models can be used to re-partition the load at certain time intervals (while also minimizing the redistribution or migration costs associated with the new partition).

*Ordering methods* are quite common techniques to permute matrices in special forms in order to reduce the memory and running time requirements, as well as to achieve increased parallelism in direct methods (such as LU and Cholesky decompositions) used for solving systems of linear equations. Nested-dissection is a well-known ordering method that has been used quite efficiently and successfully. In the current state-of-the-art variations of the nested-dissection approach, a matrix is symmetrically permuted with a permutation matrix  $\mathbf{P}$  into doubly bordered block diagonal form

$$\mathbf{A}_{DB} = \mathbf{P} \mathbf{A} \mathbf{P}^T \begin{bmatrix} A_{11} & & & A_{1S} \\ & A_{22} & & A_{2S} \\ & & \ddots & \vdots \\ & & & A_{KK} & A_{KS} \\ A_{S1} & A_{S2} & \cdots & A_{SK} & A_{SS} \end{bmatrix},$$

where the nonzeros are only in the marked blocks (the blocks on the diagonal and the row and column borders). The aim in such a permutation is to have reduced numbers of rows/columns in the borders and to have equal-sized square blocks in the diagonal. One way to achieve such a permutation when  $\mathbf{A}$  has symmetric pattern is as follows. Suppose a matrix  $\mathbf{B}$  is given (if not, it is possible to find one) where the sparsity pattern of  $\mathbf{B}^T \mathbf{B}$  equals to that of  $\mathbf{A}$  (here arithmetic cancellations are ignored). Then, one can permute  $\mathbf{B}$  nonsymmetrically into the singly bordered form

$$\mathbf{B}_{SB} = \mathbf{Q} \mathbf{B} \mathbf{P}^T \begin{bmatrix} B_{11} & & & B_{1S} \\ & B_{22} & & B_{2S} \\ & & \ddots & \vdots \\ & & & B_{KK} & B_{KS} \end{bmatrix},$$

so that  $\mathbf{B}_{SB}^T \mathbf{B}_{SB} = \mathbf{P} \mathbf{A} \mathbf{P}^T$ ; that is, one can use the column permutation of  $\mathbf{B}$  resulting in  $\mathbf{B}_{SB}$  to obtain a symmetric permutation for  $\mathbf{A}$  which results in  $\mathbf{A}_{DB}$ . Clearly, the column dimension of  $B_{kk}$  will be the size of the square matrix  $A_{kk}$  and the number of rows and columns in the border will be equal to the number of columns in the column border of  $\mathbf{B}_{SB}$ . One can achieve such a permutation of  $\mathbf{B}$  by partitioning the column-net model of  $\mathbf{B}$  while reducing the cutsize according to the cut-net metric (2), with unit net costs, to obtain the permutation  $\mathbf{P}$  as follows. First, the permutation  $\mathbf{Q}$  is defined to be able to define  $\mathbf{P}$ . Permute all rows corresponding to the vertices in part  $k$  before those in a part  $\ell$ , for  $1 \leq k < \ell \leq K$ . Then, permute all columns corresponding to the nets that are internal to a part  $k$  before those that are internal to a part  $\ell$ , for  $1 \leq k < \ell \leq K$ , yielding the diagonal blocks, and then permute all columns corresponding to the cut nets to the end, yielding the column border (the order of column defining a diagonal block). Clearly the correspondence between the size of the column border of  $\mathbf{B}_{SB}$  and the doubly border of  $\mathbf{A}_{DB}$  is exact, and hence the cutsize according to the cut-net metric is an exact measure. The requirement to have almost equal sized square blocks  $A_{kk}$  decoded as the requirement that each part should have an almost equal number of internal nets in the partition of the column-net model of  $\mathbf{B}$ . Although such a requirement is neither the objective nor the constraint of the hypergraph partitioning problem, the common hypergraph-partitioning heuristics easily accommodate such requirements.

## Bibliographic Notes and Further Reading

The first use of the hypergraph partitioning methods for efficient parallel sparse matrix-vector multiply

operations is seen in [10]. A more comprehensive study [11] describes the use of the row-net and column-net hypergraph models in 1D sparse matrix partitioning. For different views and alternatives on vector partitioning see [5, 22, 24].

A fair treatment of parallel sparse matrix-vector multiplication, analysis, and investigations on certain matrix types along with the use of hypergraph partitioning is given in [4, Chapter 4]. Further analysis of hypergraph partitioning on some model problems is given in [25].

Hypergraph partitioning schemes for preconditioned iterative methods are given in [23], where vertex amalgamation and multi-constraint weighting to represent different phases of computations are given. Discussions on application of such methodology for multiphase, multiphysics, and multi-mesh simulations are also discussed in the same paper.

Some different methods for sparse matrix partitioning using hypergraphs can be found in [26], including jagged-like and checkerboard partitioning methods, and in [27], the orthogonal recursive bisection approach. A recipe to choose a partitioning method for a given matrix is given in [16].

The use of hypergraph models for permuting matrices into special forms such as singly bordered block-diagonal form can be found in [3]. This permutation can be leveraged to develop hypergraph partitioning-based symmetric [9, 15] and nonsymmetric [17] nested-dissection orderings.

The standard hypergraph partitioning and the hypergraph partitioning with fixed vertices formulation, respectively, is used for static and dynamic load balancing for some scientific applications in [7, 8].

Some other applications of hypergraph partitioning are briefly summarized in [2]. These include image-space parallel direct volume rendering, parallel mixed integer linear programming, data declustering for multi-disk databases, scheduling file-sharing tasks in heterogeneous master-slave computing environments, and work-stealing scheduling, road network clustering methods for efficient query processing, pattern-based data clustering, reducing software development and maintenance costs, processing spatial join operations, and improving locality in memory or cache performance.

### Definition

HyperTransport is a scalable packet-based, high-bandwidth, and low-latency point-to-point interconnect technology intended to interconnect processors and also link them to I/O peripheral devices. HyperTransport was initially devised as an efficient replacement for traditional system buses for on-board communications. Nevertheless, the last extension to the standard, referred to as High Node Count HyperTransport, as well as the recent standardization of new cables and connectors, allow HyperTransport to efficiently extend its interconnection capabilities beyond a single motherboard and become a very efficient technology to interconnect processors and I/O devices in a cluster. HyperTransport is an open standard managed by the HyperTransport Consortium.

### Discussion

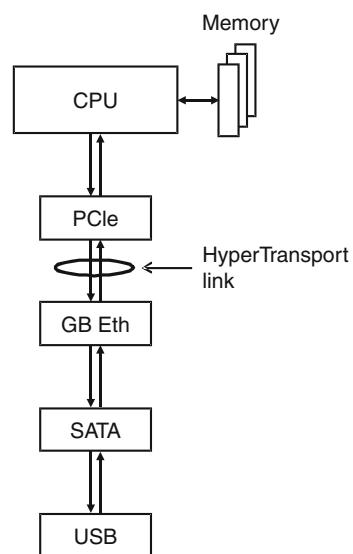

A complete description of the HyperTransport technology should include both an introduction to the protocol used by communicating devices to exchange data and also a description of the electrical interface that this technology makes use of in order to achieve its tremendous performance. However, describing the electrical interface seems to be less interesting than the protocol itself and, additionally, requires the reader to have a large electrical background. Therefore, the following description will be focused on the protocol used by the HyperTransport technology, leaving aside the electrical details. On the other hand, the protocol used by HyperTransport is a quite complex piece of technology, thus requiring an extensive explanation, which may be out of the scope of this encyclopedia. For this reason, the following description just tries to be a brief introduction to HyperTransport. Finally, the reader should note that AMD uses an extended version of the HyperTransport protocol in order to provide cache coherency among the processors in a system. Such extended protocol, usually

referred to as coherent HyperTransport (cHT), is proprietary to AMD, and therefore it is not described in this document. Nevertheless, the main difference between both protocols is that the coherent one includes some additional types of packets.

### HyperTransport Links

The HyperTransport technology is a point-to-point communication standard, meaning that each of the HyperTransport links in the system connects exactly two devices. [Figure 1](#) shows a simplified diagram of a system that deploys HyperTransport in order to interconnect the devices it is composed of. As can be seen in that figure, the main processor is connected to a PCIe device by means of a HyperTransport link. That PCIe device is, at the same time, connected to a GigaByte Ethernet device, which is, additionally, connected to a SATA device. This device connects to a USB device. All of these devices make up a HyperTransport daisy chain. Nevertheless, devices can implement multiple HyperTransport links in order to build larger HyperTransport fabrics.

Each of the links depicted in [Fig. 1](#) consists of two unidirectional and independent sets of signals. Each of these sets includes its own CAD signal, as well as CTL and CLK signals.

**HyperTransport. Fig. 1** System deploying HyperTransport

The CAD signal (named after Command, Address, and Data) carries control and data packets. The CTL signal (named after ConTroL) is intended to differentiate control from data packets in the CAD signal. Finally, the CLK signal (named after CLock) carries the clock for the CAD and CTL signals. [Figure 2](#) shows a diagram presenting all these signals.

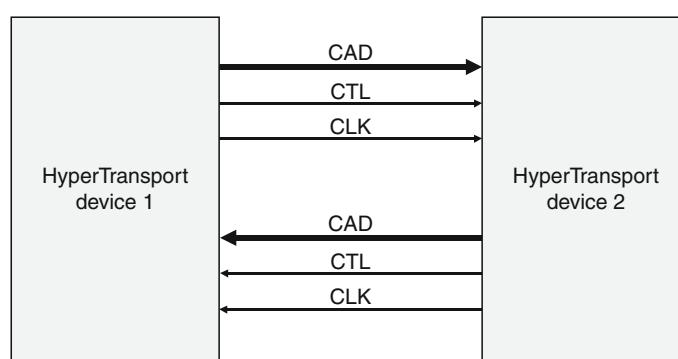

The width of the CAD signal is variable from 2 to 32 bits. Actually, not all values are possible. Only widths of 2-, 4-, 8-, 16-, or 32-bits are allowed. Nevertheless, note that the HyperTransport protocol remains the same independently of the exact link width. More precisely, the format of the packets exchanged among HyperTransport devices does not depend on link width. However, a given packet will require more time to be transmitted in a 2-bit link than in a 32-bit one. The reason for having several widths for the CAD signal is allowing system developers to tune their system for a given performance/cost design point. Narrower links will be cheaper to implement, but they will also provide lower performance.

On the other hand, the width of the CAD signal in each of the unidirectional portions of the link may be different, that is, HyperTransport allows asymmetrical link widths. Therefore, a given device may implement a 32-bit wide link in one direction while deploying a 4-bit link in the other, for example. The usefulness of such asymmetry is based on the fact that, if such a device sends most of its data in one direction and receives a limited amount of data in the other direction, then the system designer can reduce manufacturing cost by providing a wide link in the direction that requires higher

bandwidth and a narrow link for the opposite direction, which requires much less bandwidth.

In addition to the variable link width, HyperTransport also supports variable clock speeds, thus increasing even more the possibilities the system designer has for tuning the bandwidth of the links. The clock speeds currently supported by the HyperTransport specification are 200 MHz, 300 MHz, 400 MHz, 500 MHz, 600 MHz, 800 MHz, 1 GHz, 1.2 GHz, 1.6 GHz, 2 GHz, 2.4 GHz, 2.6 GHz, 2.8 GHz, 3 GHz, and 3.2 GHz. Moreover, clock frequency in both directions of a link does not need to be the same, thus introducing an additional degree of asymmetry. On the other hand, the clock mechanism used in HyperTransport is referred to as double data rate (DDR), which means that rising and falling edges of the clock signal are used to latch data, thus achieving an effective clock frequency that doubles the actual clock rate.

In summary, when variable link width is combined with variable clock frequency, HyperTransport links present an extraordinary scalability in terms of performance. For example, when both directions of a link are 2-bit wide working at 200 MHz, link bandwidth is 200 MB/s. This would be the lowest performance/lowest cost configuration. On the opposite, when 32-bit wide links are used at 3.2 GHz, overall link performance rises up to 51.2 GB/s. This implementation represents the highest bandwidth configuration, also presenting the highest manufacturing cost. This link configuration could be interesting for extreme performance systems, for example, which usually require as much bandwidth as possible. On the other hand, slow devices not

HyperTransport. [Fig. 2](#) Signals in a HyperTransport link

requiring high bandwidth could reduce cost by using narrow links. If these links are additionally clocked at low frequencies, then power consumption is further reduced.

In the same way that the CAD signal can be implemented with a variable width, the CTL and CLK signals can also be implemented with several widths. However, their width does not depend on the implementer's criterion to choose a performance/cost design point, but on the width of the CAD signal. Additionally, as the CAD signal can present a different width in each direction of the link, then the width of the CTL and CLK signals can also be different in each direction, depending on the corresponding CAD signal in that direction.

In the case of the CTL signal, there is an individual CTL bit for each set of 8, or fewer, CAD bits. Therefore, 1, 2, or 4 CTL bits can be found in a HyperTransport link. Moreover, the CTL bits are encoded in such a way that four CTL bits are transferred every 32 CAD bits. These four bits are intended to denote different flavors of the information being transmitted in the CAD signal. These different flavors may include, for example, that a command is being transmitted, that a CRC for a command without data is in the CAD signal, that the CAD signal is being used by a data packet, etc.

In the case for the CLK signal, a HyperTransport link has an individual CLK bit for every set of 8, or fewer, CAD bits. Thus, the number of CTL and CLK bits in a given link is the same. The reason for having a CLK bit for every 8 bits of the CAD signal is because link implementation is made easier. Effectively, the HyperTransport clocking scheme requires that the skew between clock and data signals must be minimized in order to achieve high transmission rates. Therefore, having a CLK bit for every 8 CAD bits allows that differences in trace lengths in the board layout are much lower than just having a CLK bit for the entire set of CAD bits.

In addition to the signals mentioned above, all HyperTransport devices share one PWROK and one RESET# signals for initialization and reset purposes. Moreover, if devices require power management, they should additionally include LDTSTOP# and LDTREQ# signals.

## HyperTransport Packets

Once described the links that connect devices in a HyperTransport fabric, this section presents the packets

that are forwarded along those links. Packets in HyperTransport are multiples of 4-bytes long and carry the command, address, and data associated with each transaction among devices. Packets can be classified into control and data packets.

Control packets are used to initiate and finalize transactions as well as to manage several HyperTransport features, and consist of 4 or 8 bytes. Control packets can be classified into information, request, and response packets.

Information packets are used for several link management purposes, like link synchronization, error condition signaling, and updating flow control information. Information packets are always 4 bytes long and can only be exchanged among adjacent devices directly interconnected by a link.

On the other hand, request and response control packets are used to build HyperTransport transactions. Request packets, which are 4- or 8-bytes long, are used to initiate HyperTransport transactions. On the other hand, response packets, which are always 4-bytes long, are used in the response phase of transactions to reply to a previous request. [Table 1](#) shows the different request and response types of packets. As can be seen, there are two different types of sized writes: posted and non-posted. Although both types write data to the target device of the request packet, their semantics are different. Non-posted writes require a response packet to be sent back to the requesting device in order to confirm that the operation has completed. On the other hand, posted writes do not require such confirmation.

**HyperTransport. Table 1** Types of request and response control packets

|                 | Packet type                 |
|-----------------|-----------------------------|
| Request packet  | Sized read                  |
|                 | Sized write (non-posted)    |
|                 | Sized write (posted)        |
|                 | Atomic read-modify-write    |
|                 | Broadcast                   |
|                 | Flush                       |
|                 | Fence                       |
|                 | Address extension           |
|                 | Source identifier extension |
| Response packet | Read response               |
|                 | Target done                 |

All the packet types will be further described in next section, except the extension packets. These packets are 4-bytes long extensions that prepend some of the other packets, when required. Their purpose is to allow 64-bit addressing instead of the 40-bit one used by default, in the case of the Address Extension, or 16-bit source identifiers in bus-device-function format in the case of the Source Identifier Extension.

With respect to data packets, they carry the actual data transferred among devices. Data packets only include data, with no associated control field. Therefore, data packets immediately follow the associated control packet. For example, a read response control packet, which includes no data, will be followed by the associated data packet carrying the read data. In the same way, a write request control packet will be followed by the data to be written.

Data packet length depends on the command that generated that data packet. Nevertheless, the maximum length is 64 bytes.

## HyperTransport Transactions

HyperTransport devices transfer data by means of transactions. For example, every time a device requests some data from another device, the former initiates a read transaction targeted to the latter. Write transactions happen in a similar way. For example, when a program writes some data to disk, a write transaction is initiated among the processor, which reads the data from main memory, and the SATA device depicted in Fig. 1. Other transactions include broadcasting a message or explicitly taking control of the order of pending transactions.

Every transaction has a request phase. Request control packets are used in this phase. The exact request control packet to be used depends on the particular transaction taking place. On the other hand, many transactions require a response stage. Response control packets are used in this case, for example, to return read data from the target of the transaction, or to confirm its completion.

There are six basic transaction types:

- Sized read transaction
- Sized write transaction
- Atomic read-modify-write transaction
- Broadcast transaction

- Flush transaction
- Fence transaction

### Sized Read Transaction

Sized read transactions are used by devices when they request data located in the address space of another device. For example, when a device wants to read data from main memory, it starts a read transaction targeted to the main processor. Also, when the processor requires some data from the USB device in Fig. 1, it will issue a read transaction destined to that device.

Read transactions begin with a sized read request control packet being issued by the device requesting the data. Once this packet reaches the destination device, it accesses the requested data and generates a response. This response will be composed of a read response control packet followed by the read data, included in a data packet. Once these two packets arrive at the device that initiated the process, the transaction is completed.

It is noteworthy mentioning that during the time elapsed since the requestor delivered the read request on the link until it receives the corresponding response, the HyperTransport chain is not idle. On the opposite, as HyperTransport is a split transaction protocol, other transactions can be issued (even finalized) before our requestor receives the required data.

### Sized Write Transaction

Sized write transactions are similar to sized read ones, with the difference that the requestor device writes data to the target device instead of requesting data from it. A write transaction may happen when a device sends data to memory, or when the processor writes back data from memory to disk, for example.

There are two different sized write transactions: posted and non-posted. Posted write transactions start when the requestor sends to the target a posted write request control packet followed by a data packet containing the data to be written. In this case, because of the posted nature of the transaction, no response packet is sent back to the requestor. On the other hand, non-posted write transactions begin with a non-posted write control packet being issued by the requestor (followed by a data packet). In this case, when both packets reach the destination and the data are written, the target issues back a target-done response control packet to the requestor. When the requestor receives this response, the transaction is finished.

## Atomic Read-Modify-Write Transaction

Atomic read-modify-write transactions are intended to atomically access a memory location and modify it. This means that no other device in the system may access the same memory location during the time required to read and modify it. This is useful to avoid race conditions among devices while performing the mutual exclusion required to access a critical section, for example.

Two different types of atomic operations are allowed:

- Fetch and Add
- Compare and Swap

The Fetch and Add operation is:

```
Fetch_and_Add(Out, Addr, In) {
 Out = Mem[Addr];
 Mem[Addr] = Mem[Addr] + In;
}
```

The Compare and Swap operation is:

```
Compare_and_Swap(Out, Addr, Compare,
 In) {
 Out = Mem[Addr];
 If (Mem[Addr] == Compare) Mem[Addr]
 = In;
}
```

The atomic transaction begins when the requestor issues an atomic read-modify-write request control packet on the link followed by a data packet containing the argument of the atomic operation. Once both packets are received at the target and it performs the requested atomic operation, it will send back a read response control packet followed by a data packet containing the original data read from the memory location.

## Broadcast Transaction

This transaction is used by the processor to communicate information to all HyperTransport devices in the system. This transaction is started with a broadcast request control packet, which can only be issued by the processor. All the other devices accept that packet and forward it to the rest of devices in the system. Broadcast requests include halt, shutdown, and End-Of-Interrupt commands.

## Flush Transaction

Posted writes do not generate any response once completed. Therefore, when a device issues one or more posted writes targeted to the main processor in order to write some data to main memory, the issuing device has no way to know that those writes have effectively completed their way to memory. Thus, if some of the posted writes have not been completely written to memory, that data will not be visible to other devices in the system. In this scenario, flush transactions allow the device that issued the posted writes to make sure that data has reached main memory by flushing all pending posted writes to memory.

Flush transactions begin when a device issues a flush control packet targeted to the processor. Once this control packet reaches the destination, all pending transactions will be flushed to memory and then the processor will generate a target-done response control packet back to the requestor. Once this packet is received, the transaction is completed.

## Fence Transaction

The fence transaction is intended to provide a barrier among posted writes. When a processor (the only possible target of a fence transaction) receives a fence command, it will make sure that no posted write received after the fence command is written to memory before any of the posted writes received earlier than the fence command.

The fence transaction begins when a device issues a fence control packet. No response is generated for this transaction.

## Virtual Channels and Flow Control in HyperTransport

All the different types of control and data packets are multiplexed on the same link and stored in input buffers when they reach the receiving end of the link. Then, they are either accepted by that device in case they are targeted to it or forwarded to the next link in the chain.

If packets are not carefully managed, a protocol deadlock may occur. For example, if many devices in the system issue a large number of non-posted requests, those requests may fill up all the available buffers and hinder responses to make forward progress back to the initial requestors. In this case, requestors would stop

forever because they are waiting for responses that will never arrive because the interconnect is full of requests that avoid responses to advance. Additionally, requests stored in the intermediate buffers will not be able to advance toward their destination because output buffers at the targets will be filled with responses that cannot enter the link, thus hindering targets to accept new requests from the link because they have no free space neither to store them nor to store the responses they would generate. As can be seen, in this situation, no packet can advance because of lack of available free buffers. The result is that the system freezes.

In order to avoid such deadlocks, HyperTransport splits traffic into virtual channels and stores different types of packets in buffers belonging to different virtual channels. Additionally, HyperTransport does not allow that packets traveling in one virtual channel move to another virtual channel. In this way, if non-posted requests use a virtual channel different from the one used by responses, the deadlock described above can be avoided.

HyperTransport defines a base set of virtual channels that must be supported by all HyperTransport devices. Moreover, some additional virtual channel sets are also defined, although support for them is optional. Regarding the base set, it includes three different virtual channels:

- The posted request virtual channel, which carries posted write transactions
- The non-posted request virtual channel, which includes reads, non-posted writes, and flush packets
- The response virtual channel, which is responsible for read responses and target-done control packets

In addition to separate traffic into the three virtual channels mentioned above, each device must implement separate control and data buffers for each of the virtual channels. Therefore, there are six types of buffers:

- Non-posted request control buffer
- Posted request control buffer
- Response control buffer
- Non-posted request data buffer
- Posted request data buffer
- Response data buffer

Figure 3 shows the basic buffer configuration for a HyperTransport link. The exact number of packets that

can be stored in each buffer depends on the implementation. Nevertheless, request and response buffers must contain, at least, enough space to store the largest control packet of that type. Also, all data buffers can hold 64 bytes. Moreover, in order to improve performance, a HyperTransport device may have larger buffers, able to store multiple packets of each type.

The HyperTransport protocol states that a transmitter should not issue a packet that cannot be stored by the receiver. Thus, the transmitter must know how many buffers of each type the receiver has available. To achieve this, a credit-based scheme is used between transmitters and receivers. With such scheme, the transmitter has a counter for each type of buffer implemented at the receiver. When the transmitter sends a packet, it decrements the associated counter. When one of the counters reaches zero, the transmitter stops sending packets of that type. On the other hand, when the receiver frees a buffer, it sends back a NOP control packet (No Operation Packet) to the transmitter in order to update it about space availability.

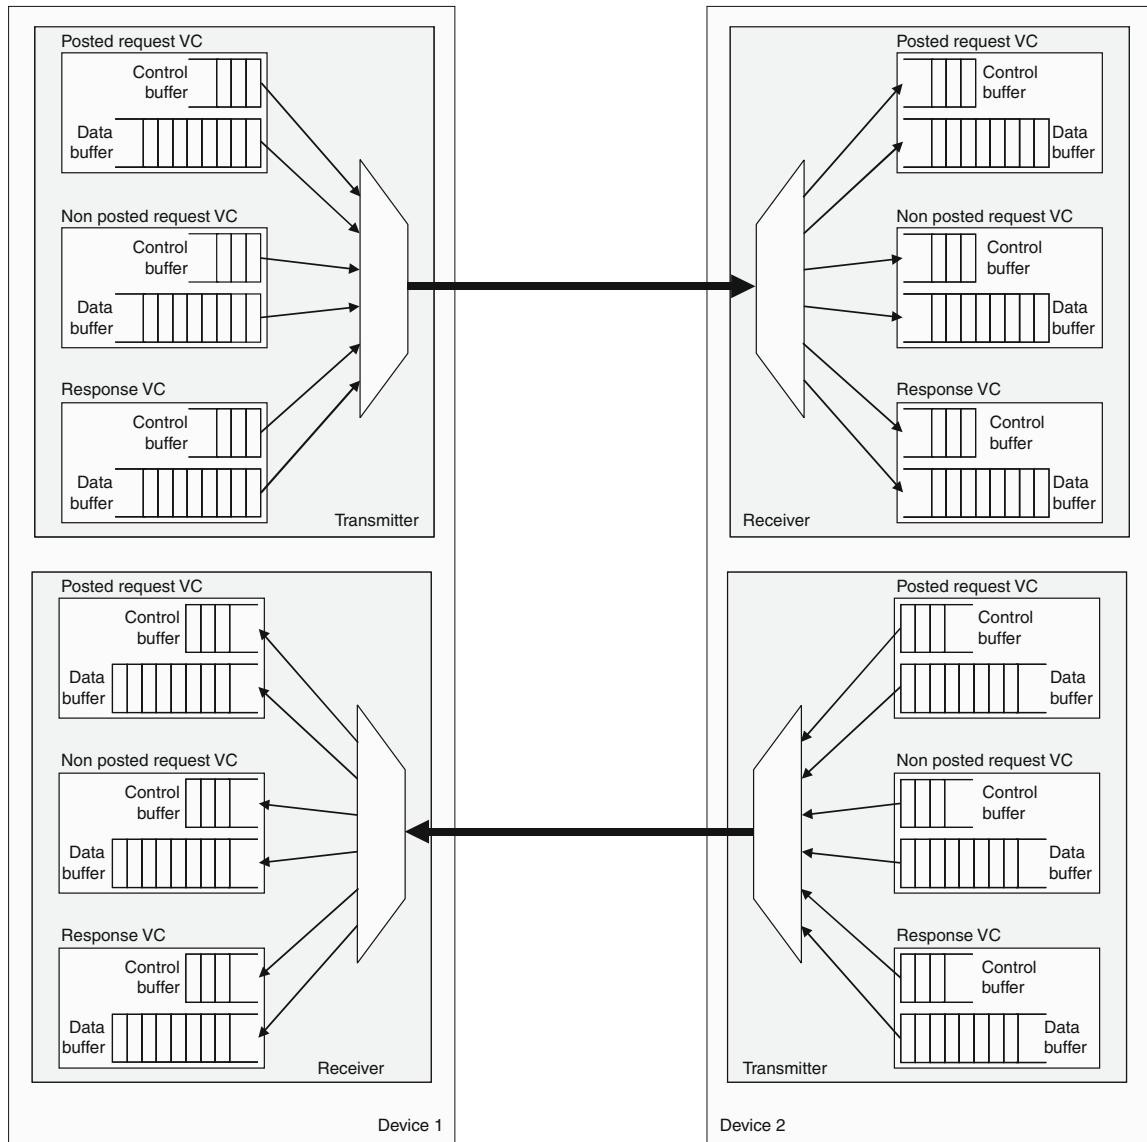

### Extending the HyperTransport Fabric

The system depicted in Fig. 1 consists of several HyperTransport devices interconnected in a daisy chain. However, more complex topologies can also be implemented by using HyperTransport bridges. Bridges in HyperTransport are devices having a primary link connecting toward the processor and one or more secondary links that allow extending the topology in the opposite direction. In this way, HyperTransport trees, like the one shown in Fig. 4, can be implemented.

In addition to the use of bridges, HyperTransport defines two more features able to expand a HyperTransport system. These features are the AC mode and the HTX connector. The AC mode allows devices to be connected over longer distances than allowed by regular links, which make use of the DC mode. On the other hand, the HTX connector allows external expansion cards to be plugged to the HyperTransport link, and be presented to the rest of the system as any other HyperTransport device.

### Improving the Scalability of HyperTransport

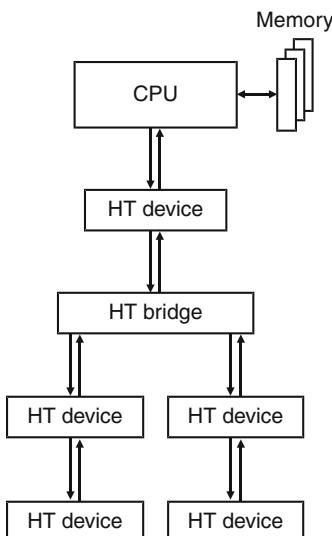

As shown above, HyperTransport offers some degree of scalability that enables the implementation of efficient

HyperTransport. Fig. 3 Buffer configuration for a HyperTransport link

topologies. Nevertheless, as HyperTransport was initially designed to replace traditional system buses, its benefits are mainly confined to interconnects within a single motherboard. Therefore, when HyperTransport topologies are to be scaled to larger sizes, in order to interconnect the processors and I/O subsystems in several motherboards (e.g., an entire cluster), HyperTransport is not able to do so because such large system sizes require routing capabilities that exceed current

HyperTransport ones. More specifically, HyperTransport is not able to provide device addressability beyond 32 devices. Additionally, it does not support efficient routing in scalable network topologies. As a result, high-performance computing vendors have no choice but to complement HyperTransport with other interconnect technologies, like Infiniband in the case for general purpose clusters, or proprietary interconnects, like in the case for Cray's XT4 and XT5 supercomputers [1].

**HyperTransport. Fig. 4** HyperTransport tree topology

In order to overcome the limitations of HyperTransport 3.10, an extension to it named High Node Count HyperTransport Specification was recently released. This extension supports very large system sizes, like the ones found in large data centers, at the same time that it is fully compatible with the HyperTransport specification. Additionally, the new extension adds a few bytes to current HyperTransport packets, but only in the cases where strictly required, thus minimizing the protocol overhead.

Briefly, the new extension provides an improved addressing scheme and a new control packet that allow HyperTransport devices to address any other device in large clusters. Additionally, new HyperTransport connectors and cables have been recently standardized in order to efficiently allow the deployment of the High Node Count HyperTransport Specification.

## Definition

The IBM Blue Gene Supercomputer is a massively parallel system based on the PowerPC processor. A Blue Gene/L system at Lawrence Livermore National Laboratory held the number 1 position in the TOP500 list of fastest computers in the world from November 2004 to November 2007.

## Discussion

### Introduction

The IBM Blue Gene Supercomputer is a massively parallel system based on the PowerPC processor. It derives its computing power from scalability and energy efficiency. Each computing node of Blue Gene is optimized to achieve high computational rate per unit of power and to operate with other nodes in parallel. This approach results in a system that can scale to very large sizes and deliver substantial aggregate performance.

Most large parallel systems in the 2000–2010 time frame followed a model of using off-the-shelf processors (typically from Intel, AMD, or IBM) and interconnecting them with either an industry standard network (e.g., Ethernet or Infiniband) or a proprietary network (e.g., as used by Cray or IBM). Blue Gene took a different approach by designing a dedicated system-on-a-chip (SoC) that included not only processors optimized for floating-point computing, but also the networking infrastructure to interconnect these building blocks into

a large system. This customized approach led to the scalability and power efficiency characteristics that differentiated Blue Gene from other machines that existed at the time of its commercial introduction in 2004.

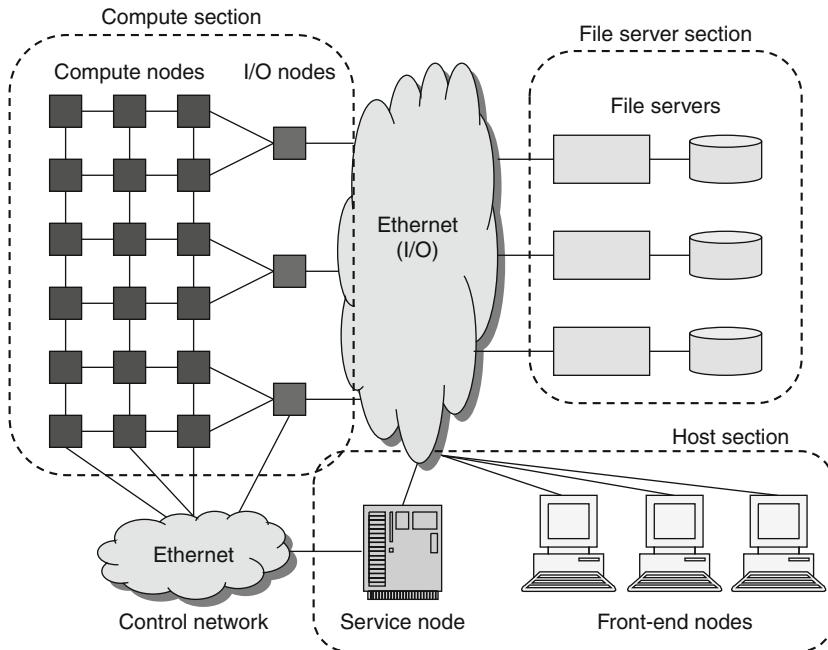

As of 2011, IBM has produced two commercial versions of Blue Gene, Blue Gene/L and Blue Gene/P, which were first delivered to customers in 2004 and 2007, respectively. A third version, Blue Gene/Q, was under development. Both delivered versions follow the same design principles, the same system architecture and the same software architecture. They differ on the specifics of the basic SoC that serves as the building block for Blue Gene. The November 2010 TOP500 list includes four Blue Gene/L system and ten Blue Gene/P systems (and one prototype Blue Gene/Q system). In this article we cover mostly the common aspects of both versions of the Blue Gene supercomputing and discuss details specific to each version as appropriate.

### System Architecture

A Blue Gene system consists of a *compute section*, a *file server section*, and a *host section* (Fig. 1). The compute and I/O nodes in the compute section form the computational core of Blue Gene. User jobs run in the compute nodes, while the I/O nodes connect the compute section to the file servers and front-end nodes through an Ethernet network. The file server section consists of a set of file servers. The host section consists of a *service node* and one or more *front-end nodes*. The service node controls the compute section through an Ethernet control network. The front-end nodes provide job compilation, job submission, and job debugging services.

### Compute Section

The compute section of Blue Gene is what is usually called a Blue Gene machine. It consists of a three-dimensional array of compute nodes interconnected in a toroidal topology along the  $x$ ,  $y$ , and  $z$  axes. I/O nodes are distinct from compute nodes and not in the toroidal

**IBM Blue Gene Supercomputer. Fig. 1** High-level view of a Blue Gene system

interconnect, but also belong to the compute section. A collective network interconnects all I/O and compute nodes of a Blue Gene machine. Each I/O node communicates outside of the machine through an Ethernet link.

Compute and I/O nodes are built out of the same Blue Gene compute ASIC (application-specific integrated circuit) and memory (DRAM) chips. The difference is in the function they perform. Whereas compute nodes connect to each other for passing application data, I/O nodes form the interface between the compute nodes and the outside world by connecting to an Ethernet network. Reflecting the difference in function, the software stacks of the compute and I/O nodes are also different, as will be discussed below.

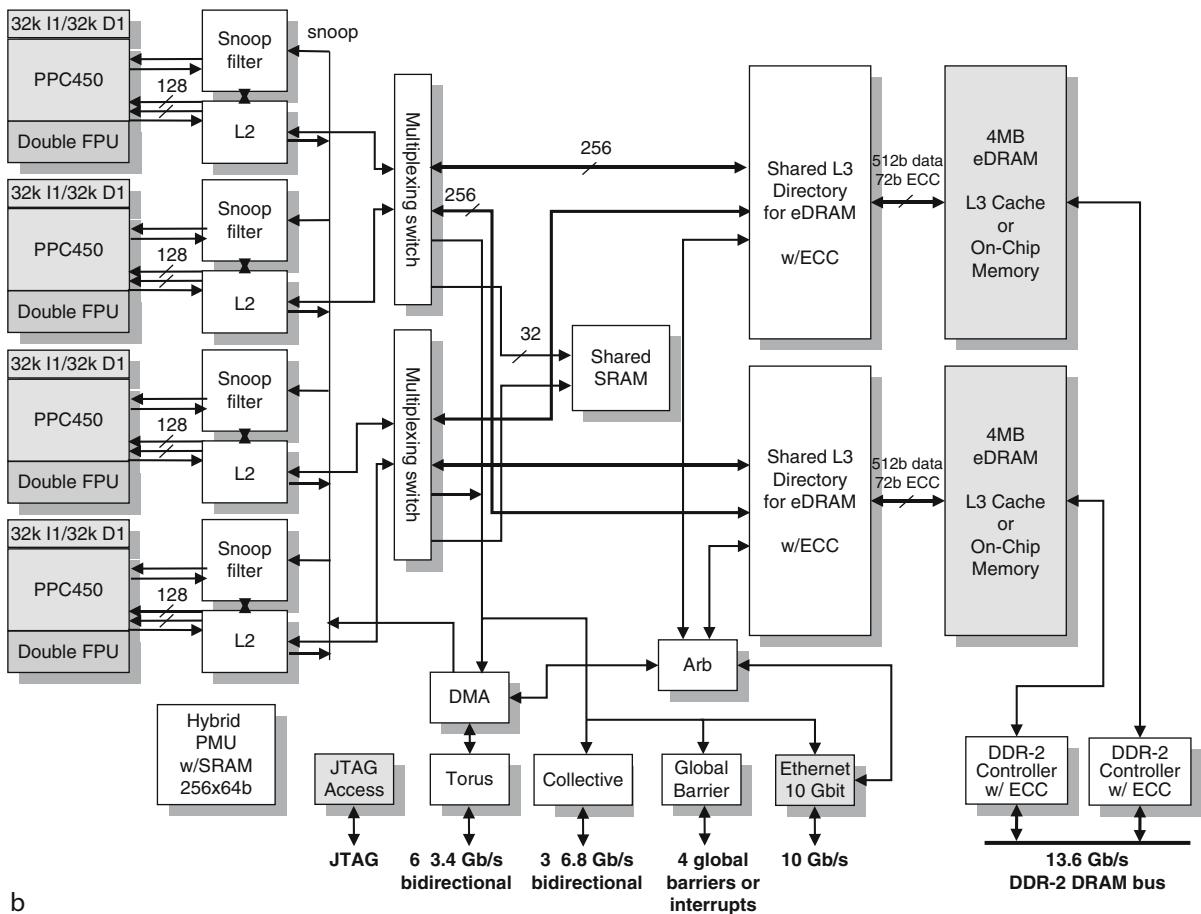

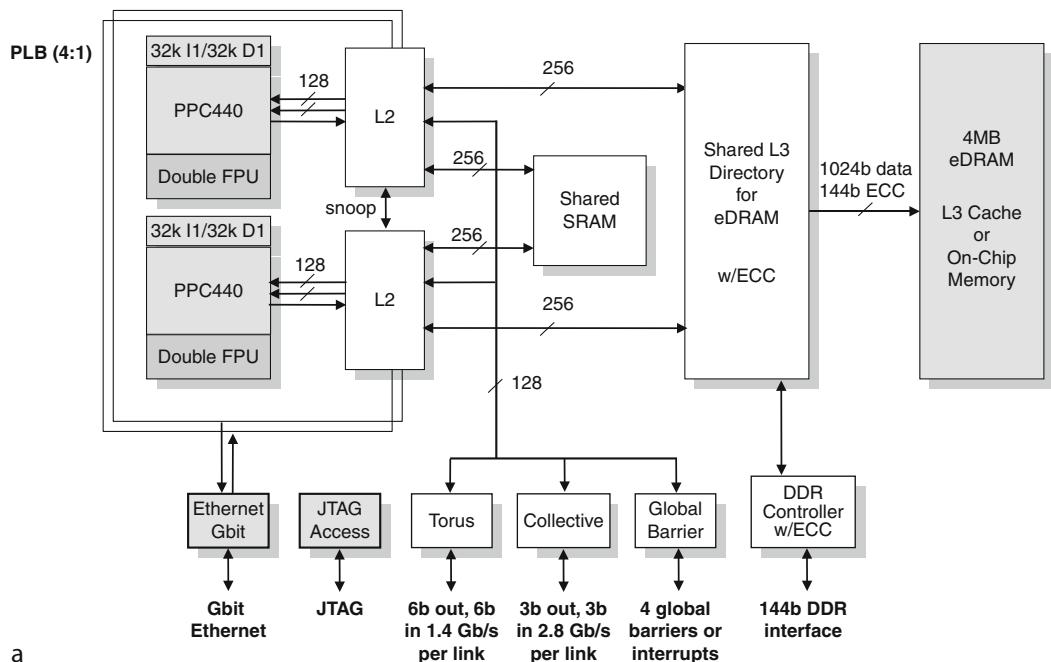

The particular characteristics of the Blue Gene compute ASIC for the two versions (Blue Gene/L and Blue Gene/P) are illustrated in [Fig. 2](#) and summarized in [Table 1](#). The Blue Gene/L compute ASIC contains two non-memory coherent PowerPC 440 cores, each with private L1 data and instruction caches (32 KiB each). Associated with each core is a small (2 KiB) L2 cache that acts as a prefetch engine. Completing the on-chip memory hierarchy is 4 MiB of embedded DRAM (eDRAM) that is configured to operate as a shared L3 cache. Also on the ASIC is a memory controller

(for external DRAM) and interfaces to the five networks used to interconnect Blue Gene/L compute and I/O nodes: torus, collective, global barrier, Ethernet, and control (JTAG) network.

The Blue Gene/P compute ASIC contains four memory coherent PowerPC 450 cores, each with private L1 data and instruction caches (32 KiB each). Associated with each core are both a small (2 KiB) L2 cache that acts as a prefetch engine, as in Blue Gene/L, and a snoop filter to reduce coherence traffic into each core. Two banks of 4 MiB EDRAM are configured to operate as a shared L3 cache. Completing the ASIC are a dual memory controller (for external DRAM), interfaces to the same five networks as Blue Gene/L, and a DMA engine to transfer data directly from the memory of one node to another.

Both the PowerPC 440 and PowerPC 450 cores include a vector floating-point unit that extends the PowerPC instruction set architecture with instructions that assist in matrix and complex-arithmetic operations. The vector floating-point unit can perform two fused multiply-add operations per second for a total of four floating-point operations per cycle per core.

The interconnection networks are primarily used for communication primitives used in parallel high-performance computing applications. The main

**IBM Blue Gene Supercomputer. Table 1** Summary of differences between Blue Gene/L and Blue Gene/P nodes

| Node characteristics                | Blue Gene/L                      | Blue Gene/P                       |
|-------------------------------------|----------------------------------|-----------------------------------|
| Processors                          | Two PowerPC 440                  | Four PowerPC 450                  |
| Processor frequency                 | 700 MHz                          | 850 MHz                           |
| Peak computing capacity             | 5.6 Gflop/s (4 flops/cycle/core) | 13.6 Gflop/s (4 flops/cycle/core) |
| Main memory capacity                | 512 MiB or 1 GiB                 | 2 GiB or 4 GiB                    |
| Main memory bandwidth               | 5.6 GB/s (16 byte @ 350 MHz)     | 13.6 GB/s (2 × 16 byte @ 425 MHz) |
| Torus link bandwidth (6 links)      | 175 MB/s per direction           | 425 MB/s per direction            |
| Collective link bandwidth (3 links) | 350 MB/s per direction           | 850 MB/s per direction            |

interconnection network is the torus network, which provides point-to-point and multicast communication across compute nodes. A collective network in a tree topology interconnects all compute and I/O nodes and supports efficient collective operations, such as reductions and broadcasts. Arithmetic and logical operations are implemented as part of the communication primitives to facilitate low-latency collective operations. A global barrier network supports fast synchronization and notification across compute and I/O nodes. The Ethernet network is used to connect the I/O nodes outside the machine, as previously discussed. Finally, the control network is used to control the hardware from the service node. [Figure 3](#) illustrates the topology of the various networks.

Compute and I/O nodes are grouped into units of *midplanes*. A midplane contains 16 node cards and each node card contains 32 compute nodes and up to four (Blue Gene/L) or two (Blue Gene/P) I/O nodes. The 512 compute nodes in a midplane are arranged as an  $8 \times 8 \times 8$  three-dimensional mesh. Midplanes are typically configured with 8–32 (Blue Gene/P) or 8–64 (Blue Gene/L) I/O nodes. Each midplane also has 24 link chips used for inter-midplane connection to build larger systems. The link chips also implement the “closing” of the toroidal interconnect, by connecting the two ends of a dimension. Midplanes are arranged two to a rack, and racks are arranged in a two-dimensional layout of rows and columns. Because the midplane is the basic replication unit, the dimensions of the array of compute nodes must be a multiple of 8.

The configuration of the original Blue Gene/L system at Lawrence Livermore National Laboratory (LLNL) is shown in [Fig. 4](#). That machine was later upgraded to 104 racks and is the largest Blue Gene

system delivered to date. The highest performing Blue Gene system delivered to date is a 72-rack Blue Gene/P system at Juelich Research Center. Several single-rack (1,024 compute nodes) Blue Gene systems, as well as systems of intermediate size, were also delivered to various customers.

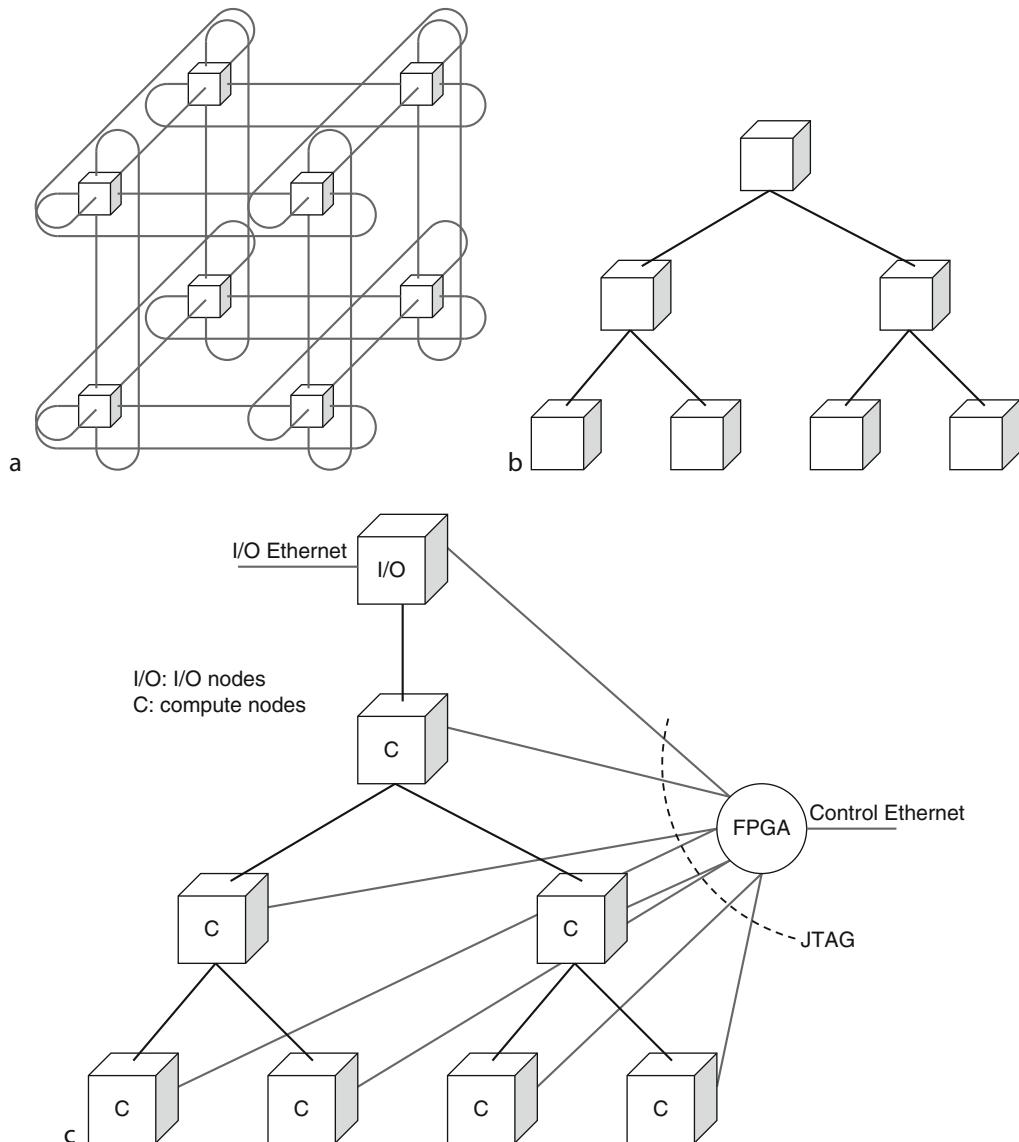

A given Blue Gene machine can be partitioned along midplane boundaries. A partition is formed by a rectangular arrangement of midplanes. Each partition can run only one job at any given time. During each job, all the compute nodes of a partition stay in the same execution mode for the duration of the job. These modes of execution are described in section Overall Operating System Architecture.

## File Server Section

The file server section of a Blue Gene system provides the storage for the file system that runs on the Blue Gene I/O nodes. Several parallel file systems have been ported to Blue Gene, including GPFS, PVFS2, and Lustre. To feed data to a Blue Gene system, multiple servers are required to achieve the required bandwidth. The original Blue Gene/L system at LLNL, for example, uses 224 servers operating in parallel. Data is striped across those servers, and a multi-level switching Ethernet network is used to connect the I/O nodes to the servers. The servers themselves are standard rack-mounted machines, typically Intel, AMD, or POWER processor based.

## Host Section

The host section for a Blue Gene/L system consists of one service node and one or more front-end nodes. These nodes are standard POWER processor machines. For the LLNL machine, the service node is a

**IBM Blue Gene Supercomputer. Fig. 3** Blue Gene networks. Three-dimensional torus (**a**), collective network (**b**), and control network and Ethernet (**c**)

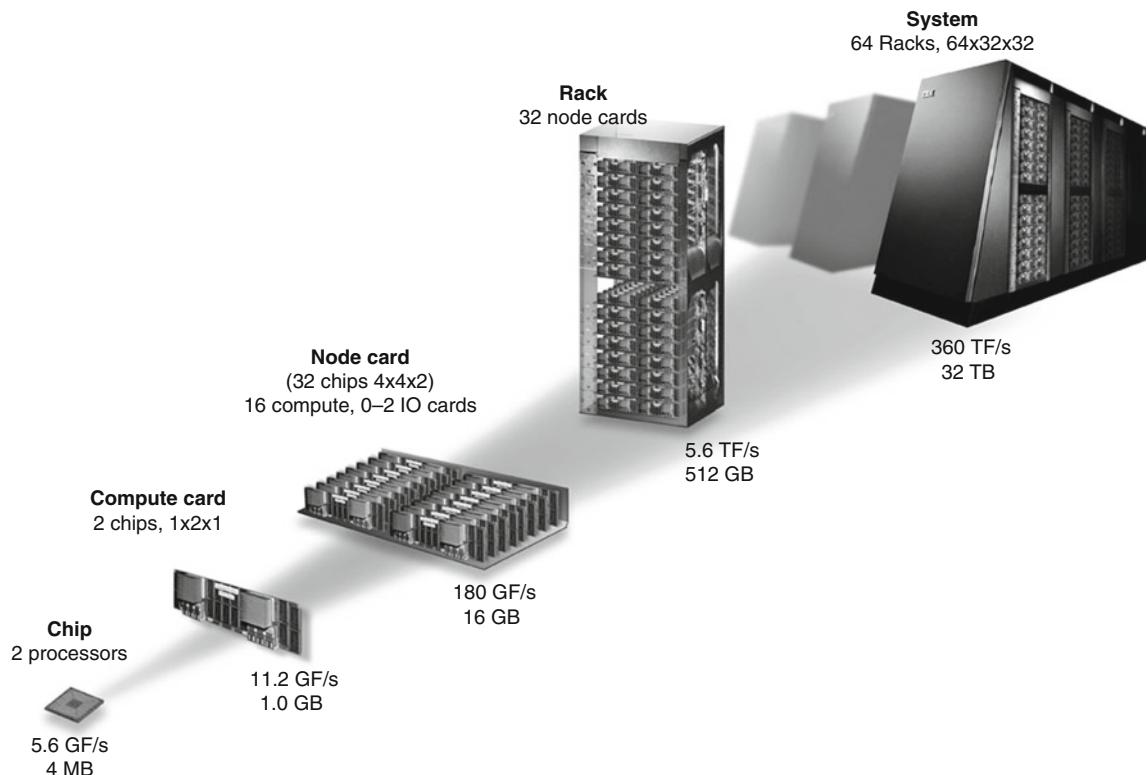

16-processor POWER4 machine, and each of the 14 front-end nodes is a PowerPC 970 blade.

The service node is responsible for controlling and monitoring the operation of the compute section. The services it implements include: machine partitioning, partition boot, application launch, standard I/O routing, application signaling and termination, event monitoring (for events generated by the compute and I/O nodes), and environmental monitoring (for things like power supply voltages, fan speeds, and temperatures).

The front-end nodes are where users work. They provide access to compilers, debuggers, and job submission services. Console I/O from user applications are routed to the submitting front-end node.

### Blue Gene System Software

The primary operating system for Blue Gene compute nodes is a lightweight operating system called the Compute Node Kernel (CNK). This simple kernel implements only a limited set of services, which are

**IBM Blue Gene Supercomputer.** Fig. 4 Packaging hierarchy for the original Blue Gene/L at Lawrence Livermore National Laboratory

complemented by services provided by the I/O nodes. The I/O nodes, in turn, run a version of the Linux operating system. The I/O nodes act as gateways between the outside world and the compute nodes, complementing the services provided by the CNK with file and socket operations, debugging, and signaling.

This split of functions between I/O and compute nodes, with the I/O nodes dedicated to system services and the compute nodes dedicated to application execution, resulted in a simplified design for both components. It also enables Blue Gene scalability and robustness and achieves a deterministic execution environment.

Scientific middleware for Blue Gene includes a user-level library implementation of the MPI standard, optimized to take advantage of Blue Gene networks, and various math libraries, also in the user level. Implementing all the message passing functions in user mode simplifies the supervisor (kernel) code of Blue Gene and results in better performance by reducing the number of kernel system calls that an application performs.

### Overall Operating System Architecture

A key concept in the Blue Gene operating system solution is the organization of compute and I/O nodes into logical entities called processing sets or psets. A pset consists of one I/O node and a collection of compute nodes. Every system partition, in turn, is organized as a collection of psets. All psets in a partition must have the same number of compute nodes, and the psets of a partition must cover all the I/O and compute nodes of the partition. The psets of a partition never overlap. The supported pset sizes are 8 (Blue Gene/L only), 16, 32, 64, and 128 compute nodes, plus the I/O node. The psets are a purely logical concept implemented by the Blue Gene system software stack. They are built to reflect the topological proximity between I/O and compute nodes, thus improving communication performance within a pset.

A Blue Gene job consists of a collection of  $N$  compute processes. Each process has its own private address space and two processes of the same job communicate only through message passing. The

primary communication model for Blue Gene is MPI. The  $N$  compute processes of a Blue Gene job correspond to tasks with ranks 0 to  $N - 1$  in the MPI COMM WORLD communicator. Compute processes run only on compute nodes; conversely, compute nodes run only compute processes.

In Blue Gene/L, the CNK implements two modes of operation for the compute nodes: coprocessor mode and virtual node mode. In the coprocessor mode, the single process in the node has access to the entire node memory. One processor executes user code while the other performs communication functions. In virtual node mode, the node memory is split in half between the two processes running on the two processors. Each process performs both computation and communication functions.

In Blue Gene/P, the CNK provides three modes of operation for the compute nodes: SMP mode, dual mode, and quad mode. The SMP mode supports a single multithreaded (up to four threads) application process per compute node. That process has access to the entire node memory. Dual mode supports two multithreaded (up to two threads each) application processes per compute node. Quad mode supports four single-threaded application processes per compute node. In dual and quad modes, the application processes in a node split the memory of that node. Blue Gene/P supports at most one application thread per processor. It also supports an optional communication thread in each processor.

Each I/O node runs one image of the Linux operating system. It can offer the entire spectrum of services expected in a Linux box, such as multiprocessing, file systems, and a TCP/IP communication stack. These services are used to extend the capabilities of the compute node kernel, providing a richer functionality to the compute processes. Due to the lack of cache coherency between the processors of a Blue Gene/L node, only one of the processors of each I/O node is used by Linux, while the other processor remains idle. Since the processors in a Blue Gene/P node are cache coherent, Blue Gene/P I/O nodes can run a true multiprocessor Linux instance.

## The Compute Node Kernel

CNK is a lean operating system that performs a simple sequence of operations at job start time. This sequence

of operations happens in every compute node of a partition, at the start of each job:

1. It creates the address space(s) for execution of compute process(es) in a compute node.
2. It loads code and initialized data for the executable of that (those) process(es).
3. It transfers processor control to the loaded executable, changing from supervisor to user mode.

The address spaces of the processes are flat and fixed, with no paging. The entire mapping is designed to fit statically in the TLBs of the PowerPC processors. The loading of code and data occurs in push mode. The I/O node of a pset reads the executable from the file system and forwards it to all compute nodes in the pset. The CNK in a compute node receives that executable and stores the appropriate memory values in the address space(s) of the compute process(es).

Once the CNK transfers control to the user application, its primary mission is to “stay out of the way.” In normal execution, the processor control stays with the compute process until it requests an operating system service through a system call. Exceptions to this normal execution are caused by hardware interrupts: either timer alarms requested by the user code, communication interrupts caused by arriving packets, or an abnormal hardware event that requires attention by the compute node kernel.

When a compute process makes a system call, three things may happen:

1. “Simple” system calls that require little operating system functionality, such as getting the time or setting an alarm, are handled locally by the compute node kernel. Control is transferred back to the compute process at completion of the call.
2. “I/O” system calls that require infrastructure for file systems and IP stack are shipped for execution in the I/O node associated with that compute node (i.e., the I/O node in the pset of the compute node). The compute node kernel waits for a reply from the I/O node, and then returns control back to the compute process.
3. “Unsupported” system calls that require infrastructure not present in Blue Gene are returned right away with an error condition.

There are two main benefits from the simple approach for a compute node operating system: robustness and scalability. Robustness comes from the fact that the compute node kernel performs few services, which greatly simplify its design, implementation, and test. Scalability comes from lack of interference with running compute processes.

### System Software for the I/O Node

The I/O node plays a dual role in Blue Gene. On one hand, it acts as an effective master of its corresponding pset. On the other hand, it services requests from compute nodes in that pset. Jobs are launched in a partition by contacting corresponding I/O nodes. Each I/O node is then responsible for loading and starting the execution of the processes in each of the compute nodes of its pset. Once the compute processes start running, the I/O nodes wait for requests from those processes. Those requests are mainly I/O operations to be performed against the file systems mounted in the I/O node.

Blue Gene I/O nodes execute an embedded version of the Linux operating system. It is classified as an embedded version because it does not use any swap space, it has an in-memory root file system, it uses little memory, and it lacks the majority of daemons and services found in a server-grade configuration of Linux. It is, however, a complete port of the Linux kernel and those services can be, and in various cases have been, turned on for specific purposes. The Linux in Blue Gene I/O nodes includes a full TCP/IP stack, supporting communications to the outside world through Ethernet. It also includes file system support. Various network file systems have been ported to the Blue Gene/L I/O node, including GPFS, Lustre, NFS, and PVFS2.

Blue Gene/L I/O nodes never run application processes. That duty is reserved to the compute nodes. The main user-level process running on the Blue Gene/L I/O node is the control and I/O daemon (CIOD). CIOD is the process that links the compute processes of an application running on compute nodes to the outside world. To launch a user job in a partition, the service node contacts the CIOD of each I/O node of the partition and passes the parameters of the job (user ID, group ID, supplementary groups, executable name, starting working directory, command-line arguments, and environment variables). CIOD swaps itself to the user's identity,

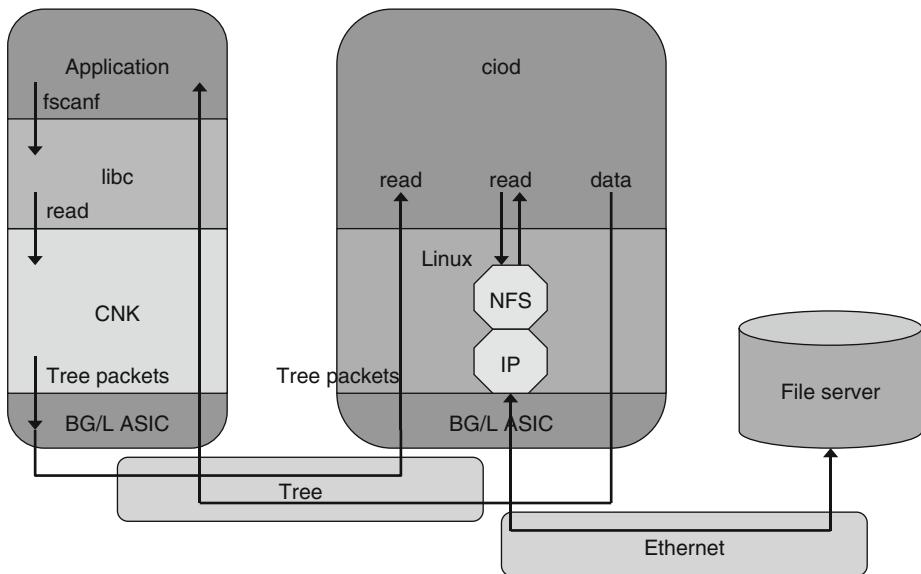

which includes the user ID, group ID, and supplementary groups. It then retrieves the executable from the file system and sends the code and initialized data through the collective network to each of the compute nodes in the pset. It also sends the command-line arguments and environment variables, together with a start signal.

[Figure 5](#) illustrates how I/O system calls are handled in Blue Gene. When a compute process performs a system call requiring I/O (e.g., open, close, read, write), that call is trapped by the compute node kernel, which packages the parameters of the system call and sends that message to the CIOD in its corresponding I/O node. CIOD unpacks the message and then reissues the system call, this time under the Linux operating system of the I/O node. Once the system call completes, CIOD packages the result and sends it back to the originating compute node kernel, which, in turn, returns the result to the compute process.

There is a synergistic effect between simplification and separation of responsibilities. By offloading complex system operations to the I/O node, Blue Gene keeps the compute node operating system simple. Correspondingly, by keeping application processes separate from the I/O node activity, it avoids many security and safety issues regarding execution in the I/O nodes. In particular, there is never a need for the common scrubbing daemons typically used in Linux clusters to clean up after misbehaving jobs. Just as keeping system services in the I/O nodes prevents interference with compute processes, keeping those processes in compute nodes prevents interference with system services in the I/O node. This isolation is particularly helpful during performance debugging work. The overall simplification of the operating system has enabled the scalability, reproducibility (performance results for Blue Gene applications are very close across runs), and high-performance of important Blue Gene/L applications.

### System Software for the Service Node

The Blue Gene service node runs its control software, typically referred to as the Blue Gene control system. The control system is responsible for the operation and monitoring of all compute and I/O nodes. It is also responsible for other hardware components such as link chips, power supplies, and fans. Tight integration between the Blue Gene control system and the I/O and compute nodes operating systems is central to the Blue

**IBM Blue Gene Supercomputer. Fig. 5** Function shipping between CNK and CIOD

Gene software stack. It represents one more step in the specialization of services that characterize that stack.

In Blue Gene, the control system is responsible for setting up system partitions and loading the initial code and state in the nodes of a partition. The Blue Gene compute and I/O nodes are completely stateless: no hard drives and no persistent memory. When a partition is created, the control system programs the hardware to isolate that partition from others in the system. It computes the network routing for the torus, collective, and global interrupt networks, thus simplifying the compute node kernel. It loads the operating system code for all compute and I/O nodes of a partition through the dedicated control network. It also loads an initial state in each node (called the personality of the node). The personality of a node contains information specific to the node.

### Blue Gene and Its Impact on Science

Blue Gene was designed to deliver a level of performance for scientific computing that enables entire new studies and new applications. One of the main areas of applications of the original LLNL system is in materials' science. Scientists at LLNL use a variety of models, including quantum molecular dynamics, classical molecular dynamics, and dislocation dynamics, to study materials at different levels of resolution.

Typically, each model is applicable to a range of system sizes being studied. First principle models can be used for small systems, while more phenomenological models have to be used for large systems. The original Blue Gene/L at LLNL was the first system that allowed crossing of those boundaries. Scientists can use first principle models in systems large enough to validate the phenomenological models, which in turn can be used in even larger systems.

Applications of notable significance at LLNL include ddcMD, a classical molecular dynamics code that has been used to simulate systems with approximately half a billion atoms (and in the process win the 2005 Gordon Bell award), and QBox, a quantum molecular dynamics code that won the 2006 Gordon Bell award. Other success stories for Blue Gene in science include: (1) astrophysical simulations in Argonne National Laboratory (ANL) using the FLASH code; (2) global climate simulations in the National Center for Atmospheric Research (NCAR) using the HOMME code; (3) biomolecular simulations at the T.J. Watson Research Center using the Blue Matter code; and (4) quantum chromo dynamics (QCD) at IBM T.J. Watson Research Center, LLNL, San Diego Supercomputing Center, Juelich Research Center, Massachusetts Institute of Technology, Boston University, University of Edinburgh, and KEK (Japan) using a variety of codes.

One of the most innovative uses of Blue Gene is as the central processor for the large-scale LOFAR radio telescope in the Netherlands.

## Definition

The IBM Power architecture is an instruction set architecture (ISA) implemented by a variety of processors from IBM and other vendors, including Power7, IBM's

latest server processor. The IBM Power architecture is designed to exploit parallelism at the instruction-, data-, and thread-level.

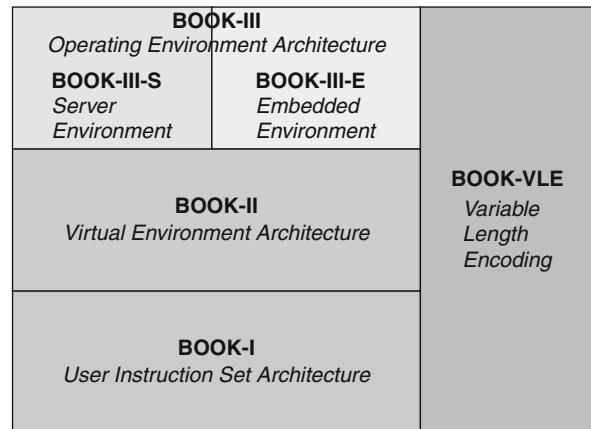

## Discussion

### Introduction

IBM's Power ISA™ is an instruction set architecture designed to expose and exploit parallelism in a wide range of applications, from embedded computing to high-end scientific computing to traditional transaction processing. Processors implementing the Power ISA have been used to create several notable parallel computing systems, including the IBM RS/6000 SP, the Blue Gene family of computers, the Deep Blue chess playing machine, the PERCS system, the Sony Playstation 3 game console, and the Watson system that competed in the popular television show Jeopardy!

Power ISA covers both 32-bit and 64-bit variants and, as of its latest version (2.06 Revision B [8]), is organized in a set of four “books,” as shown in Fig. 1. Books I and II are common to all implementations. Book I, Power ISA User Instruction Set Architecture, covers the base instruction set and related facilities available to the application programmer. Book II, Power ISA Virtual Environment Architecture, defines the storage (memory) model and related instructions and facilities available to the application programmer. In addition to the specifications of Books I and II, implementations of the Power ISA need to follow either Book III-S or Book III-E. Book III-S, Power ISA Operating Environment Architecture – Server Environment, defines the supervisor instructions and related facilities used for general purpose implementations. Book III-E, Power ISA Operating Environment Architecture – Embedded Environment, defines the supervisor instructions and related facilities used for embedded implementations. Finally, Book VLE, Power ISA Operating Environment Architecture – Variable Length Encoding Environment, defines alternative instruction encodings and definitions intended to increase instruction density for very low end implementations.

Figure 2 shows the evolution of the main line of Power architecture server processors from IBM, just one of the many families of products based on Power ISA. The figure shows, for each generation of processors, its introduction date, the silicon technology used,

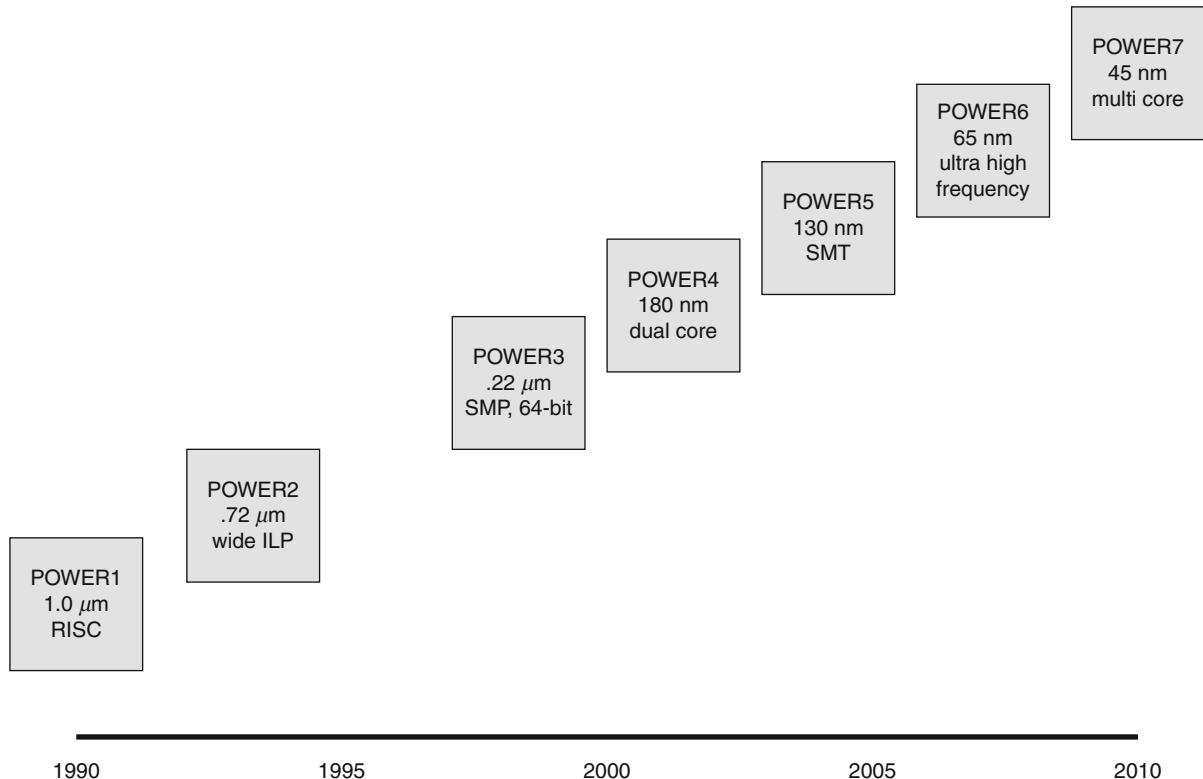

**IBM Power Architecture. Fig. 1** Books of Power ISA version 2.06

and the main architectural innovations delivered in that generation. Power7 [9] is IBM's latest-generations server processor and implements the Power ISA according to Books I, II, and III-S of [8]. Power7 is used in both the PERCS and Watson systems and in a variety of servers offered by IBM. The latest machine in the Blue Gene family, Blue Gene/Q, follows a Book III-E implementation.

Power ISA was designed to support high program execution performance and efficient utilization of hardware resources. To that end, Power ISA provides facilities for expressing instruction-level parallelism, data-level parallelism, and thread-level parallelism. Providing facilities for a variety of parallelism types gives the programmer the flexibility in extracting the particular combination of parallelism that is optimal for his or her program.

### Instruction-Level Parallelism

Instruction-level parallelism (ILP) is the simultaneous processing of several instructions by a processor. ILP is important for performance because it allows instructions to overlap, thus effectively hiding the execution latency of long latency computational and memory access instructions. Achieving ILP has been so important in the processor industry that processor core designs have gone from simple multicycle designs to complex designs that implement superscalar pipelines and out-of-order execution [15]. Key aspects of Power

**IBM Power Architecture. Fig. 2** Evolution of main line Power architecture server processors

ISA that facilitate ILP are independent instruction facilities, reduced set of instructions, fixed length instructions, and large register set.

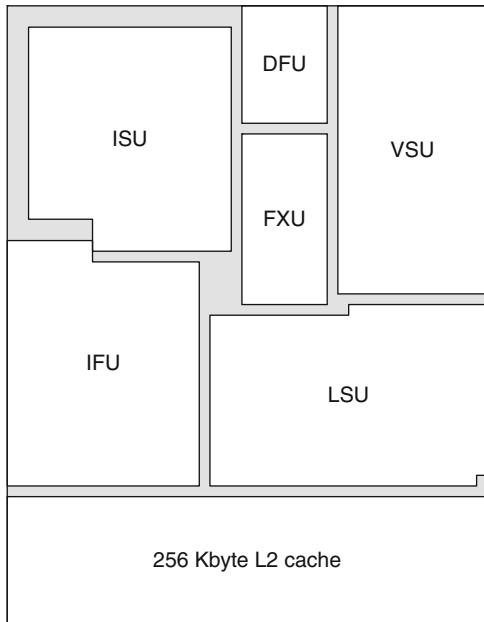

### Independent Instruction Facilities

Conceptually, Power ISA views the underlying processor as composed of several engines or units, as illustrated in the floor plan for the Power7 processor core shown in [Fig. 3](#). Book I of the Power ISA groups the instructions into “facilities,” including (1) the branch facility, with instructions implemented by the instruction fetch unit (IFU); (2) the fixed-point facility, with instructions implemented by the fixed-point unit (FXU) and load-store unit (LSU); (3) the floating-point facility, with instructions implemented by the vector and scalar unit (VSU); (4) the decimal floating-point facility, with instructions implemented by the decimal floating-point unit (DFU); and (5) the vector facility, with instructions implemented by the vector and scalar

unit (VSU). Also shown in [Fig. 3](#) is the instruction-sequencing unit (ISU), which controls the execution of instructions, and a level-2 cache.

Origins of this conceptual decomposition are in the era of building processors with multiple integrated circuits (chips). With a single processor spread across multiple chips, the communication between two integrated circuits took significantly more time relative to communication internal to a chip. Consequently, either the clock frequency would have to be reduced or the number of stages in the processor pipeline would have to be increased. Both approaches, reducing clock frequency and increasing the number of pipeline stages, can degrade performance. The decomposition into multiple units allowed a clear separation of work, and each unit could be implemented on a single chip for maximum performance.

Today, the conceptual decomposition provides two primary benefits. First, because of the conceptual decomposition, the interfaces between the engines

**IBM Power Architecture. Fig. 3** Power7 processor core floor plan, showing the main units

are clearly defined. Clearly defined interfaces lead to hardware design that is simpler to implement and to verify. Second, the conceptual decomposition addresses the inability of scaling frequency of long on-chip wires that can be a performance limiter, just as it addressed wiring issues between two or more integrated circuits when the conceptual decomposition was introduced.

### Reduced Set of Nondestructive Fixed Length Instructions

Power ISA consists of a reduced set of fixed length 32-bit instructions. A large fraction of the set of instructions are nondestructive. That is, the result register is explicitly identified, as opposed to implicitly being one of the source registers. A reduced set of instructions simplifies the design of the processor core and also verification of corner cases in the hardware.

Ignoring the Book-VLE case, which is targeted to very low end systems, Power ISA instructions are all 32-bits in length, thus the beginning and end of every instruction is known before decode. The bits in an instruction word are numbered from 0 (most significant) to 31 (least significant), following the big-endian

convention of the Power architecture. All Power ISA instructions have a major opcode that is located at instruction bits 0–5. Some instructions also have a minor opcode, to differentiate among instructions with the same major opcode. The location and length of the minor opcode depends on the major opcode. Additionally, every instruction is word-aligned. Fixed length, word aligned, and fixed opcode location make the instruction predecode, fetch, branch prediction, and decode logic simpler, when compared to the decode logic of variable length ISA. Srinivasan et al. [16] present a comprehensive study of optimality of pipeline length of Power processors from a power and performance perspective.

Instruction set architectures that employ destructive operations (i.e., one of the source registers is also the target) must temporarily save one of the source registers, if the contents of that register are required later in the program. Temporarily saving and later restoring registers often lead to store to and load from, respectively, a memory location. Memory operations can take longer to complete than a computational operation. Nondestructive operations in Power ISA eliminate the need for extra instructions for saving and restoring one of the source registers, facilitating higher instruction level parallelism.

### Large Register Set

Power ISA originally specified 32 general-purpose (fixed-point, either 32- or 64-bit) and 32 floating-point (64-bit) registers. An additional set of 32 vector (128-bit) registers were added with the first set of vector instructions. The latest specification, Power ISA 2.06, expands the number of vector registers to 64. A large number of registers means that more data, including function and subroutine parameters, can be kept in fast registers. This in turn avoids load/store operations to save and retrieve data to and from memory and supports concurrent execution of more instructions.

### Load/Store Architecture

Power ISA specifies a load-store architecture consisting of two distinct types of instructions: (1) memory access instructions, and (2) compute instructions. Memory

access instructions load data from memory into computational registers and store the data from the computational registers to the memory. Compute instructions perform computations on the data residing in the computational registers. This arrangement decouples the responsibilities of the memory instructions and computational instructions, providing a powerful lever to hide the memory access latency by overlapping the long latency of memory access instructions with compute instructions.

### **ILP in Power7**

Power7 is an out-of-order superscalar processor that can operate at frequencies exceeding 4 GHz. In a given clock cycle, a Power7 processor core can fetch up to eight instructions, decode and dispatch up to six instructions, issue and execute up to eight instructions, and commit up to six instructions. To ensure a high instruction throughput, Power7 can simultaneously maintain about 250 instructions in various stages of processing. To further extract independent instruction for parallelism, Power7 implements register renaming – each of the architected register files are mapped to a much larger set of physical registers. Execution of the instructions is carried out by a total of 12 execution units. Power7 implements the Power ISA in a way that extracts high levels of instruction-level parallelism while operating at a high clock frequency.

### **Data Level Parallelism**

Data-level parallelism (DLP) consists of simultaneously performing the same type of operations on different data values, using multiple functional units, with a single instruction. The most common approach of providing DLP in general purpose processors is the Single Instruction Multiple Data (SIMD) technique. SIMD (also called vector) instructions provide a concise and efficient way to express DLP. With SIMD instructions, fewer instructions are required to perform the same data computation resulting in lower fetch, decode and dispatch bandwidth, and consequently higher power efficiency.

Power ISA 2.06 contains two sets of SIMD instructions. The first one is the original set of instructions implemented by the vector facility since 1998 and also known as AltiVec [6] or Vector Media Extensions

(VMX) instructions. The second is a new set of SIMD instructions called Vector-Scalar Extension (VSX).

### **VMX Instructions**

VMX instructions operate on 128-bit wide data, which can be vectors of byte (8-bit), half-word (16-bit) and word (32-bit) elements. The word elements can be either integer or single-precision floating-point numbers. The VMX instructions follow the load/store model, with a 32-entry register set (each entry is 128-bit wide) that is separate from the original (scalar) fixed- and floating-point registers in Power ISA 2.06.

### **VSX Instructions**

VSX also operates on 128-bit wide data, which can be vectors of word (32-bit) and double word (64-bit) elements. Most operations are on floating-point numbers (single and double precision) but VSX also includes integer conversion and logical operations. VSX instructions also follow the load/store model, with a 64-entry register set (128 bits per entry) that overlaps the VMX and floating-point registers. VSX requires no operating-mode switches. Therefore, it is possible to interleave VSX instructions with floating point and integer instructions.

### **Power7 Vector and Scalar Unit (VSU)**

The vector and scalar unit of Power7 is responsible for execution of the VMX and VSX SIMD instructions. The unit contains one vector pipeline and four double-precision floating-point pipelines. A VSX floating-point instruction uses two floating-point pipelines, and two VSX instructions can be issued every cycle, to keep all floating-point pipelines busy. The four floating-point pipelines can each execute a double-precision fused multiply-add operation, leading to a performance of 8 flops/cycle for a Power7 core.

### **Thread Level Parallelism**

Thread-level parallelism (TLP) is the simultaneous execution of multiple threads of instructions. Unlike ILP and DLP, that rely on extracting parallelism from within the same program thread, TLP relies on explicit parallelism from multiple concurrently running threads. The multiple threads can come from the decomposition of

a single program or from multiple independent programs.

### Thread Level Parallelism Within a Processor Core

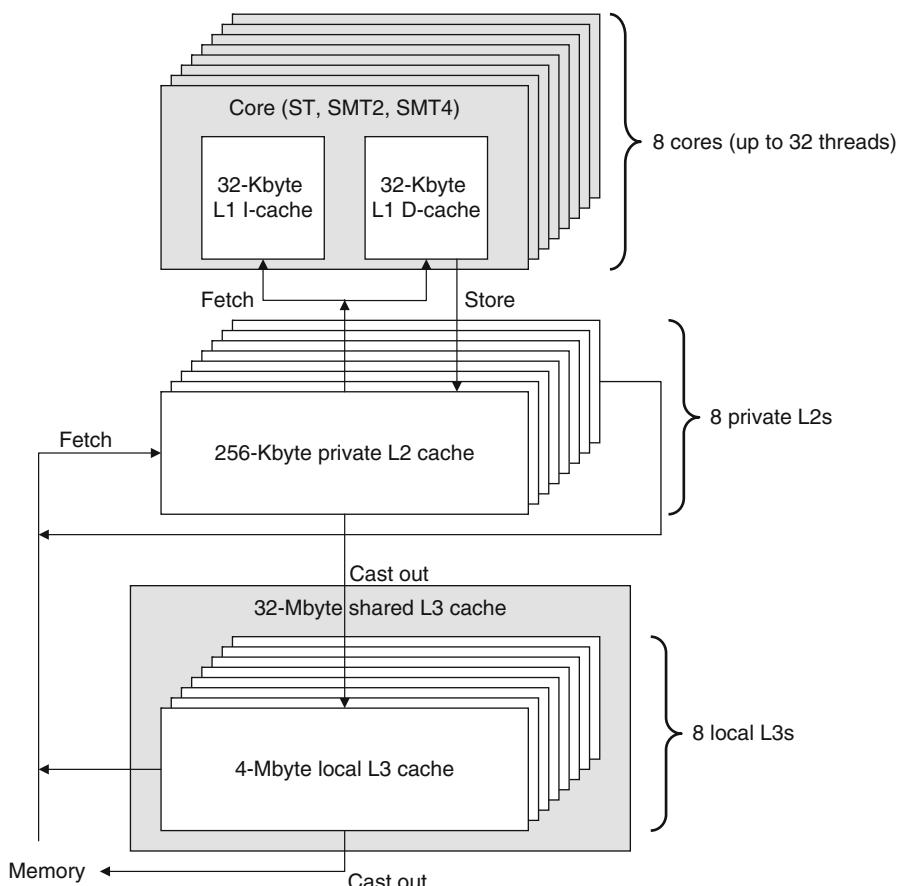

In the first systems that exploited thread-level parallelism, different threads executed on different processor cores and shared a memory system. Today, processor core designs have evolved such that multiple threads can run on single processor core. This increases resource utilization and, consequently, the computational throughput of the core. Effectively, TLP within a core enables hiding of the long latency events of stalled threads with forward progress of active threads. Examples of Power ISA processors that support multithreading within a core include Power5 [14], Power6 [10], and Power7 [9] processors.

### Memory Coherence Models

For programs where the concurrent threads share memory while working on a common task, the memory consistency model of the architectures plays a key role in the performance of TLP as a function of the number of threads. The memory consistency model specifies how memory references from different threads can be interleaved. Power ISA specifies a *release consistency* memory model. A release consistency model relaxes the ordering of memory references as seen by different threads. When a particular ordering of memory references among threads is necessary for the program, explicit synchronization operations must be used.

### TLP Support in Power7 Processor

The structure of a Power7 processor chip is shown in Fig. 4. There are eight processor cores and three levels of cache in a single chip. Each processor core (which

IBM Power Architecture. Fig. 4 Structure of a Power7 Processor Chip

includes 32-Kbyte level 1 data and instruction caches) is paired with a 256-Kbyte level 2 (L2) cache that is private to the core. There is also a 32-Mbyte level 3 (L3) cache that is shared by all cores. The level 3 cache is organized as eight 4-Mbyte caches, each local to a core/L2 pair. Cast outs from an L2 cache can only go to its local L3 cache, but from there data can be cast out across the eight local L3s.

Each core is capable of operating in three different threading modes: single-threaded (ST), dual-threaded (SMT2), or quad-threaded (SMT4). The cores can switch modes while executing, thus adapting to the needs of different applications. The ST mode delivers higher single-thread performance, since the resources of a core are dedicated to the execution of that single thread. The SMT4 mode partitions the core resources among four threads, resulting in higher total throughput at the cost of reduced performance for each thread. The SMT2 mode is an intermediate point.

A single Power7 processor chip supports up to 32 simultaneous threads of execution (8 cores, 4 threads per core). Power7 scales to systems of 32 processor chips or up to 1024 threads of execution sharing a single memory image.

## Summary

Since its inception in the Power1 processor in 1991, the Power architecture has evolved to address the technology and applications issues of the time. The ability of Power architecture to provide instruction-, data-, and thread-level parallelism has enabled a variety of parallel systems, including some notable supercomputers.

Power ISA allows exposing and extraction of ILP primarily because of the RISC principles embodied in the ISA. The reduced set of fixed length instructions enables simple hardware implementation that can be efficiently pipelined, thus increasing concurrency. The larger register set provides several optimization opportunities for the compiler as well as the hardware.

Power ISA provides facilities for data-level parallelism via SIMD instructions. VMX and VSX instructions increase the computational efficiency of the processor by performing the same operation on multiple data values. For some programs DLP can be extracted automatically by the compiler. For others, explicit SIMD programming is more appropriate.

Power ISA supports thread-level parallelism through a release consistency memory model. Because of the release consistency, Power ISA based systems permit aggressive software and hardware optimizations that would otherwise be restricted under a sequential consistency model.

The Power7 processor implements the latest version of Power ISA and exploits all forms of parallelism supported by the instruction set architecture: instruction-level parallelism, data-level parallelism, and thread-level parallelism.

## Bibliographic Notes

Official information on the Power instruction set architecture is available in the POWER.ORG website ([www.power.org](http://www.power.org)). In particular, the latest version of the Power ISA (2.06 revision B), implemented by the Power7 processor, can be found in [8].

An early history of the Power architecture is provided by Diefendorff [3]. Details of Power architecture including the instruction specification and programming environment are given in several reference manuals [7, 11–13].

Evolution of IBM's RISC philosophy is explained in [2]. More detailed information on the microarchitecture of specific Power processors can be found for Power4 [17], Power5 [14], Power6 [10], and Power7 [9] processors.

The AltiVec Programming Environment Manual [12] and AltiVec Programming Interface Manual [13] are two thorough references for effectively employing AltiVec. Gwennap [6] and Diefendorff [4] have a good survey of Power AltiVec.

Methods for extracting instruction-level parallelism for the Power architecture are described in [7]. One of the key impediments to data-level parallelism is unaligned memory accesses. To overcome these unaligned accesses Eichenberger, Wu and O'Brien [5] present some data-level parallelism optimization techniques. Finally, Adve and Gharacharloo's tutorial on

shared memory consistency model [1] is a great reference for further reading on thread-level parallelism.

## IBM RS/6000 SP

JOSÉ E. MOREIRA

IBM TJ. Watson Research Center, Yorktown Heights, NY, USA

### Synonyms

[IBM SP](#); [IBM SP1](#); [IBM SP2](#); [IBM SP3](#)

### Definition

The IBM RS/6000 SP is a distributed memory, message passing parallel system based on the IBM POWER processors. Several generations of the system were developed by IBM and thousands of systems were delivered to customers. The pinnacle of the IBM RS/6000 SP was the ASCI White machine at Lawrence Livermore National Laboratory, which held the number 1 spot in the TOP500 list from November 2000 to November 2001.

### Discussion

#### Introduction

The IBM RS/6000 SP (SP for short) is a general-purpose parallel system. It was one of the first parallel systems designed to address both technical computing applications (the usual domain of parallel supercomputers) and commercial applications (e.g., database servers, transaction processing, multimedia servers). The SP is a distributed memory, message passing parallel system. It consists of a set of nodes, each running its own operating system image, interconnected by a high-speed network. In the TOP500 classification, it falls into the cluster class of machines.

IBM delivered several generations of SP machines, all based on IBM POWER processors. The initial machines were simply called the IBM SP (or SP1) and were based on the original POWER processors. Later, IBM delivered the SP2 machines based on POWER2 and then finally a generation based on POWER3 processors (which was unofficially called the SP3 by some). IBM continued to deliver parallel systems based on later generations of POWER processors (POWER4 and beyond), but those were no longer considered IBM RS/6000 SP systems. The November 2010 TOP500 list shows 16 POWER Systems 575 machines (one based on

POWER5 processors and the rest based on POWER6 processors), which can be considered direct follow-on to the RS/6000 SP.

Notable IBM RS/6000 SP systems include the Argonne National Laboratory SP1 (installed in 1993) [6], the Cornell Theory Center IBM SP2, the Lawrence Livermore National Laboratory ASCI Blue Pacific, and the Lawrence Livermore National Laboratory ASCI White. This last system consisted of 512 nodes with 16 POWER3 processors each and held the number 1 spot in the TOP500 list from November 2000 to November 2001.

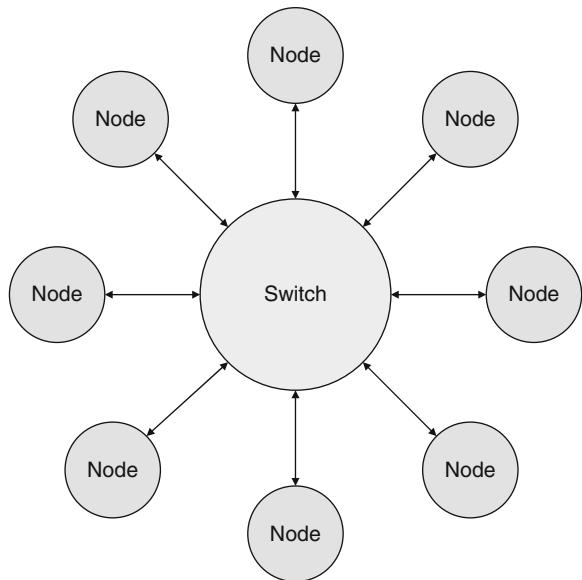

The RS/6000 SP was designed to serve a broad range of applications, from both the technical and commercial computing domains. The designers of the system followed a set of principles [1] that can be summarized as follows: maximize the use of off-the-shelf hardware and software components while developing some special-purpose components that maximize the value of the system. As a result, the RS/6000 SP utilizes the same processors, operating systems, and compilers as the contemporary IBM workstations. It also utilizes a special-purpose high-speed interconnect switch, a parallel operating environment and message passing libraries, and a parallel programming environment, including a High Performance Fortran (HPF) compiler.

To further enable the system for commercial applications, IBM and other vendors developed parallel versions of important commercial middleware such as DB2 and CICS/6000. With these parallel middleware, customers were able to quickly port applications from the more conventional single system image commercial servers to the IBM SP.

## Hardware Architecture

The IBM RS/6000 SP consists of a cluster of nodes interconnected by a switch (Fig. 1). The nodes (Fig. 2) are independent computers based on hardware (processors, memory, disks, I/O adapters) developed for IBM workstations and servers. Each node has its own private memory and runs its own image of the AIX operating system.

Through the evolution of the RS/6000 SP, different nodes were used. The initial nodes for SP1 and SP2 models were single processor nodes. Later, with the introduction of PowerPC and POWER3

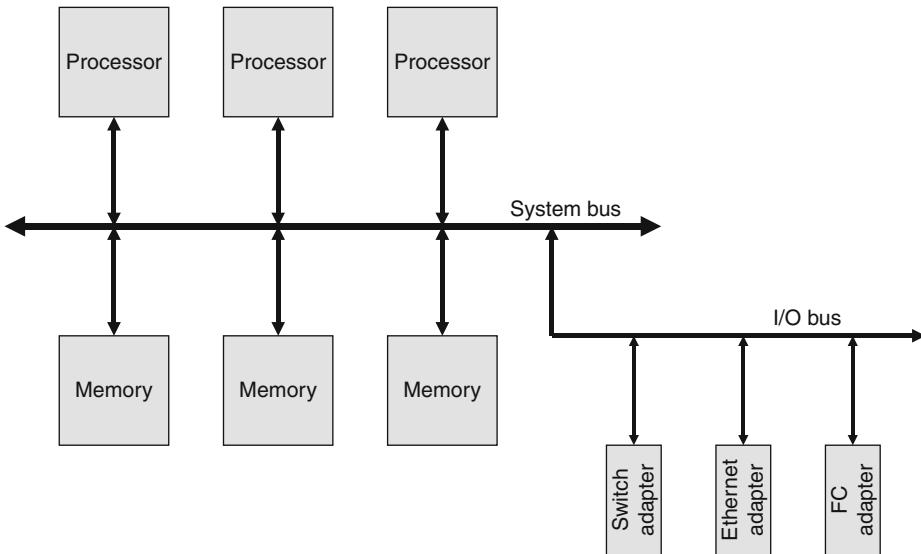

**IBM RS/6000 SP. Fig. 1** High-level hardware architecture of an IBM RS/6000 SP

processors, symmetric multiprocessing (SMP) nodes became available. Nodes could be configured to better serve specific purposes. For example, compute nodes could be configured with more processors and memory, whereas I/O nodes could be configured with more I/O adapters. The RS/6000 SP architecture supports different kinds of nodes in the same system, and it was usual to have both compute-optimized and I/O-optimized nodes in the same system.

The node architecture (illustrated in Fig. 2) is essentially the same as contemporary standalone workstations and servers based on POWER processors. Processor and memory modules are interconnected by a system bus that supports memory coherence within the node. An I/O bus also hangs off this system bus. This I/O bus supports off-the-shelf adapters found on standalone machines, such as Ethernet and Fibre Channel. It also supports the switch adapters that connect the node to the network.

Whereas the SP nodes are built primarily out of off-the-shelf hardware (except for the switch adapter), the SP switch is a special-purpose design. At the time the SP was conceived, standard interconnection networks (Ethernet, FDDI, ATM) delivered neither the bandwidth nor the latency that a large-scale general-purpose

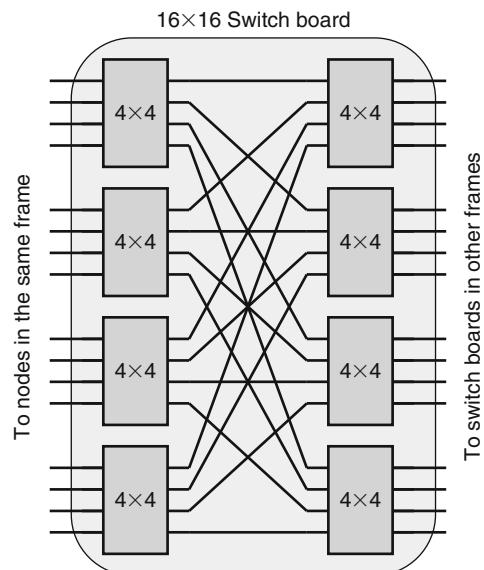

**IBM RS/6000 SP. Fig. 2** Hardware architecture of an IBM RS/6000 SP node. Different kinds of nodes can be and have been used in SP systems

parallel system like the SP required. Therefore, the designers decided that a special-purpose interconnect was necessary [1, 9].

The IBM RS/6000 SP switch [9] is an any-to-any packet-switched multistage network. The bisection bandwidth of the switch scales linearly with the size (number of nodes) of the system. The available bandwidth between any pair of communicating nodes remains constant irrespective of where in the topology the two nodes lie. These features supported both system scalability and ease of use. The system could be viewed as a flat collection of nodes, which could be freely selected for parallel jobs irrespective to their location. Selection could focus on other features, such as processor speed and memory size. As a consequence, the IBM RS/6000 SP did not suffer from the fragmentation problem that was observed in other parallel systems of the time [4].

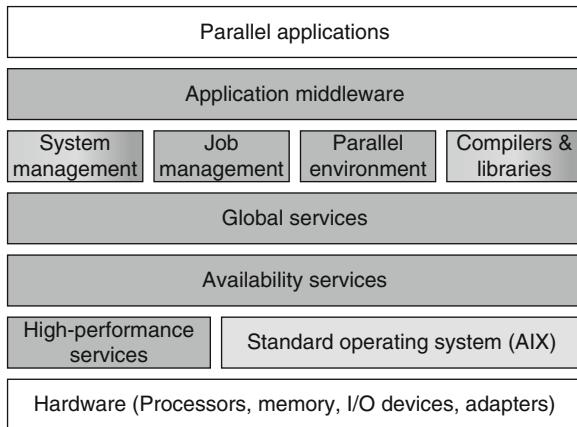

The SP switch is built from a basic  $4 \times 4$  bidirectional crossbar switching elements, which are grouped eight to a board to form a  $16 \times 16$  switch board, as shown in Fig. 3. A switch board connects to nodes on one side and to other switch boards on the other side. Systems with up to 80 nodes can be assembled with just one layer of switch boards, whereas larger systems require additional layers.

**IBM RS/6000 SP. Fig. 3** A  $16 \times 16$  switch board is built by interconnecting eight  $4 \times 4$  bidirectional crossbar switching elements. The switch board connects to nodes on one side and other boards on the other side

## Software Architecture

Figure 4 illustrates the software stack of the RS/6000 SP. That software stack is built upon off-the-shelf UNIX components and specialized services for parallel

IBM RS/6000 SP. Fig. 4 Software stack for RS/6000 SP

processing. Each node runs a full AIX operating system instance. That operating system is complemented at the bottom layer of the software stack by high-performance services that provide connectivity to the SP switch.

The availability and global services layers implement aspects of a single-system image. They are intended to be the basis for parallel applications and application middleware. The availability services of the IBM SP support heartbeat, membership, notification, and recovery coordination. Heartbeat services implement the monitoring of components to detect failures. Membership services allow processors and processes to be identified as belonging to a group. Notification services allow members of a group to be notified when new members are added or old members are removed from that group. Finally, recovery coordination services provide a mechanism for performing recovery procedures within the group in response to changes in the membership.

The global services of the IBM SP provide global access to resources such as disks, files, and networks. Global access to files is provided by networked file solutions, either with a client-server model (e.g., NFS) or with a parallel file system model (e.g., GPFS). With this approach, processes in every node have access to the same file space. Global network access is implemented through TCP/IP and UDP/IP protocols over the IBM SP switch. Gateway nodes, connected to both the SP switch and an external Ethernet network, allow all nodes to access the Ethernet network. Global access to disks is implemented by virtual shared disk (VSD) functionality. VSD allows a process running on any SP

node to access any disk in the system as if it were locally attached to that node. Another global service is the system data repository (SDR). The SDR contains system-wide information about the nodes, switches, and jobs currently in the system.

The job management system of the IBM SP supports both interactive and batch jobs. Batch jobs are submitted, scheduled, and controlled by LoadLeveler [3]. For interactive jobs, a user can login directly to any node in the SP, since the nodes all run a full version of the AIX operating system.

System management for the IBM SP is built upon components used for management of RS/6000 AIX workstations. It also includes extensions developed specifically for the SP to facilitate performing standard management functions across the many nodes of an SP. The functions supported include system installation, system operation, user management, configuration management, file management, security management, job accounting, problem management, change management, hardware monitoring and control, and print and mail services. The system management functions can be performed via a control workstation that acts as the system console.

The compilers and run-time libraries for the IBM RS/6000 SP are based on the standard software stack for IBM AIX augmented with certain features specific to the SP. Fortran, C and C++ compilers, and run-time libraries for POWER-based workstations and servers can be directly used in the SP, since the nodes of the latter are based on hardware developed for the former. The software stack for the SP also includes message-passing libraries that implement both IBM proprietary models, such as MPL, and standard models such as PVM and MPI [5, 8]. Also available for the IBM RS/6000 SP is an implementation of the High Performance Fortran (HPF) programming language [7].

In addition to middleware like MPI libraries that cater to scientific applications, the RS/6000 SP software stack also includes middleware targeted at enabling parallel commercial applications. The main example is DB2 Parallel Edition (PE) [2], an implementation of the DB2 relational database product that runs in parallel across the nodes of the SP. DB2 PE is a shared-nothing parallel database system, in which the data is partitioned across the nodes. DB2 PE splits SQL queries into multiple operations that are then shipped to the nodes for

execution against their local data. A final stage combines the results from each node into a single result. DB2 PE enables database applications to use the parallelism of the RS/6000 SP without changes to the application itself, since the exploitation of parallelism happens in the database middleware layer.

## Example Applications

Thousands of IBM RS/6000 SP systems were delivered over the product lifetime, ranging in size from as few as two nodes all the way up to 512 nodes and larger. The availability of a full workstation- and server-compatible software stack on the SP nodes allowed it to run off-the-shelf AIX applications with zero porting effort. The availability of standard message passing libraries (such as MPI), High Performance Fortran, and parallel commercial middleware such as DB2 PE also meant that existing parallel applications could be moved to the IBM RS/6000 SP with relative ease. Furthermore, several applications were specifically developed or optimized for the SP.

At a relatively early point in the product lifetime (1995), the SP was already being used in many different areas, including computational chemistry, crash analysis, electronic design analysis, seismic analysis, reservoir modeling, decision support, data analysis, on-line transaction processing, local area network consolidation, and as workgroup servers. In terms of economic sectors, SP systems were being used in manufacturing, distribution, transportation, petroleum, communications, utilities, education, government, finance, insurance, and travel [1].

The IBM RS/6000 SP played an important role in the Accelerated Strategic Computing Initiative by the US Department of Energy. That program was responsible for several of the fastest computers in the world, including two SPs: the ASCI Blue-Pacific and ASCI White machines. ASCI Blue-Pacific was the largest SP in number of nodes. It consisted of 1,464 nodes, each with four PowerPC 604e processors. Each processor had a clock speed of 332 MHz and a peak floating-point performance of 664 Mflops. As indicated in the TOP500 list, the machine had a peak performance (Rpeak) of 3856.5 Gflops and a Linpack performance (Rmax) of 2144 Gflops. It was ranked #2 in the November 1999 and June 2000 lists. ASCI White was the largest SP in number of processors (or cores). It consisted of 512 nodes,

each with 16 POWER3 processors. Each processor had a clock speed of 375 MHz and a peak floating-point performance of 1.5 Gflops. As indicated in the TOP500 list, the machine had a peak performance (Rpeak) of 12,288 Gflops and a Linpack performance (Rmax) of 7,304 Gflops. It was ranked #1 in the November 2000, June 2001 and November 2001 lists.

## IBM System/360 Model 91

MICHAEL FLYNN  
Stanford University, Stanford, CA, USA

### Definition

The Model 91 was the highest performing computer system introduced by IBM as part of its System/360 series in the 1960s. It was distinguished by a number of innovations such as out-of-order instruction execution, Tomasulo's algorithm for data flow execution, a limited

form of branch speculation, pipelined execution units, and division by binomial series approximation.

## Discussion

### Introduction

When IBM introduced System/360 in 1964, it included an announcement of a high-end computer referred to as "Model 90." This computer was realized as the Model 91 with first installation in 1967. While the Model 91 had a core memory with 750 ns cycle time, there was a fast memory version which used thin-film magnetic storage with a cycle time of 250 ns. This version was labeled the Model 95; two Model 95s were produced. Orders for the Model 91 were closed in 1968, but a revised version with improved technology and cache was introduced around 1970 as the Model 195. The Model 195 used the same logic as the Model 91. In the mid 1960s, there were some references to a Model 92 (with 500 ns memory cycle). This version was never realized.

The Model 90 series used a hybrid technology called ASLT (advanced solid logic technology), and had a processor cycle of 60 ns for Models 91 and 95; the Model 195 had a processor cycle of 54 ns.

The total production of all computers in the Model 90 series was about two dozen.

### Overview of the System and CPU

#### Instruction Processing

The instruction set was exactly that of System/360; however, instruction execution of the decimal instruction set was not supported in hardware in the Model 91. If such an instruction was invoked, it would trap and be interpreted by the processor [1, 2].

The design was predicated on the requirements of a long (20 stage) pipeline. Instructions were prefetched into an 8 entry I buffer each entry having 8 bytes. The I buffer enabled limited speculation on branch outcomes. If the branch target was backward and in the buffer, the branch was predicted to be successful otherwise the branch was predicted to be untaken and proceed in line.

A significant feature of the execution units was a mechanism called the common data bus, developed by R Tomasulo [3] and better known as Tomasulo's algorithm. This is a data flow control algorithm, which renames registers into reservation stations.

Each register in the central register set is extended to include a tag that identifies the functional unit that produces a result to be placed in a particular register. Similarly, each of the multiple functional units has one or more reservation stations. The reservation station, however, can contain either a tag identifying another functional unit or register, *or it can contain the variable needed*. Each reservation station effectively defines its own functional unit; thus, two reservations for a floating point multiplier are two functional unit tags: multiplier 1 and multiplier 2. If operands can go directly into the multiplier, then there is another tag: multiplier 3. Once a pair of operands has a designated functional unit tag, that tag remains with that operand pair until completion of the operation. Any unit (or register) that depends on that result has a copy of the functional unit tag and in gates the result that is broadcast on the common data bus. In this dataflow approach, the results to a targeted register may never actually go to that register; in fact, the computation based on the load of a particular register may be continually forwarded to various functional units, so that before the value is stored, a new value based upon a new computational sequence (a new load instruction) is able to use the targeted register.

The renaming of registers enabled out of order instruction execution, but in doing so it did not allow precise interrupts for all cases of exceptions. Since one instruction may have completed execution before a slow executing earlier issued one (such as divide) takes an exception and causes an interrupt it is impossible to reconstruct the machine state precisely.

### Execution Functional Units

The floating point units also provided significant innovation. The floating point adder executed an instruction in two cycles but it accepted a new instruction each cycle. This functional unit pipelining was novel at this time but now widely used [4].

The floating point multiplier executed an instruction in three cycles. It used a Booth 2 encoding of the multiplier, requiring the addition of 28 signed multiples of the multiplicand (the mantissa had 56 bits). These were added in Sum + Carry form, six at a time using a tree of carry save adders (CSA). The partial product was fed back into the tree for assimilation with the next six multiples. Using a newly developed Earle latch, this assimilation iteration eliminated latching overhead and

required only four logic stages (two CSAs) to implement. This allowed six signed multiples to be assimilated every 20 ns. Thus, the assimilation process took 120 ns to form the produce; another 60 ns was required for startup.

The divide process introduced the Goldschmidt algorithm based on a binomial expansion of the reciprocal. The value of the reciprocal was then multiplied by the dividend to form the quotient. In binomial expansion the divisor,  $d = 1 - x$ ; now the expansion of  $1/(1-x)$  can be represented as  $(1-x)(1+x^2)(1+x^4)(1+x^8)\dots$  Since  $d$  is binary normalized,  $x$  is less than or equal  $\frac{1}{2}$ . So each term doubles the number of zeros following the 1 and the resulting product quadratically converges to the reciprocal. A initial table lookup reduces the number of multiplies, the Model 91 took 11 cycles for floating point divide.

### Memory

The Model 91 memory system used conventional (for the day) magnetic core technology. It was interleaved 32 ways and had a 0.75 microsecond cycle time with a 10 cycle access time. A similar memory technology supported the Model 195's cache based memory. The memory system buffered 32 outstanding requests [5].

### The Technology

The machine itself was implemented with ECL (emitter coupled logic) as the basic circuit technology using multi transistor chips mounted on a  $1 \times 1$  cm aluminum ceramic substrate. Passive devices were implemented as thin-film printed components on the substrate. Two substrates were stacked one on top of each other forming a module which formed a cube about 1 cm on a side. The module provided a circuit density of about two to three circuits. Approximately 20 modules could be mounted on a daughterboard and twenty daughter boards could be plugged in to a motherboard ( $20 \times 20$  cm). Twenty motherboards formed a frame about  $2 \times 2$  m  $\times$  20 cm and four frames formed the basic CPU for the system [6–8].

The ECL circuit delay was about 1.8 ns but the transit time between logic gates added another 1.5 ns. All interconnections were made by terminated transmission line except for a small number of stubbed transmission lines. A great deal of care was paid in developing the signal transmission system. For example: a dual

impedance system of 50 and 90 ohms was used and the width of the basic 50 ohm line was reduced to create a 90 ohm line in the vicinity of loads so that the effective impedance of the loaded 90 ohm line would appear as a 50 ohm line.

The processor had in total about 120,000 gates. Since each gate had an associated interconnection delay the transit time plus loading effects made the total delay per gate approximately 3.5 ns. With 12 stages of logic as the definition for cycle time, this defined 60 ns as the basic CPU cycle. The multiply-divide unit had a subcycle of 20 ns for a partial product iteration.

The processor used water-cooled heat exchangers between motherboards for cooling. A motor generator set powered the system, isolating the system from short power disruptions. The total power consumption was a significant fraction of a megawatt.

## Bibliographic Notes and Further Reading

The basic source material for the Model 91 is the IBM J of Research and Development cited below [1–8]. The term “Tomasulo’s algorithm” and some similar designations are introduced in [9]. Thirty years after the Model 91 was initially dedicated there was a retrospective paper on its accomplishments and problems [10].

## Illiac IV

YOICHI MURAOKA  
Waseda University, Tokyo, Japan

### History

The Illiac IV computer was the first practical large-scale array computer, which can be classified as an SIMD (single-instruction-stream-multiple-data-streams)-type computer. As the name suggests, the project was managed at the University of Illinois Digital Computer Laboratory under the contract from the Defense Advanced Research Project Agency (then called ARPA). The project started in 1965, and the machine was delivered to the NASA Ames Research Center in 1971. It took 5 years to run its first successful application and was made available via the ARPANET, the predecessor of the Internet. The principal investigator was Professor Daniel Slotnick, who conceived the idea in the mid-1960s as the Solomon computer. The machine was built to answer the large computational requirements such as ballistic missile defense analysis, climate modeling, and so on. It was said then that two Illiac-IV computers would suffice to cover all computational requirements in the planet.

The design of the computer and the majority of early software suits development were done by Illinois researchers, including many ambitious graduate students, while the computer was built by the Burroughs Corporation.

To be precise, the project was transferred from the University of Illinois to the Ames Research Center in 1970 before its completion due to the heavy anti-Vietnam war protest activity on the campus.

The hardware is now being displayed in the Computer History Museum at Silicon Valley.

## Hardware

An instruction is decoded by Control Unit (CU), and the decoded signals are sent to 64 processors, called PE. PE is basically a combination of arithmetic-logic-unit, registers, and 2,048-words memory of 64-bit length (So in total, 1 MB). It operates at a 13 MHz clock. Each PE loads data to a register from its own memory. Thus, the 64 PEs perform an identical operation over independent data simultaneously. For example, two 64 elements vectors can be added by one operation.

The operation of each PE can be controlled by a mode bit. If a control bit is set, then a PE participates the operation, otherwise it does not. Thus, PE has some degree of freedom. There is an instruction to set/reset the mode bit.

A memory address to access the memory in each PE is also provided from CU. Included in each PE is an index register, so one can modify and access to a different memory address in different PEs.

To exchange data between PEs, PEs are set in the shape of a list with wrapped around connection. All PEs move data, for example, to their left neighbor PEs simultaneously. The mechanism is called the routing.

The megabyte memory is far less from ideal. So it is backed up by a 16 million word head-per-track desk with an I/O rate of 500 MB/s. The average access time is 20 ms.

To manage the operation of the computer and to provide the I/O capability, a Burroughs B6700 machine is used. The majority of operating system functions are run on this machine.

To further speed up the instruction execution, the instruction decoding in CU is overlapped with the execution in PEs, i.e., the instruction decoding and the instruction execution is pipelined.

## Software

Besides an ordinary assembler, called ASK, originally, two compilers were planned, the TRANQUIL and the GLYPNIR.

The TRANQUIL language is an extension of the ALGOL. Its main feature is the capability to specify the parallel execution of a FOR loop. For example,

FOR SIM I = (1...64) A(I) = B(I) + C(I)

adds two 64 elements vectors in one step. Furthermore, it allows a user to specify how to store data in the memory. For example, suppose we have an array of 64 columns by 64 rows. If we store each entire column in separate PE memory, then while operation on rows (e.g., addition of corresponding elements of two rows) can be done in parallel, operation on columns must be done sequentially. To avoid this situation, we may store data as

| PE1     | PE2     | PE3    | PE64    |
|---------|---------|--------|---------|
| a(1,1)  | a(1,2)  | a(1,3) | a(1,64) |
| a(2,64) | a(2,1)  | a(2,2) | a(2,63) |
| a(3,63) | a(3,64) | a(3,1) | a(3,62) |

While the simple data mapping scheme is called straight storage, this scheme is called skewed storage. TRANQUIL provides further varieties of storage scheme for an array to allow efficient parallel computation.

While the TRANQUIL language aims at a high-level programming gear, the GLYPNIR language, so to speak, provides a low-level view of the computer. In GLYPNIR, one writes a program for a PE in ALGOL like statements. The parallel execution is implicit, i.e., basically the identical program is executed in all PEs. The special features are added to take advantage of the mode-bit control and the separate memory indexing in each PE.

For example, to add two vectors, we declare variables as

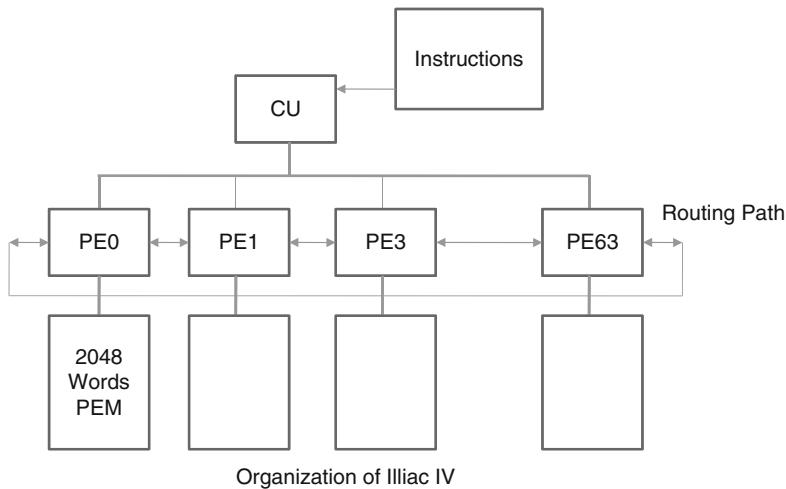

PE REAL X,Y

by which two 64 elements vectors are created, and an element X(i) is stored in PEM of PEi. Thus, the statement  $X \leftarrow X + Y$  will add two vectors in parallel.

To control the execution in each PE, there is a control statement such as

IF < BE > THEN S1

where BE is a 64 elements Boolean values, each of which corresponds the mode bit of PEs. Thus, the statement

**Illiad IV. Fig.1** Organization of Illiac IV

S1 is executed in PEs whose corresponding element of BE is true.

## Applications

The Illiac IV was the first practical parallel computer to allow writing real parallel codes.

Many original and great parallel application ideas have been developed by the project which contributed to solve real world problems. Among many influential results, we just list a few of them below. Application areas attacked by the project are:

### 1. Computational fluid dynamics

NASA people developed an aerodynamic flow simulation program on Illiac IV which helped them to replace their wind tunnel with a computer simulation system. Other programs developed include the Navier-Stokes solver for two dimensional unsteady transonic flow, a viscous-flow airfoil code, turbulence modeling for three-dimensional incompressible flow, and many more.

### 2. Image processing

Image processing may be one of the application areas that is most suited for parallel computation. Many innovative parallel algorithms were developed and implemented on the Illiac IV which include mage line detection, image skeletonizing,

shape detection, and many others. Also, the Illiac IV was successfully used to analyze LANDSAT satellite data, especially in clustering and classification.

### 3. Astronomy

Although very little research was done in this area three-dimensional galaxy simulations have been run successfully on the Illiac IV. This is a typical n-body problem.

### 4. Seismic

This is one of applications which were studied intensively to develop parallel algorithms. The application is characterized as a three-dimensional finite difference code with many irregular data structure.

### 5. Mathematical programs

Many basic numerical computations have been coded in parallel. They include dense and sparse matrix calculations, the single-value decomposition, and so on.

### 6. Weather/climate simulation

A dynamic atmospheric model incorporating chemistry and heat exchange was build.

## Assessment

The project took a decade of development and was also massively over budget. Costs escalated from the

\$8 million estimated in 1966 to \$31 million by 1972. Only a quarter of the fully planned machine, i.e., 64 PEs instead of 256 PEs, was ever built. Nevertheless, the project developed a very unique and for the time, a powerful computer. Also, many ideas in software are still vital and appreciated.

The project pushed research forward, leading the way for machines such as the Thinking Machines CM-1 and CM-2. It is also true that the software team of the project developed not only a whole new set of parallel programming ideas, but also a set of experts in parallel programming.

## Definition

ILUPACK is the abbreviation for Incomplete LU factorization PACKage. It is a software library for the iterative solution of large sparse linear systems. It is written in FORTRAN 77 and C and available at <http://ilupack.tu-bs.de>. The package implements a multilevel incomplete factorization approach (multilevel ILU) based on a special permutation strategy called “inverse-based pivoting” combined with Krylov subspace iteration methods. Its main use consists of application problems such

as linear systems arising from partial differential equations (PDEs). ILUPACK supports single and double precision arithmetic for real and complex numbers. Among the structured matrix classes that are supported by individual drivers are symmetric and/or Hermitian matrices that may or may not be positive definite and general square matrices. An interface to MATLAB (via MEX) is available. The main drivers can be called from C, C++, and FORTRAN.

## Discussion

### Introduction

Large sparse linear systems arise in many application areas such as partial differential equations, quantum physics, or problems from circuit and device simulation. They all share the same central task that consists of efficiently solving large sparse systems of equations. For a large class of application problems, sparse direct solvers have proven to be extremely efficient. However, the enormous size of the underlying applications arising in 3-D PDEs or the large number of devices in integrated circuits currently requires fast and efficient iterative solution techniques, and this need will be exacerbated as the dimension of these systems increases. This in turn demands for alternative approaches and, often, approximate factorization techniques, combined with iterative methods based on Krylov subspaces, reflecting as an attractive alternative for these kinds of application problems. A comprehensive overview over iterative methods can be found in [15].

The ILUPACK software is mainly built on incomplete factorization methods (ILUs) applied to the system matrix in conjunction with Krylov subspace methods. The ILUPACK hallmark is the so-called *inverse-based approach*. It was initially developed to connect the ILUs and their approximate inverse factors. These relations are important since, in order to solve linear systems, the inverse triangular factors resulting from the factorization are applied rather than the original incomplete factors themselves. Thus, information extracted from the inverse factors will in turn help to improve the robustness for the incomplete factorization process. While this idea has been successfully used to improve robustness, its downside was initially that the norm of the inverse

factors could become large such that small entries could hardly be dropped during Gaussian elimination. To overcome this shortcoming, a multilevel strategy was developed to limit the growth of the inverse factors. This has led to the inverse-based approach and hence the incomplete factorization process that has eventually been implemented in ILUPACK benefits from the information of bounded inverse factors while being efficient at the same time [6].

A parallel version of ILUPACK on shared-memory multiprocessors, including current multicore architectures, is under development and expected to be released in the near future. The ongoing development of the parallel code is inspired by a nested dissection hierarchy of the initial system that allows to map tasks concurrently to independent threads within each level.

### The Multilevel Method

To solve a linear system  $Ax = b$ , the multilevel approach of ILUPACK performs the following steps:

1. The given system  $A$  is scaled by diagonal matrices  $D_l$  and  $D_r$  and reordered by permutation matrices  $\Pi_l, \Pi_r$  as

$$A \rightarrow D_l A D_r \rightarrow \Pi_l^T D_l A D_r \Pi_r = \hat{A}.$$

These operations can be considered as a preprocessing prior to the numerical factorization. They typically include scaling strategies to equilibrate the system, scaling and permuting based on maximum weight matchings [7], and, finally, fill-reducing orderings such as nested dissection [14], (approximate) minimum degree [4, 11], and some more.

2. An incomplete factorization  $A \approx LDU$  is next computed for the system  $\hat{A}$ , where  $L, U^T$  are unit lower triangular factors and  $D$  is diagonal. Since the main objective of ILUPACK (*inverse-based approach*) is to limit the norm of the inverse triangular factors,  $L^{-1}$  and  $U^{-1}$ , the approximate factorization process is interlaced with a pivoting strategy that cheaply estimates the norm of these inverse factors. The pivoting process decides in each step to reject a factorization step if an imposed bound  $\kappa$  is exceeded, or to accept a pivot and continue the approximate factorization otherwise. The set of rejected rows and columns is permuted to the lower and right end of the matrix. This process is illustrated in Fig. 1.

The pivoting strategy computes a partial factorization

$$\begin{aligned} P^T \hat{A} P &= \begin{pmatrix} B & E \\ F & C \end{pmatrix} \\ &= \begin{pmatrix} L_B & 0 \\ L_F & I \end{pmatrix} \begin{pmatrix} D_B U_B & D_B U_E \\ 0 & S_C \end{pmatrix} + R, \end{aligned}$$

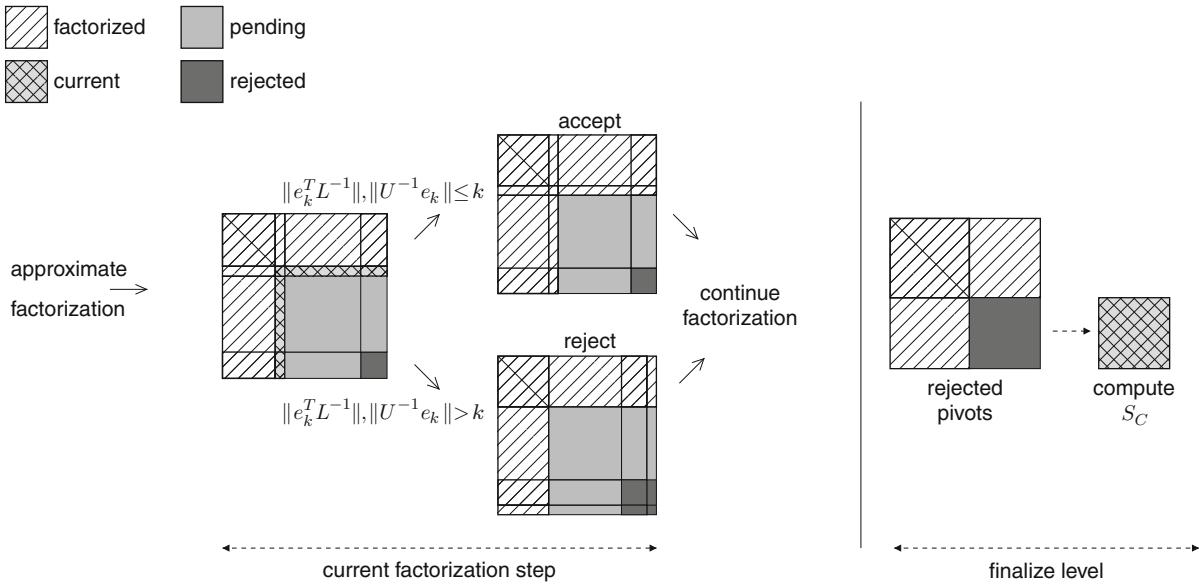

where  $R$  is the error matrix, which collects those entries of  $\hat{A}$  that were dropped during the factorization and “ $S_C$ ” is the Schur complement consisting of all rows and columns associated with the rejected pivots. By construction the inverse triangular factors satisfy

$$\left\| \begin{pmatrix} L_B & 0 \\ L_F & I \end{pmatrix}^{-1} \right\|, \left\| \begin{pmatrix} U_B & U_E \\ 0 & I \end{pmatrix}^{-1} \right\| \lesssim \kappa.$$

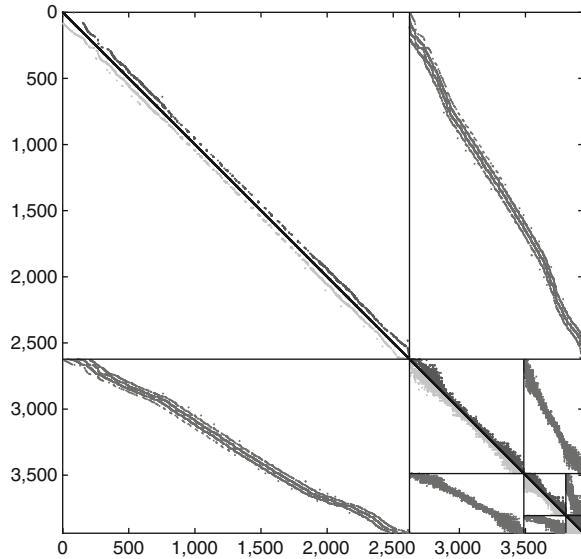

3. Steps 1 and 2 are successively applied to  $\hat{A} = S_C$  until  $S_C$  is void or “sufficiently dense” to be efficiently factorized by a level 3 BLAS-based direct factorization kernel.

When the multilevel method is applied over multiple levels, a cascade of factors  $L_B, D_B$ , and  $U_B$ , as well as matrices  $E, F$  are usually obtained (cf. Fig. 2). Solving linear systems via a multilevel ILU requires a hierarchy of forward and backward substitutions, interlaced with reordering and scaling stages. ILUPACK employs Krylov subspace methods to incorporate the approximate factorization into an iterative method.

The computed multilevel factorization is adapted to the structure of the underlying system. For real symmetric positive definite (SPD) matrices, an incomplete Cholesky decomposition is used in conjunction with the conjugate gradient method. For the symmetric and indefinite case, symmetric maximum weight matchings [8] allow to build  $1 \times 1$  and  $2 \times 2$  pivots. In this case ILUPACK constructs a blocked symmetric multilevel ILU and relies on the simplified QMR [10] as iterative solver. The general (unsymmetric) case typically uses GMRES [16] as default driver. All drivers in ILUPACK support real/complex and single/double precision arithmetic.

ILUPACK. Fig. 2 ILUPACK multilevel factorization

### Mathematical Background

The motivation for inverse-based approach of ILUPACK can be explained in two ways. First, when the approximate factorization

$$A = LDU + R$$

is computed for some error matrix  $R$ , the inverse triangular factors  $L^{-1}$  and  $U^{-1}$  have to be applied to solve a

linear system  $Ax = b$ . From this point of view,

$$L^{-1}AU^{-1} = D + L^{-1}RU^{-1}$$

ensures that the entries in the error matrix  $R$  are not amplified by some large inverse factors  $L^{-1}$  and  $U^{-1}$ . The second and more important aspect links ILUPACK's multilevel ILU to algebraic multilevel methods. The inverse  $\hat{A}^{-1}$  can be approximately written as

$$\begin{aligned} \hat{A}^{-1} \approx P &\left( \begin{pmatrix} (L_B D_B U_B)^{-1} & 0 \\ 0 & 0 \end{pmatrix} \right. \\ &\left. + \begin{pmatrix} -U_B^{-1} U_E \\ I \end{pmatrix} S_C^{-1} \begin{pmatrix} -L_F L_B^{-1} & I \end{pmatrix} \right) P^T. \end{aligned}$$

In this expression, all terms on the right hand side are constructed to be bounded except  $S_C^{-1}$ . Since in general  $\hat{A}^{-1}$  has a relatively large norm, so does  $S_C^{-1}$ . In principle this justifies that eigenvalues of small modulus are revealed by the approximate Schur complement  $S_C$  (a precise explanation is given in [5]).  $S_C$  serves as some kind of coarse grid system in the sense of discretized partial differential equations. This observation goes hand in hand with the observation that the inverse-based pivoting approach selects pivots similar to coarsening strategies in algebraic multilevel methods,

which is demonstrated for the following simple model problem:

$$\begin{aligned} -10^{-2}u_{xx}(x,y) - u_{yy}(x,y) &= f(x,y) \text{ for all} \\ (x,y) \in [0,1]^2, u(x,y) &= 0 \text{ on } \partial[0,1]^2. \end{aligned}$$

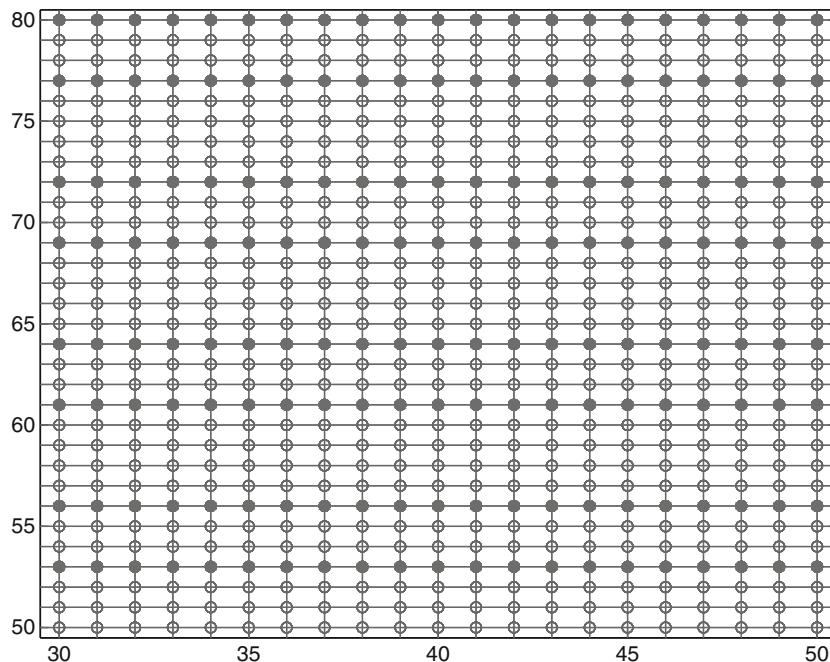

This partial differential equation can be easily discretized on a square grid  $\Omega_h = \{(kh, lh) : k, l = 0, \dots, N+1\}$ , where  $h = \frac{1}{N+1}$  is the mesh size, using standard finite difference techniques. Algebraic approaches to multilevel methods roughly treat the system as if the term  $-10^{-2}u_{xx}(x,y)$  is hardly present, i.e., the coarsening process treats it as if it were a sequence of one-dimensional differential equations in the  $y$ -direction. Thus, semi-coarsening in the  $y$ -direction is the usual approach to build a coarse grid. ILUPACK inverse-based pivoting algebraically picks and rejects the pivots precisely in the same way as in semi-coarsening. In Fig. 3, this is illustrated for a portion of the grid  $\Omega_h$  using  $\kappa = 3$ . In the  $y$ -direction, pivots are rejected after 3–5 steps while in the  $x$ -direction all pivots are kept or rejected (in blue and red, resp.).

The number of rejected pivots in ILUPACK strongly depends on the underlying application problem.

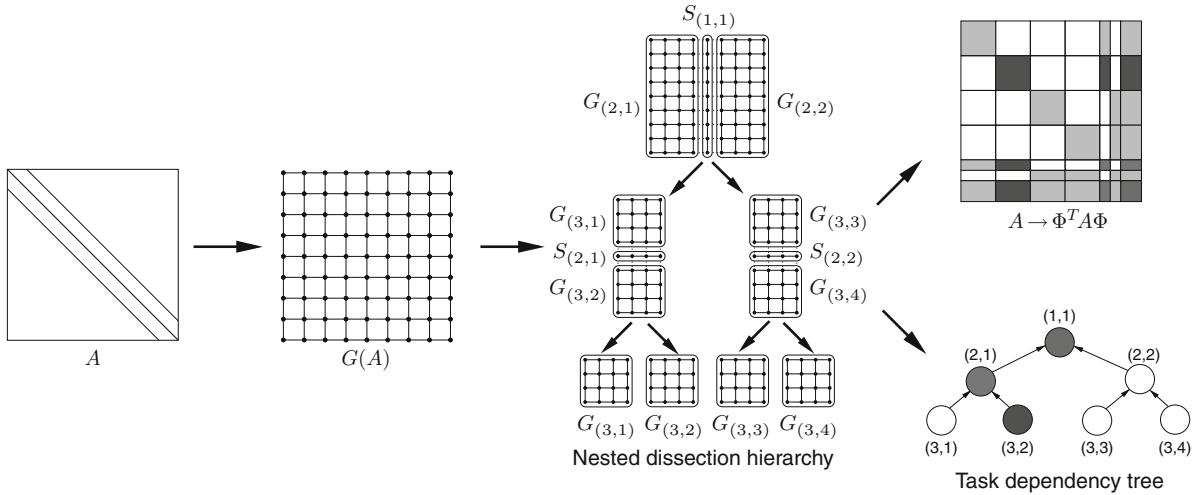

As a rule of thumb, the more rows (and columns) of the coefficient matrix satisfy  $|a_{ii}| \gg \sum_{j \neq i} |a_{ij}|$ , the less pivots tend to be rejected.

### The Parallelization Approach

Parallelism in the computation of approximate factorizations can be exposed by means of graph-based symmetric reordering algorithms, such as graph coloring or graph partitioning techniques. Among these classes of algorithms, nested dissection orderings enhance parallelism in the approximate factorization of  $A$  by partitioning its associated adjacency graph  $G(A)$  into a hierarchy of vertex separators and independent subgraphs. For example, in Fig. 4,  $G(A)$  is partitioned after two levels of recursion into four independent subgraphs,  $G_{(3,1)}$ ,  $G_{(3,2)}$ ,  $G_{(3,3)}$ , and  $G_{(3,4)}$ , first by separator  $S_{(1,1)}$ , and then by separators  $S_{(2,1)}$  and  $S_{(2,2)}$ . This hierarchy is constructed so that the size of vertex separators is minimized while simultaneously balancing the size of the independent subgraphs. Therefore, relabeling the nodes of  $G(A)$  according to the levels in the hierarchy leads to a reordered matrix,  $A \rightarrow \Phi^T A \Phi$ , with a structure amenable to efficient parallelization. In particular, the leading diagonal blocks of

**ILUPACK. Fig. 3** ILUPACK pivoting for partial differential equations. Blue and red dots denote, respectively, accepted and rejected pivots

**ILUPACK. Fig. 4** Nested dissection reordering

$\Phi^T A \Phi$  associated with the independent subgraphs can be first eliminated independently; after that,  $S_{(2,1)}$  and  $S_{(2,2)}$  can be eliminated in parallel, and finally separator  $S_{(1,1)}$  is processed. This type of parallelism can be expressed by a binary task dependency tree, where nodes represent concurrent tasks and arcs dependencies among them. State-of-the-art reordering software packages e.g., METIS (<http://glaros.dtc.umn.edu/gkhome/views/metis>) or SCOTCH (<http://www.labri.fr/perso/pelegrin/scotch>), provide fast and efficient multilevel variants [14] of nested dissection orderings.

The dependencies in the task tree are resolved while the computational data and results are generated and passed from the leaves toward the root. The leaves are responsible for approximating the leading diagonal blocks of  $\Phi^T A \Phi$ , while those blocks which will be later factorized by their ancestors are updated. For example, in Fig. 4, colors are used to illustrate the correspondence between the blocks of  $\Phi^T A \Phi$  to be factorized by tasks (3,2), (2,1), and (1,1). Besides, (3,2) only updates those blocks that will be later factorized by tasks (2,1) and (1,1). Taking this into consideration,  $\Phi^T A \Phi$  is decomposed into the sum of several submatrices, one local block per each leaf of the tree, as shown in Fig. 5. Each local submatrix is composed of the blocks to be factorized by the corresponding task, together with its local contributions to the blocks that are later factorized by its ancestors, hereafter referred as contribution blocks. This strategy significantly increases the degree of parallelism,

because the updates from descendant nodes to an ancestor node can also be performed locally/independently by its descendants.

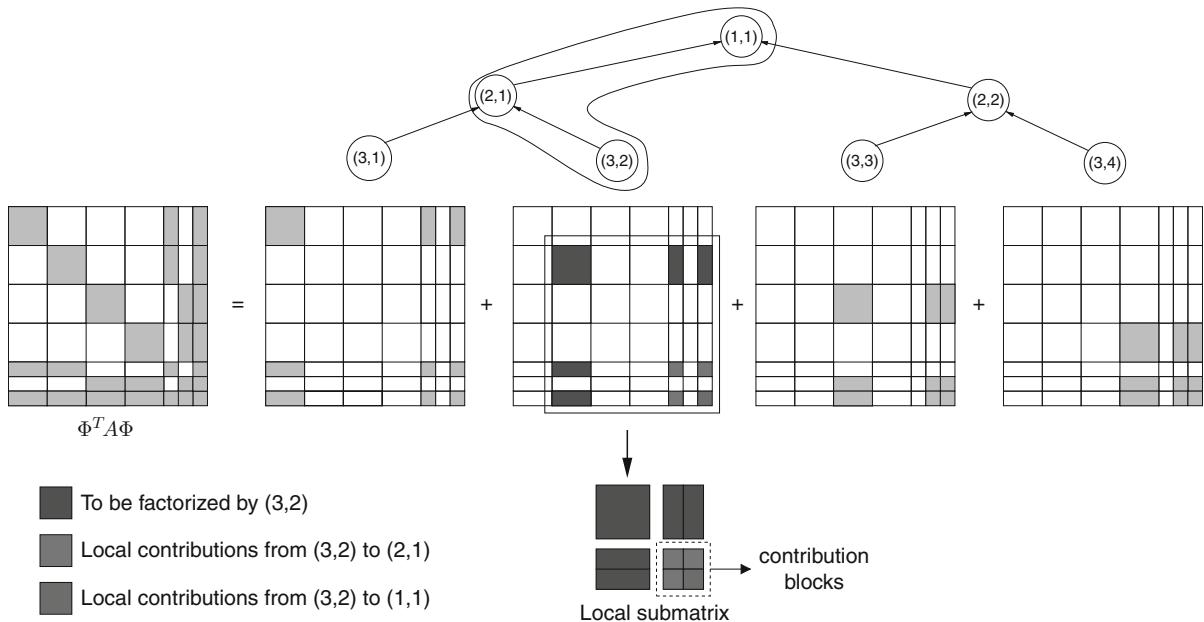

The parallel multilevel method considers the following partition of the local submatrices into  $2 \times 2$  block matrices

$$A_{\text{par}} = \begin{pmatrix} A_X & | & A_V \\ \hline A_W & | & A_Z \end{pmatrix},$$

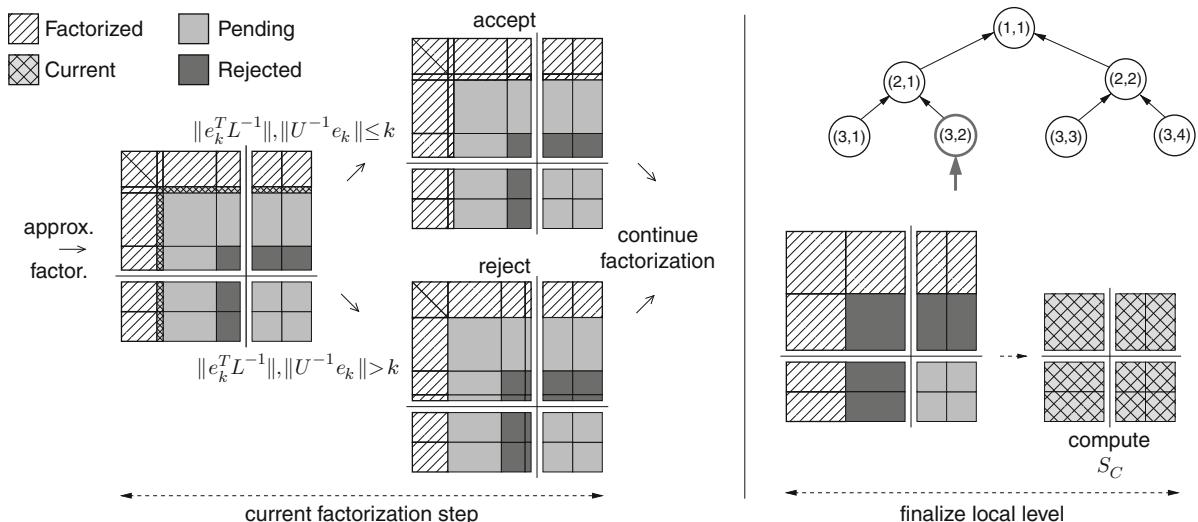

where the partitioning lines separate the blocks to be factorized by the task, i.e.,  $A_X$ ,  $A_W$ , and  $A_V$ , and its contribution blocks, i.e.,  $A_Z$ . It then performs the following steps:

1. Scaling and permutation matrices are only applied to the blocks to be factorized,

$$\begin{aligned} A_{\text{par}} &\rightarrow \left( \begin{array}{c|c} \Pi_l^T & 0 \\ \hline 0 & I \end{array} \right) \left( \begin{array}{c|c} D_l & 0 \\ \hline 0 & I \end{array} \right) \\ &\quad \times \left( \begin{array}{c|c} A_X & A_V \\ \hline A_W & A_Z \end{array} \right) \left( \begin{array}{c|c} D_r & 0 \\ \hline 0 & I \end{array} \right) \\ &\quad \times \left( \begin{array}{c|c} \Pi_r & 0 \\ \hline 0 & I \end{array} \right) = \left( \begin{array}{c|c} \hat{A}_X & \hat{A}_V \\ \hline \hat{A}_W & \hat{A}_Z \end{array} \right) = \hat{A}_{\text{par}}. \end{aligned}$$

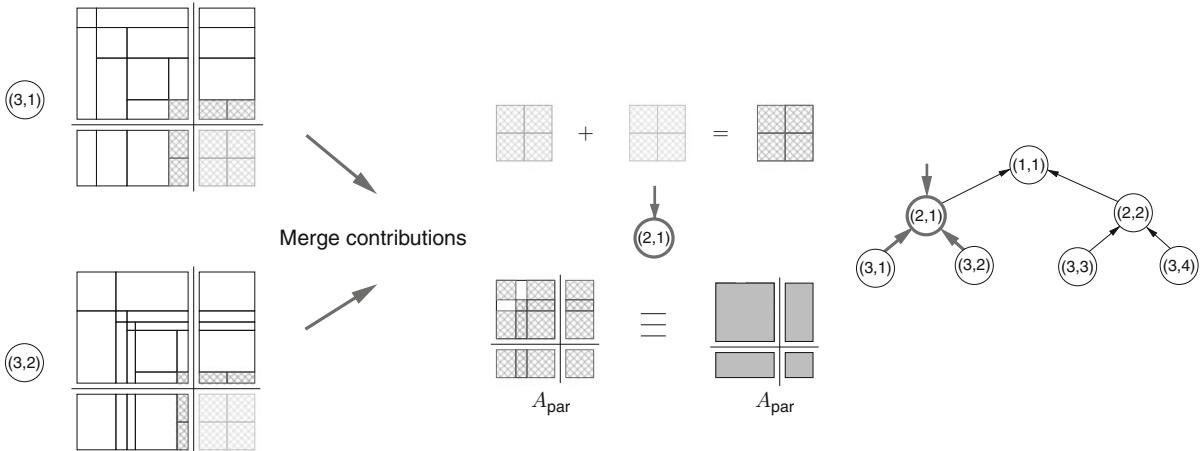

**ILUPACK. Fig. 5** Matrix decomposition and local submatrix associated to a single node of the task tree

**ILUPACK. Fig. 6** Local incomplete factorization computed by a single node of the task tree

2. These blocks are next approximately factorized using inverse-based pivoting, while  $\hat{A}_Z$  is only updated. For this purpose, during the incomplete

factorization of  $\hat{A}_{\text{par}}$ , rejected rows and columns are permuted to the lower and right end of the leading block  $\hat{A}_X$ . This is illustrated in [Fig. 6](#).

ILUPACK. Fig. 7 Parent nodes construct their local submatrix from the data generated by their children

This step computes a partial factorization

$$\begin{aligned} \left( \begin{array}{c|c} P^T & 0 \\ \hline 0 & I \end{array} \right) \hat{A}_{\text{par}} \left( \begin{array}{c|c} P & 0 \\ \hline 0 & I \end{array} \right) &= \left( \begin{array}{ccc|c} B_X & E_X & & E_V \\ F_X & C_X & & C_V \\ \hline F_W & C_W & & C_Z \end{array} \right) \\ &= \left( \begin{array}{cc|c} L_{B_X} & 0 & 0 \\ L_{F_X} & I & 0 \\ \hline L_{F_W} & 0 & I \end{array} \right) \left( \begin{array}{ccc|c} D_{B_X} U_{B_X} & D_{B_X} U_{E_X} & D_{B_X} U_{E_V} & \\ 0 & S_{C_X} & S_{C_V} & \\ \hline 0 & S_{C_W} & S_{C_Z} & \end{array} \right) + R, \end{aligned}$$

where the inverse triangular factors approximately satisfy

$$\left\| \left( \begin{array}{cc|c} L_{B_X} & 0 & 0 \\ L_{F_X} & I & 0 \\ \hline L_{F_W} & 0 & I \end{array} \right)^{-1} \right\|, \quad \left\| \left( \begin{array}{cc|c} U_{B_X} & U_{E_X} & U_{E_V} \\ 0 & I & 0 \\ \hline 0 & 0 & I \end{array} \right)^{-1} \right\| \lesssim \kappa.$$

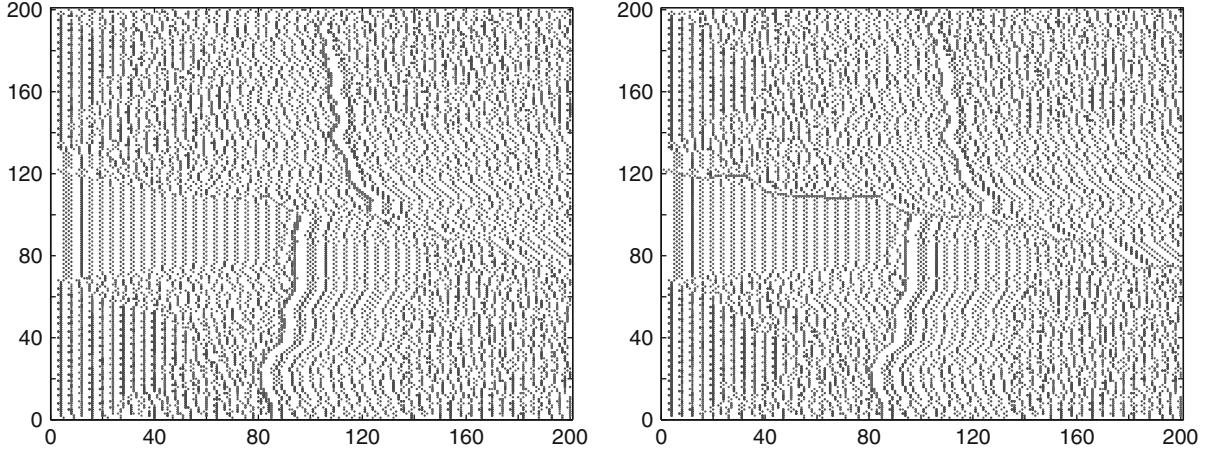

3. Steps 1 and 2 are successively applied to the Schur complement until  $S_{C_X}$  is void or “sufficiently small”, i.e.,  $A_{\text{par}}$  and its  $2 \times 2$  block partition are redefined as

$$A_{\text{par}} = \left( \begin{array}{c|c} A_X & A_V \\ \hline A_W & A_Z \end{array} \right) := \left( \begin{array}{c|c} S_{C_X} & S_{C_V} \\ \hline S_{C_W} & S_{C_Z} \end{array} \right).$$

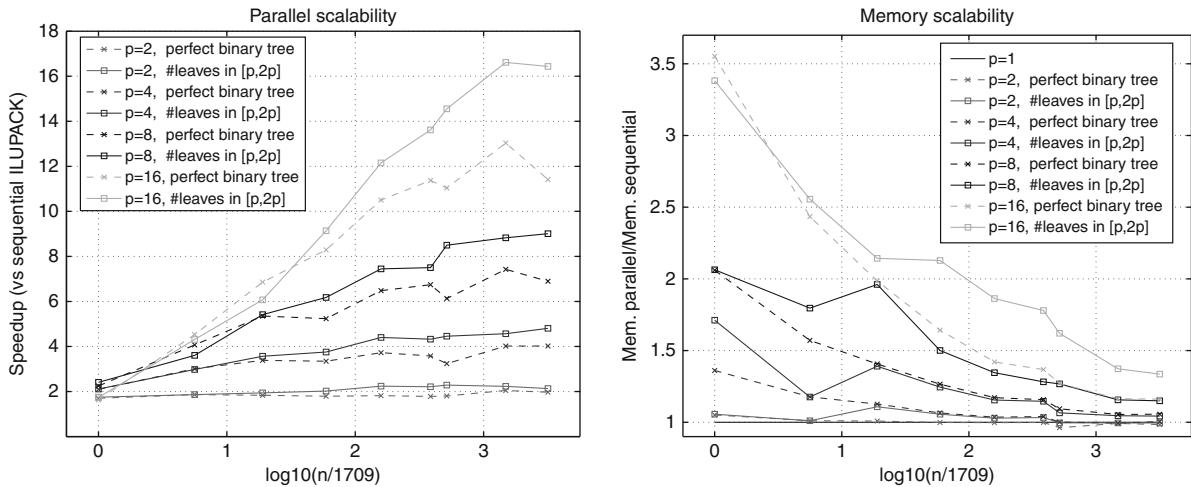

4. The task completes its local computations and the result  $A_{\text{par}}$  is sent to the parent node in the task dependency tree. When a parent node receives the

data from its children, it must first construct its local submatrix  $A_{\text{par}}$ . To achieve this, it incorporates the pivots rejected from its children and accumulates their contribution blocks, as shown in Fig. 7. If the parent node is the root of the task dependency tree, it applies the sequential multilevel algorithm to the new constructed submatrix  $A_{\text{par}}$ . Otherwise, the parallel multilevel method is restarted on this matrix at step 1.

To compare the cascade of approximations computed by the sequential multilevel method and its parallel variant, it is helpful to consider the latter as an algorithmic variant, which enforces a certain order of elimination. Thus, the parallel variant interlaces the algebraic levels generated by the pivoting strategy of ILUPACK with the nested dissection hierarchy levels in order to expose a high degree of parallelism. The leading diagonal blocks associated with the last nested dissection hierarchy level are first factorized using inverse-based pivoting, while those corresponding to previous hierarchy levels are only updated, i.e., the nodes belonging to the separators are rejected by construction. The multilevel algorithm is restarted on the rejected nodes, and only when it has eliminated the bulk of the nodes of the last hierarchy level, it starts approximating the blocks belonging to previous hierarchy levels. Figure 8 compares the distribution of

**ILUPACK. Fig. 8** ILUPACK pivoting strategy (*left*) and its parallel variant (*right*). Blue and red dots denote, respectively, accepted and rejected nodes

**ILUPACK. Fig. 9** Parallel speedup as a function of problem size (*left*) and ratio among the memory consumed by the parallel multilevel method and that of the sequential method (*right*) for a discretized 3-D elliptic PDE

accepted and rejected nodes (in blue and red, resp.) by the sequential and parallel inverse-based incomplete factorizations when they are applied to the Laplace PDE with discontinuous coefficients discretized with a standard  $200 \times 200$  finite-difference grid. In both cases, the grid was reordered using nested dissection. These diagrams confirm the strong similarity between the sequential inverse-based incomplete factorization and its parallel variant for this particular example. The experimentation with this approach in the SPD case reveals that this compromise has a negligible impact on

the numerical properties of the inverse-based preconditioning approach, in the sense that the convergence rate of the preconditioned iterative method is largely independent on the number of processors involved in the parallel computation.

### Numerical Example

The example illustrates the parallel and memory scalability of the parallel multilevel method on a SGI Altix 350 CC-NUMA shared-memory multiprocessor with 16 Intel Itanium2@1.5 GHz processors

sharing 32 GBytes of RAM connected via a SGI NUMA-link network. The nine linear systems considered in this experiment are derived from the linear finite element discretization of the irregular 3-D elliptic PDE  $[-\operatorname{div}(A \operatorname{grad} u) = f]$  in a 3-D domain, where  $A(x, y, z)$  is chosen with positive random coefficients. The size of the systems ranges from  $n = 1,709\text{--}5,413,520$  equations/unknowns.

The parallel execution of the task tree on shared-memory multiprocessors is orchestrated by a runtime which dynamically maps tasks to threads (processors) in order to improve load balance requirements during the computation of the multilevel preconditioner. Figure 9 displays two lines for each number of processors: dashed lines are obtained for a perfect binary tree with the same number of leaves as processors, while solid lines correspond to a binary tree with (potentially) more leaves than processors (up to  $2p$  leaves). The higher speedups revealed in the solid lines demonstrate the benefit of dynamic scheduling on shared-memory multiprocessors.

As shown in Fig. 9 (left), the speedup always increases with the number of processors for a fixed problem size, and the parallel efficiency rapidly grows with problem size for a given number of processors. Besides, as shown in Fig. 9 (right), the memory overhead associated with parallelization relatively decreases with the problem size for a fixed number of processors, and it is below 1.5 for the two largest linear systems; this is very moderate taking into consideration that the amount of available physical memory typically increases linearly with the number of processors. These observations confirm the excellent scalability of the parallelization approach up to 16 cores.

### Future Research Directions

ILUPACK is currently parallelized for SPD matrices only. Further classes of matrices such as symmetric and indefinite matrices or unsymmetric, but symmetrically structured matrices are subject to ongoing research. The parallelization of these cases shares many similarities with the SPD case. However, maximum weight matching, or more generally, methods to rescale and reorder the system to improve the size of the diagonal entries (resp. diagonal blocks) are hard to parallelize [9]. Although the current implementation of ILUPACK is designed for shared-memory

multiprocessors using OpenMP, the basic principle is currently being transferred to distributed-memory parallel architectures via MPI. Future research will be devoted to block-structured algorithms to improve cache performance. Block structures have been proven to be extremely efficient for direct methods, but their integration into incomplete factorizations remains a challenge; on the other hand, recent research indicates the high potential of block-structured algorithms also for ILUs [12, 13].

### Bibliographic Notes and Further Reading

Around 1985, a first package also called ILUPACK was developed by H.D. Simon [18], which used reorderings, incomplete factorizations, and iterative methods in one package. Nowadays, as the development of preconditioning methods has advanced significantly by novel approaches like improved reorderings, multilevel methods, maximum weight matchings, and inverse-based pivoting, incomplete factorization methods have changed completely and gained wide acceptance among the scientific community. Besides ILUPACK, there exist several software packages based on incomplete factorizations and on multilevel factorizations. For example, Y. Saad (<http://www-users.cs.umn.edu/~saad/software/>) et al. developed the software packages SPARSKIT, ITSOL, and pARMS, which also inspired the development of ILUPACK. In particular, pARMS is a parallel code based on multilevel ILU interlaced with reorderings. J. Mayer (<http://iamlasun8.mathematik.uni-karlsruhe.de/~ae04/iluplusplus.html>) developed ILU++, also for multilevel ILU. MRILU, by F.W. Wubs (<http://www.math.rug.nl/~wubs/mrilu/>) et al., uses multilevel incomplete factorizations and has successfully been applied to problems arising from partial differential equations. There are many other scientific publications on multilevel ILU methods, most of them especially tailored for the use in partial differential equations.

ILUPACK has been successfully applied to several large scale application problems, in particular, to the Anderson model of localization [17] or the Helmholtz equation [5]. Its symmetric version is integrated into the software package JADAMILU (<http://homepages.ulb.ac.be/~jadamilu/>), which is a Jacobi-Davidson-based eigenvalue solver for symmetric eigenvalue problems.

More details on the design aspects of the parallel multilevel preconditioner (including dynamic scheduling) and experimental data with a benchmark of irregular matrices from the UF sparse matrix collection (<http://www.cise.ufl.edu/research/sparse/matrices/>) can be found in [1, 2]. The computed parallel multilevel factorization is incorporated to a Krylov subspace solver, and the underlying parallel structure of the former, expressed by the task dependency tree, is exploited for the application of the preconditioner as well as other major operations in iterative solvers [2]. The experience with these parallel techniques has revealed that the sequential computation of the nested dissection hierarchy (included in, e.g., METIS or SCOTCH) dominates the execution time of the whole solution process when the number of processors is large. Therefore, additional types of parallelism have to be exploited during this stage in order to develop scalable parallel solutions; in [3], two parallel partitioning packages, ParMETIS (<http://glaros.dtc.umn.edu/gkhome/metis/parmetis/overview>) and PTSCOTCH (<http://www.labri.fr/perso/pelegrin/scotch>), are evaluated with this purpose.

### Definition

The InfiniBand Architecture (IBA) describes a switched interconnect technology for inter-processor communication and I/O in a multiprocessor system. The architecture is independent of the host operating system and the processor platform. InfiniBand is based on a widely adopted open standard.

### Discussion

#### Introduction

As the commodity clusters started getting popular around mid-nineties, the common interconnect used for such clusters was Fast Ethernet (100 Mbps). These clusters were identified as Beowulf clusters [1]. Even though it was cost effective to design such clusters with Ethernet/Fast Ethernet, the communication performance was not very good because of the high overhead associated with the standard TCP/IP communication protocol stack. The high overhead was because of the TCP/IP protocol stack being completely executed on the host processor. The network interface cards ((NICs) or commonly known as network adapters) on those systems were also not intelligent. Thus, these adapters did not allow any overlap of computation with communication or I/O. This led to high latency, low bandwidth, and high CPU requirement for communication and I/O operations on those clusters.

The above limitations led to a goal for designing a new and converged interconnect with open standard. Seven industry leaders (Compaq, Dell, IBM, Intel, Microsoft, HP, and Sun) formed a new InfiniBand Trade association [2]. The charter for this association was “to

design a scalable and high performance communication and I/O architecture by taking an integrated view of computing, networking and storage technologies.” Many other companies participated in this consortium later. The members of this consortium deliberated and defined the InfiniBand architecture specification. The first specification (Volume 1, Version 1.0) was released to the public on October 24, 2000. Since then this standard is becoming enhanced periodically. The latest version is 1.2.1 was released in January 2008.

The word “InfiniBand” is coined from two words “Infinite Bandwidth”. The architecture is defined in such a manner that as the speed of computing and networking technologies improve over time, the InfiniBand architecture should be able to deliver higher and higher bandwidth. During the inception in 2001, InfiniBand was delivering a link speed of 2.5 Gbps (payload data rate of 2 Gbps due to the underlying 8/10 encoding and decoding). Now in 2011, it is able to deliver a link speed of 40 Gbps (payload data rate of 32 Gbps).

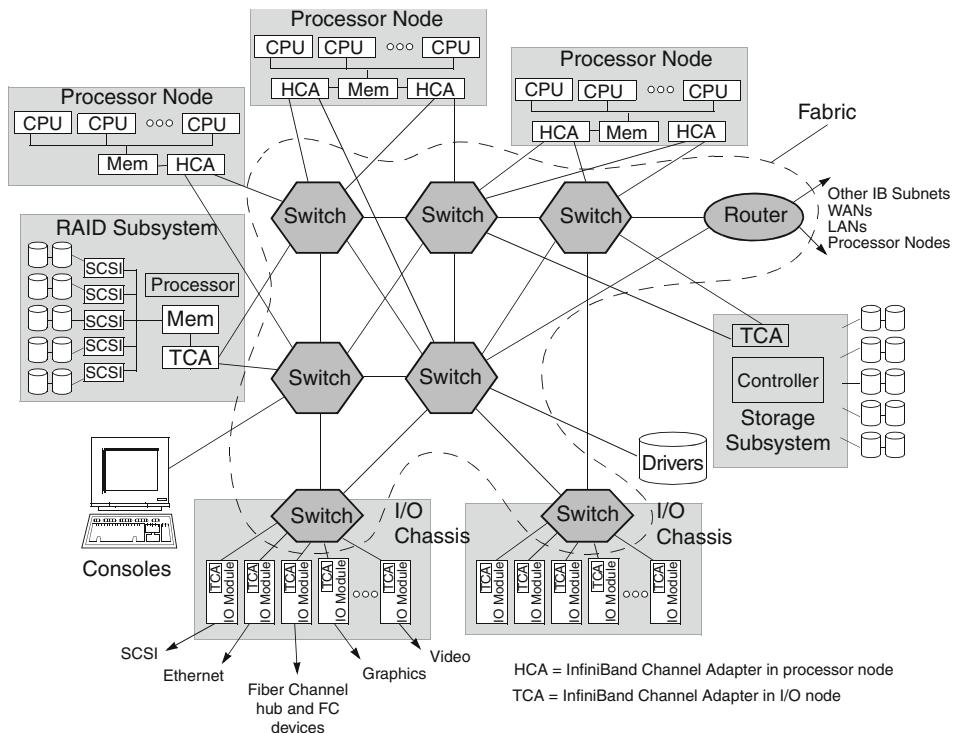

#### Communication Model

The communication model comprises of an interaction of multiple components in the interconnect system. The major components and their interaction are described below.

#### Topology and Network Components

At a high level, IBA serves as an interconnection of nodes, where each node can be a processor node, an I/O unit, a switch or a router to another network, as illustrated in Fig. 1. Processor nodes or I/O units are typically referred to as “end nodes,” while switches and routers are referred to as “intermediate nodes” (or sometimes as “routing elements”). An IB network is subdivided into subnets interconnected by routers. Overall, the IB fabric is comprised of four different components: (a) channel adapters, (b) links and repeaters, (c) switches, and (d) routers.

*Channel adapters:* A processor or I/O node connects to the fabric using channel adapters connecting them to the IB fabric. These channel adapters consume and generate IB packets. Most current channel adapters are equipped with programmable direct memory access (DMA) engines with protection features implemented in hardware. Each adapter can have one or more physical ports connecting it to either a

**InfiniBand. Fig. 1** Typical InfiniBand Cluster (Courtesy InfiniBand Standard)

switch/router or another adapter. Each physical port itself internally maintains two or more virtual channels (or virtual lanes) with independent buffering for each of them. The channel adapters also provide a memory translation and protection (MTP) mechanism that translates virtual addresses to physical addresses and validates access rights. Each channel adapter has a globally unique identifier (GUID) assigned by the channel adapter vendor. Additionally, each port on the channel adapter has a unique port GUID assigned by the vendor as well.

*Links and repeaters:* Links interconnect channel adapters, switches, routers, and repeaters to form an IB network fabric. Different forms of IB links are currently available, including copper links, optical links, and printed circuit wiring on a backplane. Repeaters are transparent devices that extend the range of a link. Links and repeaters themselves are not accessible in the IB architecture. However, the status of a link (e.g., whether it is up or down) can be determined through the devices which the link connects.

**Switches:** IBA switches are the fundamental routing components for intra-subnet routing. Switches do not generate or consume data packets (they generate/consume management packets). Every destination within the subnet is configured with one or more unique local identifiers (LIDs). Packets contain a destination address that specifies the LID of the destination (DLID). The switch is typically configured out-of-band with a forwarding table that allows it to route the packet to the appropriate output port. This out-of-band configuration of the switch is handled by a separate component within IBA called as the subnet manager, as we will discuss later in this chapter. It is to be noted that such LID-based forwarding allows the subnet manager to configure multiple routes between the same two destinations. This, in turn, allows the network to maximize availability by rerouting packets around failed links through reconfiguration of the forwarding tables.

**Routers:** IBA routers are the fundamental routing component for inter-subnet routing. Like switches, routers do not generate or consume data packets; they

simply pass them along. Routers forward packets based on the packet's global route header and replace the packet's local route header as the packet passes from one subnet to another. The primary difference between a router and a switch is that routers are not completely transparent to the end nodes since the source must specify the LID of the router and also provide the global identifier (GID) of the destination. IB routers use the IPv6 protocol to derive their forwarding tables.

## Messaging

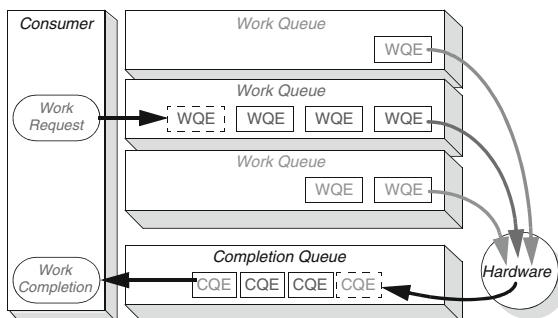

Communication operations in InfiniBand are initiated by the consumer by setting up a list of instructions that the hardware executes. In IB terminology, this facility is referred to as a work queue. In general, work queues are created in pairs, referred to as queue pairs (QPs), one for send operations and one for receive operations. The consumer process submits a work queue element (WQE) to be placed in the appropriate work queue. The channel adapter executes WQEs in the order in which they were placed. After executing a WQE, the channel adapter places a completion queue entry (CQE) in a completion queue (CQ); each CQE contains or points to all the information corresponding to the completed request. This is illustrated in Fig. 2.

*Send operations:* There are three classes of send queue operations: (a) Send, (b) Remote Direct Memory Access (RDMA), and (c) Memory Binding. For a send operation, the WQE specifies a block of data in the consumer's memory. The IB hardware uses this information to send the associated data to the destination. The send operation requires the consumer process

to prepost a receive WQE, which the consumer network adapter uses to place the incoming data in the appropriate location.

For an RDMA operation, together with the information about the local buffer and the destination end point, the WQE also specifies the address of the remote consumer's memory. Thus, RDMA operations do not need the consumer to specify the target memory location using a receive WQE. There are four types of RDMA operations: RDMA write, RDMA write with immediate data, RDMA read, and Atomic. In an RDMA write operation, the sender specifies the target location to which the data has to be written. In this case, the consumer process does not need to post any receive WQE at all. In an RDMA write with immediate data operation, the sender again specifies the target location to write data, but the receiver still needs to post a receive WQE. The receive WQE is marked complete when all the data is written. An RDMA read operation is similar to an RDMA write operation, except that instead of writing data to the target location, data is read from the target location. Finally, there are two types of atomic operations specified of RDMA operations: RDMA write, RDMA write with immediate data, RDMA read, and Atomic. In an RDMA write operation, the sender specifies the target location to which the data has to be written. In this case, the consumer process does not need to post any receive WQE at all. In an RDMA write with immediate operation requests for the same location simultaneously, the second operation is not started till the first one completes. However, such atomicity is not guaranteed when another device is operating on the same data. For example, if the CPU or another InfiniBand adapter modifies data while one InfiniBand adapter is performing an atomic operation on this data, the target location might get corrupted.

*Receive operations:* Unlike the send operations, there is only one type of receive operation. For a send operation, the corresponding receive WQE specifies where to place data that is received, and if requested places the receive WQE in the completion queue. For an RDMA write with immediate data operation, the consumer process does not have to specify where to place the data (if specified, the hardware will ignore it). When the message arrives, the receive WQE is updated with

InfiniBand. Fig. 2 Consumer Queuing Model (Courtesy InfiniBand Standard)

the memory location specified by the sender, and the WQE placed in the completion queue, if requested.

## Overview of Features

IBA describes a multilayer network protocol stack. Each layer provides several features that are usable by applications : (1) link layer features, (2) network layer features, and (3) transport layer features.

### Link Layer Features

*CRC-based data integrity:* IBA provides two forms of CRC-based data integrity to achieve both early error detection as well as end-to-end reliability: invariant CRC and variant CRC. Invariant CRC (ICRC) covers fields that do not change on each network hop. Variant CRC (VCRC), on the other hand, covers the entire packet including the variant as well as the invariant fields.

*Buffering and flow control:* IBA provides an absolute credit-based flow control where the receiver guarantees that it has enough space allotted to receive  $N$  blocks of data. The sender sends only  $N$  blocks of data before waiting for an acknowledgment from the receiver. The receiver occasionally updates the sender with an acknowledgment as and when the receive buffers get freed up. Note that this link-level flow control has no relation to the number of messages sent, but only to the total amount of data that has been sent.

*Virtual lanes, service levels, and QoS:* Virtual lanes (VLs) are a mechanism that allow the emulation of multiple virtual links within a single physical link as illustrated in Fig. 3. Each port provides at least 2 and up to 16 virtual lanes (VL0 to VL15). VL15 is reserved exclusively for subnet management traffic.

*Congestion control:* Together with flow-control, IBA also defines a multistep congestion control mechanism for the network fabric. Specifically, congestion control when used in conjunction with the flow-control mechanism is intended to alleviate head-of-line blocking for non-congested flows in a congested environment. To achieve effective congestion control, IB switch ports need to first identify whether they are the root or the victim of a congestion. A switch port is a root of a congestion if it is sending data to a destination faster than it can receive, thus using up all the flow-control credits available on the switch link. On the other hand, a port is a victim of a congestion if it is unable to send

data on a link because another node is using up all of the available flow-control credits on the link. In order to identify whether a port is the root of the victim of a congestion, IBA specifies a simple approach. When a switch port notices congestion, if it has no flow-control credits left, then it assumes that it is a victim of congestion. On the other hand, when a switch port notices congestion, if it has flow-control credits left, then it assumes that it is the root of a congestion. This approach is not perfect: it is possible that even a root of a congestion may not have flow-control credits remaining at some point of the communication (for example, if the receiver process is too slow in receiving data); in this case, even the root of the congestion would assume that it is a victim of the congestion. Thus, though not required by the IBA, in practice, IB switches are configured to react with the congestion control protocol irrespective of whether they are the root of the victim of the congestion or not.

*Static rate control:* IBA defines a number of different link bit rates, such as 1x SDR (2.5 Gbps), 4x SDR (10 Gbps), 12x SDR (30 Gbps), 4x DDR (20 Gbps), and 4x QDR (40Gbps), and so on. It is to be noted that these rates are signaling rates; with an 8b/10b data encoding, the actual maximum data rates would be 2 Gbps (1x SDR), 8 Gbps (4x SDR), 24 Gbps (12x SDR), 16 Gbps (4x DDR), and 32 Gbps (4x QDR), respectively. To simultaneously support multiple link speeds within a fabric, IBA defines a static rate control mechanism that prevents faster links from overrunning the capacity of ports with slower links. Using a static rate control mechanism, each destination has a timeout value based on the ratio of the destination and source link speeds.

### Network Layer Features

*IB routing:* IB network-layer routing is similar to the link-layer switching, except for two primary differences. First, network-layer routing relies on a global routing header (GRH) that allows packets to be routed between subnets. Second, VL15 (the virtual lane reserved for management traffic) is not respected by IB routers since management traffic stays within the subnet and is never routed across subnets.

*Flow labels:* Flow labels identify a single flow of packets. For example, these can identify packets belonging to a single connection that need to be delivered in order, thus allowing routers to optimize traffic routing when

| Attribute                                                                                           | Reliable Connection                                                                                                                       | Reliable Datagram                                                                                                                                                                                                                                                                                                                                       | Unreliable Datagram                                                          | Unreliable Connection                                                                                                                          | Raw Datagram (both IPv6 & ethertype)                                                                                                               |

| Connection oriented?                                                                                | <b>Connected.</b> The client connects the local QP to one and only one remote QP. No other traffic flows over these QPs.                  | <b>Connectionless.</b> Appears connectionless to the client – uses one or more End-to-End contexts per CA to provide reliability service.                                                                                                                                                                                                               | <b>Connectionless.</b> No prior connection is needed for communication.      | <b>Connected.</b> The client connects the local QP to one and only one remote QP. No other traffic flows over these QPs.                       | <b>Connectionless.</b> No prior connection is needed for communication.                                                                            |

InfiniBand. Fig. 3 IB Transport Services (Courtesy InfiniBand Standard)

using multiple paths for communication. IB routers are allowed to change flow labels as needed, for example, to distinguish two different flows which have been given the same label. However, during such relabeling, routers ensure that all packets corresponding to the same flow will have the same label.

### Transport Layer Features

*IB transport services:* IBA defines four types of transport services (reliable connection, reliable datagram, unreliable connection, and unreliable datagram) and two types of raw communication services (raw IPv6 datagram and raw Ethertype datagram) to allow for

encapsulation of non-IBA protocols. The transport service describes the degree of reliability and how the data is communicated.

As illustrated in Fig. 3, each transport service provides a trade-off in the amount of resources used and the capabilities provided. For example, while the reliable connection provides the most features, it has to establish a QP for each peer process it communicates with, thus requiring a quadratically increasing number of QPs with the number of processes. Reliable and unreliable datagram services on the other hand utilize fewer resources since a single QP can be used to communicate with all peer processes.

*Automatic path migration:* The Automatic Path Migration (APM) feature of InfiniBand allows a connection end point to specify a fallback path, together with a primary path for a data connection. All data is initially sent over the primary path. However, if the primary path starts throwing excessive errors or is heavily loaded, the hardware can automatically migrate the connection to the new path, after which all data is only sent over the new path.

*Message-level flow control:* Together with the link-level flow control, for reliable connection, IBA also defines an end-to-end message-level flow-control mechanism. This message-level flow control does not deal with the number of bytes of data being communicated, but rather with the number of messages being communicated. Specifically, a sender is only allowed to send as many messages that use up receive WQEs as there are receive WQEs posted by the consumer. That is, if the consumer has posted 10 receive WQEs, after the sender sends out 10 send or RDMA write with immediate data messages, the next message is not communicated till the receiver posts another receive WQE.

*Shared Receive Queue (SRQ):* Introduced in the InfiniBand 1.2 specification, shared receive queues (SRQs) were added to help address scalability issues with InfiniBand memory usage. When using the RC transport of InfiniBand, one QP is required per communicating peer. To prepost receives on each QP, however, can have very high memory requirements for communication buffers. To give an example, consider a fully connected MPI job of 1K processes. Each process in the job will require 1K - 1 QPs, each with n buffers of size s posted to it. Given a conservative setting of  $n = 5$  and  $s = 8 \text{ KB}$ , over 40 MB of memory per process

would be required simply for communication buffers that may not be used. Given that current InfiniBand clusters now reach 60K processes, maximum memory usage would potentially be over 2 GB per process in that configuration.

Recognizing that such buffers could be pooled, SRQ support was added, so instead of connecting a QP to a dedicated RQ, buffers could be shared across QPs. In this method, a smaller pool can be allocated and then refilled as needed instead of pre-posting on each connection.

*Extended Reliable Connection (XRC):* eXtended reliable connection (XRC) provides the services of the RC transport, but defines a very different connection model and method for determining data placement on the receiver in channel semantics. This mode was mostly designed to address multi-core clusters and lower memory consumption of QPs. For one process to communicate with another over RC, each side of communication must have a dedicated QP for the other. There is no distinction as to the node in terms of allowing communication. In XRC, a process no longer needs to have a QP to every process on a remote node. Instead, once one QP to a node has been set up, messages can be routed to the other processes by giving the address/number of a shared receive queue (SRQ). In this model, the number of QPs required is based on the number of nodes in the job rather than the number of processes.

## Management and Services

Together with the regular communication capabilities, IBA also defines an elaborate management semantics and several services. The basic management messaging is handled through special packets called as management datagrams (MADs). The IBA management model defines several management classes as described below.

*Subnet Management:* The subnet management class deals with discovering, initializing, and maintaining an IB subnet. It also deals with interfacing with diagnostic frameworks for handling subnet and protocol errors. For subnet management, each IB subnet has at least one subnet manager (SM). An SM can be a collection of multiple processing elements, though they appear as a single logical management entity. These processes can internally make management decisions, for example, to manage large networks in a distributed fashion. Each

channel adapter, switch, and router, also maintains a subnet management agent (SMA) that interacts with the SM and handles management of the specific device on which it resides as directed by the SM. An SMA can be viewed as a worker process, though in practice it could be implemented as hardware logic.

*Subnet Administration:* Subnet administration (SA) deals with providing consumers with access to information related to the subnet through the subnet management interface (SMI). Most of this information is collected by the SM, and hence the SA works very closely with the SM. In fact, in most implementations, a single logical SM processing unit performs the tasks of both the SM and the SA. The SA typically provides information that cannot be locally computed to consumer processes (such as data paths, SL-to-VL mappings, and partitioning information). Further, it also deals with inter-SM management such as handling standby SMs.

*Communication Management:* Communication management deals with the protocols and mechanisms used to establish, maintain, and release channels for RC, UC, and RD transport services. At creation, QPs are not ready for communication. The CM infrastructure is responsible for preparing the QPs for communication by exchanging appropriate information.

*Performance Management:* The performance management class allows performance management entities to retrieve performance and error statistics from IB components. There are two classes of statistics: (a) mandatory statistics that have to be supported by all IB devices and (b) optional statistics that are specified to allow for future standardization. There are several mandatory statistics supported by current IB devices including the amount of bytes/packets sent and received, transmit queue depth at various intervals, number of ticks during which the port had data to send but had no flow-control credits, etc.

*Device Management:* Device management is an optional class that mainly focuses on devices that do not directly connect to the IB fabric, such as I/O devices and I/O controllers. An I/O unit (IOU) containing one or more IOCs is attached to the fabric using a channel adapter. The channel adapter is responsible for receiving packets from the fabric and delivering them to the relevant devices and vice versa. The device management class does not deal with directly managing the end

I/O devices, but rather focuses on the communication with the channel adapter. Any other communication between the adapter and the I/O devices is unspecified by the IB standard and depends on the device vendor.

## InfiniBand Today

To achieve high performance, adapters are continually updated with the latest in speeds (SDR, DDR and QDR) and I/O interface technology. Earlier InfiniBand adapters supported only PCI-X I/O interface technology, but have now moved to PCI-Express (x8 and x16) and Hyper-Transport. More recently, QDR cards have moved to the PCI-Express 2.0 standard to further increase I/O bandwidth. Although InfiniBand adapters have traditionally been add-on components in expansion slots, they have recently started moving onto the motherboard. Many boards including some designed by Tyan and SuperMicro include adapters directly on the motherboard.

In 2008, Mellanox Technologies released the fourth generation of their adapter called ConnectX. This was the first InfiniBand adapter to support QDR speed. This adapter in addition to increasing speeds and lowering latency included support for 10 Gigabit Ethernet. Depending on the cable connected to the adapter port, it either performs as an Ethernet adapter or an InfiniBand adapter. The current version of ConnectX adapter, ConnectX-2 supports advanced offloading of arbitrary lists of send, receive and wait tasks to the network interface. This enables network offloaded collective operations, which are critical to scaling messaging libraries to very large systems.

The IBA specification does not specify the exact software interface through which hardware is accessed. OpenFabrics is an industry consortium that has specified an interface through which IB hardware can be accessed. It also includes support for other RDMA capable interconnects, such as iWARP.

A few current usage environments for IB are mentioned below:

*Message passing interface:* MVAPICH [3] and MPICH2 [4] are implementations of MPI over InfiniBand. They are based on MPICH1 [5] and MPICH2 [6], respectively. As of January 2011, these stacks are used by more than 1,330 organizations in 60 countries around

the world. There have been more than 53,000 downloads from the Ohio State University site directly. These stacks are empowering many powerful computers, including “Ranger,” which is the sixth ranked cluster according to the November 2008 TOP500 rankings. It has 62,976 cores and is located at the Texas Advanced Computing Center (TACC). MVAPICH/MVAPICH2 work with many existing IB software layers, including the OpenFabrics Gen2 interface. These software stacks are also available in an integrated manner with the software stacks of many other InfiniBand vendors, server vendors, and Linux distributors (such as RedHat and SuSE).

The OpenMPI project [7] is yet another implementation of MPI. Open MPI also works on InfiniBand using the OpenFabrics interface and is widely used. In addition to the open-source implementations of MPI, there are several commercial implementations of MPI, such as Intel MPI and Platform MPI.

*File systems:* Modern parallel applications use terabytes and petabytes of data. Thus, parallel file systems are significant components in designing large-scale clusters. Multiple features (low latency, high bandwidth and low CPU utilization) of IB are quite attractive for designing such parallel file systems. There are implementations of widely used parallel file systems such as Lustre [8] and Parallel Virtual File Systems [9] over InfiniBand using OpenFabrics interface.

*Data-centers:* Together with scientific computing domains such as the MPI and parallel file-systems, IB is also making significant inroads into enterprise computing environments such as web data centers and financial markets. There are two ways in which sockets-based applications can execute on top of IB. In the first approach, IB provides a simple driver (known as IPoIB) that emulates the functionality of Ethernet on top of IB. This allows the kernel-based TCP/IP stack to communicate over IB. However, this approach does not utilize any of the advanced features of IB and thus is restricted in the performance it can achieve. The second approach utilizes the Sockets Direct Protocol (SDP) [10]. SDP is a byte-stream transport protocol that closely mimics TCP socket’s stream semantics. It is an industry-standard specification for IB that utilizes advanced capabilities provided by the network stack (such as the hardware offloaded protocol stack and RDMA) to achieve high

performance without requiring modifications to existing sockets-based applications.

Recently, companies such as RNA Networks are providing memory virtualization using IB. These products are based on the core concept of RDMA and os-bypass protocols.

## Future Directions

Strong features and mechanisms of IB, together with the continuous advancements in IB hardware and software products, are leading many high-end clusters and parallel file systems. In less than 9 years of its introduction, the open standard IB is already claiming more than 40% share in TOP500 systems. This market share is expected to grow significantly during the next few years. Multiple parallel file systems, storage systems, database systems, and visualization systems are also using InfiniBand. As indicated in this entry, InfiniBand is also gradually moving into campus backbones and WANs. This is opening up multiple new applications and environments to utilize InfiniBand.

IB 4x QDR products are currently available in the market in a commodity manner. These are getting to be used in modern clusters with multi-core nodes (8–16 cores per node). IB Roadmap also talks about the availability of FDR (Fourteen Data Rate) products during the 2012 time frame. The FDR technology promises to use 64/66 bit encoding and deliver 56 Gbps data rate. The next generation IB products with EDR (Enhanced Data Rate) technology, supporting 100 Gbps data rate, are planned for 2013. The future IB technologies promise to build high performance, scalable and balanced systems with next generation multi-core nodes (16–100 cores per node) and accelerate the field of high-end computing.

## Bibliographic Notes and Further Reading

Open-standard high-performance networking technologies, such as InfiniBand have spurred a lot of interest among researchers. This is an active area of research. There are several sub-domains: scalability and performance, routing, fault-tolerance, design of file-systems etc.

The reader is encouraged to peruse [11–16] for more details on scalability and performance. Routing and

management are covered in [17–20]. Fault-tolerance issues are covered in [21, 22].

## Instruction-Level Parallelism

Instruction-level parallelism is the possibility of scheduling multiple machine instructions from a single program so that their executions overlap in time. Instruction-level parallelism was exploited by some early machines such as the CDC 6600 and IBM 360/91.

Today, superscalar, EPIC, and VLIW machines take advantage of this form of parallelism.

### Definition

The *Intel Core Microarchitecture* is the name of the internal architecture of multicore processor implementations from *Intel Corporation* introduced in 2006. The processing cores of the Core Microarchitecture use

sophisticated ways to get the highest level of *Instruction Level Parallelism* (ILP) from sequential instruction streams, using out-of-order, superscalar pipelining. The on-chip memory hierarchy employs multiple levels of inclusive caches, uses different kinds of hardware prefetching techniques, and is partly shared among the cores on the chip.

These processors belong to the family of *x86-compatible* processors, originating in the 8086 processor from Intel in 1978. Their Instruction Set Architecture (ISA) – i.e., the programming interface – is classified as CISC (Complex Instruction Set Computing), which means that the assembly code is compact but quite complex and irregular. The 32-bit and 64-bit extensions of the original x86 ISA are called *IA-32* and *Intel 64* by Intel, respectively. Starting their success in Personal Computers (PC) from IBM, processors with these ISAs are dominating today in desktop and laptop machines, but are also used heavily in the server market as well as in HPC systems.

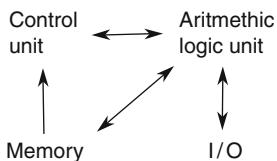

### Discussion

This entry describes Intels Core Microarchitecture as example of a machine with Instruction Level Parallelism (ILP), that is, it focuses on how parallelism is exploited in a processor core of this micro-architecture, executing a single sequential instruction stream. For detailed description of techniques used as well as more about these processors when embedded into shared-memory multiprocessors, see related entries as mentioned in the according section at the end of this entry. Before the description of the micro-architecture, a short overview of microprocessor components, ILP techniques, and the x86 ISA is given as basis. One has to note that the term “processor architecture” itself is used in different ways, one being the pure programming interface (i.e., the ISA), and the other describing the inner workings of the processor, i.e., the micro-architecture.

### Introduction

#### Microprocessor components

Processor cores of Intels x86 family, as almost any processor core nowadays, work according to the von-Neumann architecture: the main components are a control unit, an arithmetic logic unit (ALU), memory, and

**Intel Core Microarchitecture, x86 Processor Family, Fig. 1**  
Components of a von-Neumann architecture

an I/O subsystem as well as connections between all components. This can be seen in [Fig. 1](#). The first two make up a *Central Processing Unit* (CPU). The memory consists of a one-dimensional array of equal-sized memory cells, which both hold data used in computation done by the ALU as well as program code to be executed by the control unit. This makes it possible to treat program code as data, thus vastly simplifying mechanisms needed, for example, to load/store data and code from/to I/O devices. It also allows programs to generate new code, or modify their code. However, as memory regularly needs to be accessed both from the control unit as well as the ALU, this becomes a potential bottleneck. In fact, memory performance (access latency and bandwidth) is a limiting factor for the performance of modern processors (see entry [►Memory Wall](#), also called the von-Neumann bottleneck). The reason is that memory on the one hand, and control unit/ALU on the other hand, are manufactured as separate chips, such that memory accesses have to cross chip boundaries. This is done for more flexibility, for example, enabling the use of different manufacturing technologies. In the von-Neumann architecture, a program is executed by using an instruction pointer. An instruction at the memory pointed to by the instruction pointer is fetched from memory, and afterward interpreted by the control unit. For every instruction type, the control unit has to know the exact sequence of actions to do, be it the execution of a calculation via the ALU, probably involving loading/storing data from memory, or directly influencing the instruction pointer, which otherwise is just incremented to point at the next instruction.

As can be seen from the above description, fast program execution requires fast memory access. This can be improved by not forcing every memory access to reach out to the off-chip memory module, which

is relatively far away. Instead, buffers are introduced which are able to hold copies of memory cells. The fastest buffers are called the register file, and are accessed explicitly by mentioning register numbers in the instructions, and adding instructions to move data between memory and registers. Further, larger on-chip buffers are added, so-called *caches*, which are able to transparently hold copies of memory cells. As access time to these buffers are reciprocal to buffer sizes, it is beneficial to have a hierarchy of caches. Together with register files on the one end and main memory on the other end, this is called the memory hierarchy. As memory accesses for fetching instructions are different from other accesses, it is beneficial to provide separate buffers for these uses, that is, have separate instruction and data caches on the first level. On the second, larger level, a unified cache is used.

One way to make a processor run faster is increasing the clock frequency, another one is to do multiple things simultaneously. Regarding the latter, from the point of view of a programmer, the worst way of doing things simultaneously is the requirement to explicitly have to specify what can be done in parallel and what not. Therefore, processor architects first try to exploit parallelism which is implicitly available in a single sequential instruction stream. An easy way is to increase bit-level parallelism: as long as it is useful for programs without wasting too much resources, it is the best to work with data paths as wide as possible. This is reflected by the x86 ISA starting as 16-bit architecture with the 8086, going to 32-bit with the 80386, and recently to 64-bit. The respective bit-width is used as register width and width of signal paths for data and memory addresses. Similar is data-level parallelism (DLP): if multiple data can be worked on in the same way, these can be packed in vector registers with multiple calculations done synchronously in one clock cycle in enhanced ALUs, following the SIMD (Single Instruction Multiple Data) concept. The according x86 ISA enhancements are called MMX and SSE (see [►Vector Extensions, Instruction-Set Architecture \(ISA\)](#)). Another type of parallelism possible with one instruction stream is called *Instruction Level Parallelism* (ILP). It exploits the fact that sub-actions of one or multiple instructions (if there are no data dependencies) can

be done at the same time. The techniques are described in the next section in more detail, as this is needed to understand the micro-architecture of modern processors. The last type of parallelism is called *Thread Level Parallelism* (TLP), where multiple instruction streams work in parallel to increase performance of a program. This needs special support at different levels: hardware must be added to allow for multiple processors/processor cores to be put together, for example, special care is needed to keep the multiple copies found in different caches consistent. Instructions for synchronization and communication among the processors have to be added. Also, the software, starting with the Operating System, needs to be able to control multiple streams of execution. Finally, correctness of a parallel program is far more difficult to check. Therefore, on smaller systems with only one processor chip, for a long time, only execution of a single instruction stream at a time was supported. However, after exploiting DLP/ILP to the maximum, only increasing the clock frequency was available for improving performance.

From the beginning of microprocessor technology, it could be observed that there was a constant development of miniaturization. This observation manifested in the so-called Moore's Law: every 18 month, the number of transistor budget available for use on one chip doubles. Astonishingly, this "law" holds true up to now and into the foreseeable future. Processor manufacturers were able to extract ever increasing computing power from the exponentially growing transistor budget, by enlarging caches, increasing bit- and data-level parallelism as well as ILP to the maximum (the latter making the control units extremely complex). At the same time, miniaturization allowed to increase the clock frequency. However, this came to a halt in recent years. The high clock rates reached, together with the small structure widths, result in a lot of energy lost because of leakage current in the chip, and thus requires expensive cooling. To be able to further sell processors, the only way for processor manufactures was to add TLP inside one chip while keeping clock rate constant. This was the beginning of the multicore era, with the need to feed current processor chips with parallel programs in the hope to further get exponential performance increase for programs from Moore's law still proving true. Thus, modern processes consist of multiple control/execution units, working in parallel. Yet,

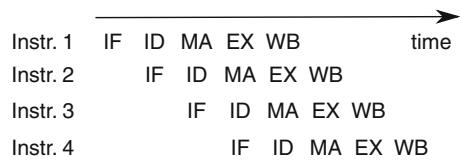

the cores can share resources, the most obvious being caches.

### Instruction Level Parallelism

As written before, Instruction Level Parallelism (ILP) exploits the fact that sub-actions of one or multiple consecutive instruction in one sequential instruction stream can be executed simultaneously. The most important principle is that instructions can be subdivided into sub-actions, also called stages. Each instruction stage is executed in one clock cycle by different hardware. While one instruction "flows" through the different hardware stages (the so-called pipeline), multiple instructions can be in execution at the same time, as shown in Fig. 2. Typical stages are IF (instruction fetch), ID (instruction decode), MA (memory access), EX (execute calculation), and WB (write back).

For a given chip manufacturing technology (typically identified by a structure width metric such as 90 nm, 60 nm, or 45 nm), the time needed for a signal to reliably bypass a gate level is fixed. Smaller stages need less successive gate levels inside, therefore the clock rate can be higher. Yet, the pipeline design makes sure that at every clock cycle one instruction will finish execution. Thus, by increasing the number of stages (with every stage responsible for simpler sub-actions), the performance is increased. However, the number of stages is limited by a few factors: simplifications cannot be done indefinitely, but more important, different conflict cases can appear:

- Resource conflicts happen when hardware resources shared by multiple stages need to be accessed at the same time, such as access paths to registers/caches. Then, the later instructions have to wait. This can be overcome by duplicating resources, for example, by adding multiple access ports to register files.

**Intel Core Microarchitecture, x86 Processor Family. Fig. 2**  
Pipelined execution of instructions

- Data conflicts happen when there is a data dependence between instructions, allowing the execution of the later instruction not to proceed in the pipeline as long as a given result is not available. To avoid this, a compiler should schedule instructions with data dependencies as far away from each other as possible. Anti-dependencies can be avoided by using temporary (shadow) registers. Another possibility is to allow instructions to be reordered, that is, instructions to overtake each other in the pipeline (so-called out-of-order). Aside from the need for complex dependence checking hardware, a final stage needs to be added to get instruction retirement in correct order again.
- Control conflicts arise when the next instruction to be executed is not known. This happens with conditional branches, where the condition is yet to be calculated. Thus, the pipeline cannot be kept filled. To overcome this, the compiler should schedule calculation of branch conditions way before the branch. Another solution is to predict the condition, and to speculatively execute instructions following the branch. If the prediction is wrong, results of already, but wrongly executed stages have to be thrown away. To minimize this problem, sophisticated branch prediction algorithms are used, which store the history of previous branch decisions in a so-called branch target buffer (BTB).

Complementing the pipelining principle described up to now, another technique to exploit ILP is superscalarity. For every stage of a pipeline, there are multiple hardware units available. This allows to feed multiple instructions into the *superscalar* pipeline in one clock cycle. Typically, implementation involves multiple queues filling up with instructions to be executed by different execution units. Extra care has to be taken to meet data dependencies. The number of instructions that can be executed by duplicated execution units for the same pipeline stages is called the *issue width* of the pipeline at this stage. For the execution stage involving the ALU, usually, there is not a complete duplication done. Instead, floating point units, especially for multiplication or division, are available only once, as these take up much space. Therefore, the issue width of the execution stage usually is higher than the rest of the pipeline to minimize the probability that

there are not enough ALUs of needed type available for the instructions in flow.

With this knowledge, the components of the Core Pipeline in the later section are easy to explain. For more details on Pipelining, see the corresponding entry.

## CISC Versus RISC

The programming interface of a processor is called its *Instruction Set Architecture* (ISA). The ISA of x86-compatible processors is classified as CISC (Complex Instruction Set Computing), which means that the assembly code is compact but quite complex and irregular. When the first x86 processor was developed by Intel, this was the standard way: CISC is found in the Motorola 68000, the Zilog Z80, and in IBM mainframe CPUs at that time. A compact ISA was a benefit, as memory was expensive. As programmers often used assembly language, instructions for specific use cases and complex addressing modes made sense. Later in the 1980s, compilers did not make use of such complex assembly instructions, and thus, processors with simpler ISA were designed, reducing resource consumption of the decoding step. Such designs belong to the RISC (Reduced Instruction Set Computing) idea. They use regular instructions of same size, have load/store instructions as only means to access memory, and work with large register files. Examples are the PowerPC, MIPS, SPARC, and ARM processor designs. Traditionally, each CISC instruction was executed by running a microcode program. Starting with the Intel Pentium (see below), instructions are decoded into a sequence of microoperations, similar to RISC instructions. Therefore, aside from the added cost of a decoding step, there is not much difference between CISC and RISC implementations. However, the compactness of CISC code reduces memory pressure, and allows for smaller L1 instruction caches.

## History of x86 Processors

In 1978, Intel introduced its 8086 processor, a 16-bit architecture meant to compete with the Z80 processor famous at that time. Clocking at 10 MHz, it consisted of around 29,000 transistors, and was able to address 1 MB of external memory by adding 16-bit offsets to special segment registers providing the upper bits. The 8086 had seven general-purpose registers plus the stack

pointer, a flag register, and the segment registers. Using an extended version called 8088, IBM sold its first PC in 1981 with an Intel processor. While being able to only do integer calculation, it was possible to add the floating point coprocessor 8087. A significant enhancement to the x86 family happened in 1985 with the introduction of the i386 processor, which was clocked at 33 MHz, added a 32-bit execution mode, enlarged registers and most importantly, introduced virtual memory with 32-bit flat address spaces. The successor i486 integrated the floating point unit.

Intel's x86 processor success strongly relates to the early success of the component-based design of the IBM PC, resulting in a mass market for x86-compatible processors, and thus also competition. To make it more difficult for competitors to place their products, Intel registered the trademark "Pentium" as name of the next processor update in 1993. As the first in the x86 family, this processor ("P5") added 8 kB instruction and 8 kB data caches on-chip, and allowed for an off-chip L2 cache. Further, a superscalar pipeline design was introduced, with two instruction decoders and two ALUs. To reduce pipeline stalls, it introduced a branch prediction unit. A later version, the "Pentium MMX," extended the x86 ISA by data-level parallelism with vector registers and operations working on 8 bytes at once. This parallelism has to be found by the compiler, and correct data layout needs to be used. Yet, this technique proved successful for a set of applications, and is still being extended (Intel recently announced x86 processors supporting vector operations with 64-byte width, marketed as LNI: Larrabee New Instructions). Similar instructions can, for example, be found in the PowerPC (called AltiVec) or SPARC (VIS).

The micro-architecture following P5 in 1995, called P6, increased the superscalarity in the decoding stage to three, and execution stage to five. To effectively allow to exploit these units, support for out-of-order execution in the pipeline was added. While increasing the complexity significantly with hardware for data dependence checking, more physical registers, and new stages, for example, for register renaming and instruction reordering, it significantly improves ILP even with badly scheduled code by some compiler. The P6 needs an increased number of pipeline stages, for example, in total 12 stages for execution of integer instructions. As further improvement, the L1 caches were doubled in size, and chips were packaged together

with modules for 256 kB up to 1 MB of L2 caches. In the following years, the P6 architecture got successive improvements - partly triggered by competition from the company AMD: the "Pentium-III" implementation had improved, 16-byte wide vector support (SSE), on-chip L2 caches, and almost reached 1 GHz clock rate in 1999.

At this time, the clock rate was a selling point for x86 compatible processors. Competitor AMD had a small advantage in this regard. Therefore, the next micro-architecture from Intel, Netburst, was designed to reach extremely high clock rates. While forcing L1 cache sizes back to 8 kB again, more importantly, pipeline stages had to be simplified, resulting in stage numbers of 20 up to 31 in later implementations. However, performance often does not increase accordingly because of much higher probability of pipeline conflicts, and thus pipeline stalls. Netburst has 3 integer and 2 floating point ALUs. However, together with the extremely deep pipeline, one instruction stream rarely can exploit these execution units. As important enhancement, Intel integrated, for the first time, a form of thread-level parallelism (TLP) into its processors. *Simultaneous Multithreading* (SMT), by Intel called Hyperthreading, keeps two instruction stream contexts with own register sets for one superscalar pipeline. The pipeline is filled with instructions from both streams, effectively reducing pipeline conflicts and enhancing utilization of the ALUs. Intel promised a performance increase up to 40%. However, with a big drawback: programs need to be parallelized. An interesting enhancement of Netburst is the *Trace Cache*, an instruction cache containing up to 16 k decoded microoperations. Further, the L2 size was improved up to 2 MB. An important addition to the ISA in the later implementations of Netburst was actually only in reaction to competitor AMD: Intel had to introduce a 64-bit extension, compatible to the 64-bit extension of AMD processors. The problem was that Intel originally intended to reserve 64-bit for its new Itanium architecture for the high-end server and HPC market. With x86 processors supporting 64-bit, customers could choose the cheaper platform for their needs. To emphasize intentions, the Itanium ISA was called IA-64 by Intel, and the 32-bit x86-ISA was renamed IA-32 at that time. After first naming the 64-bit x86 extension EM64T, then IA-32e, it is now simply called "Intel 64" to avoid confusion.

In some way, Hyperthreading allowed Intel to estimate the acceptance of TLP on a chip, and lead to increased interest in multithreaded programming and language extensions such as OpenMP. On the other hand, the race for highest clock rates showed the limits reached: together with the small structure lengths of technology, leakage effects raised the power consumption and heat disposal, requiring expensive cooling techniques. The solution is to cut the clock rate and add more processor cores on a chip instead. The last implementation of Netburst, "Pentium D", was built as dual-core, combining two single-core dies in one package. The multicore era for x86-compatible processors had started.

## The Core Microarchitecture

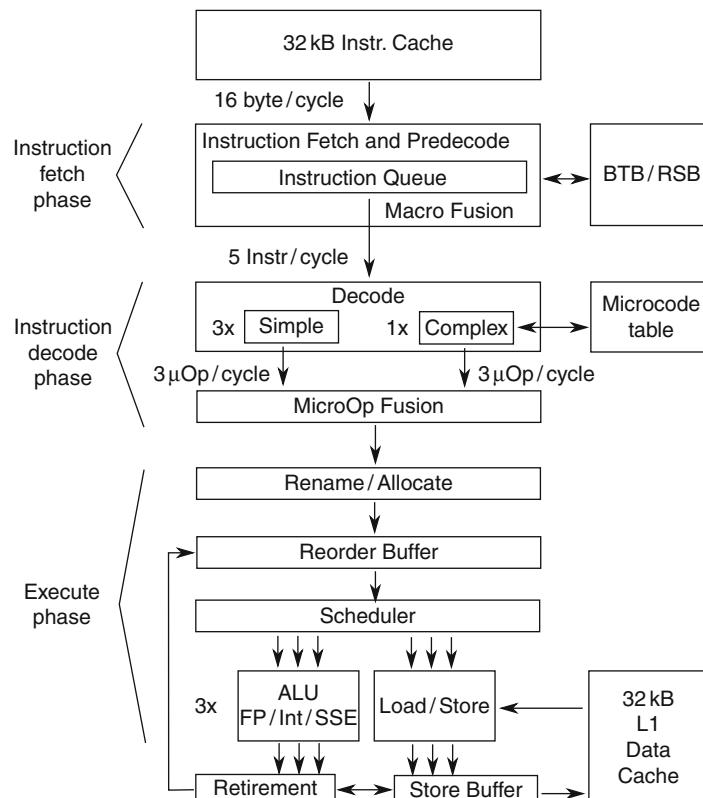

After the architectural problems of Netburst, the following micro-architecture from Intel, just called "Core," is explicitly designed as basis for multicore processors. For a performance increase in contrast to the previous single-core processors, the clock rate can be reduced

with multiple cores. This allows for more complex pipeline stages than found in Netburst, and thus a reduced pipeline depth. The Core architecture goes back to 14 stages, resulting in reduced potential for pipeline stalls, and increased performance when compared to Netburst at same clock rate. Intel used its successful P6 architecture as base for Core. The first implementations, called "Core-2" were introduced in 2006, first as dual-core, later as quad-core designs. The quad-core versions using the Core Microarchitecture always can be seen as coupling two dual-core designs on one chip. The later processor implementations for servers (Xeon) contain a shared L3 for all four cores.

### Pipeline Structure

A simplified version of the pipeline of the Core Microarchitecture with its 14 stages is shown in Fig. 3.

The instruction fetch stage is able to fetch 16 bytes per cycle, filled from a 32 kB instruction cache, and assisted by branch prediction. The prediction uses a branch target buffer (BTB) which holds the history of last branch decisions indexed by instruction address.

Intel Core Microarchitecture, x86 Processor Family. Fig. 3 Block diagram of the Core Microarchitecture

Further, to accurately predict function returns, it has a 16-entry *Return Stack Buffer* (RSB). The prefetched bytes are put into the predecoding stage, where length of instructions is determined, and decoding of any prefix bytes is done (the need for a two-phase decoding shows the reached level of complexity of the x86 ISA). Pre-decoded instructions are put into a instruction queue. From there, four decoders can decode up to five original x86 instructions per cycle. This is possible as some often-used two-instruction sequences are recognized at once (called *Macro-Fusion*). One of the decoders is able to handle complex instructions by looking up corresponding sequences of operations in a microcode table. The generated sequence of microoperations ( $\mu$ Ops) is checked for possibility of so-called  $\mu$ Op-fusion. Some primitive sequences can be joined to form more complex microoperations. This saves bandwidth in the pipeline. An example would be a comparison operation directly followed by a branch.

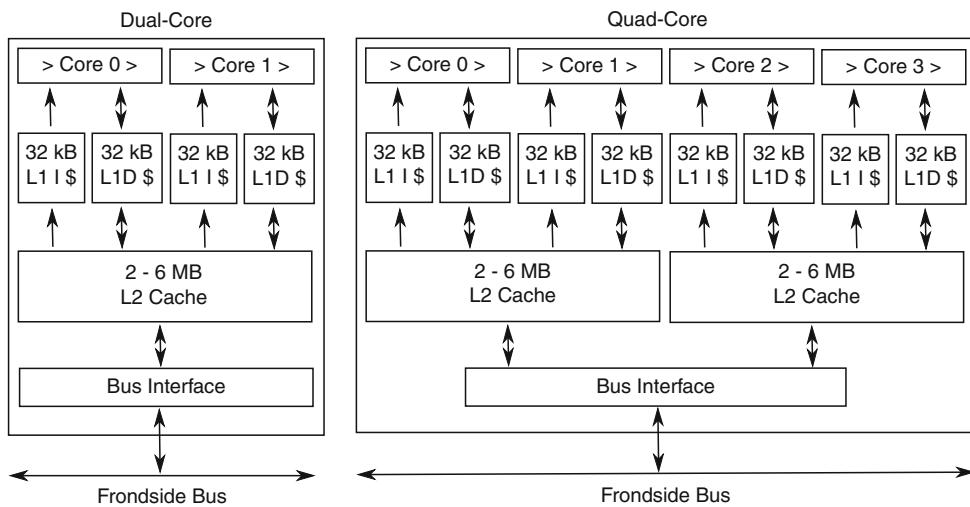

After decoding into microoperations, mapping of ISA registers to physical registers is done (register renaming/allocation). This enables reduction of data dependencies (such as write-after-write hazards), and allows for more ILP to be exploited by out-of-order execution. The following stage is the reorder buffer, where dependencies are checked. Here, operations are allowed to overtake each other. The next stage, the scheduler, is able to dispatch up to six microoperations per cycle. It feeds three ALUs and another three execution units responsible for memory access. All ALUs can handle 128-bit vector operations at a throughput of one result per clock cycle. At most, this allows eight floating point operations to be executed in one cycle (via SSE instructions). The results of the ALUs lead to notifications back to the reorder buffer, allowing waiting operations then to be dispatched by the scheduler according to previously calculated data dependencies. All loads and stores to memory first pass a store buffer before the memory access operations are retired. The store buffer allows loads to directly use the result of store instructions, and allows multiple stores to nearside memory cells to be combined, thus increasing the effective bandwidth to the L1 data cache. Finally, the retirement stage is able to complete the execution of up to four microoperations per cycle, by reordering their retirement in program order of original instructions.

## Cache Subsystem

Figure 4 shows memory hierarchies used in implementations of the Core Microarchitecture, including the cache subsystem. The Core Microarchitecture has separate L1 instruction and data caches, each with a size of 32 kB. Separate L1 caches for different uses is important to reduce access conflicts, but also allows to tune the caches for the different access behavior. The unified L2 cache is 2 up to 6 MB large, serving L1 caches of two cores. With a quad-core design, this means that there are two L2 caches, as can be seen in the figure. For best exploitation, each L1 as well as L2 cache has its own prefetch units, with all load and store operations between cores and L1s done with 128-bit width. Both the L1 data as well as the L2 cache use a write-back scheme, that is, writes done are kept in the fastest caches as long as possible, reducing store transactions.

L1 data caches employ two kinds of prefetchers each: one to detect streaming accesses, the other to detect stride accesses by single instructions, that is, access behavior is detected based on instruction address. Similarly, the L2 caches have stream prefetchers. In addition, the x86 ISA (part of instructions added with SSE) allow for software prefetching, that is, loading instructions without effect aside from loading data into caches. Together, hardware and software prefetching can prove quite effective to reduce cache misses. The memory system of multiple processors with the Core architecture uses a bus to access memory (the so-called, Intel-proprietary *Frontside Bus*). On the bus, a chipset is attached with memory controllers talking to the memory modules. Thus, all cores in the system share the bus. In server systems, more expensive chipsets allow to have point-to-point connections to each processor chip. This way, multiple processors can access memory at the same time.

To assure cache coherence, that is, to make sure that processor cores do not use outdated data because of modified data in other caches, a cache coherency protocol has to be used when there are multiple caches at the same level. This is done on the one side by observing bus transactions done by other processors (“snooping” the bypassing traffic), but because of write-back, also by asking other cores at load time whether they have modified copies. On the level of a multiprocessor system with one Frontside bus, the so-called MESI-protocol is used

**Intel Core Microarchitecture, x86 Processor Family. Fig. 4** Memory hierarchies used in implementations of the Core Microarchitecture

(the four characters represent the four possible states for a cache line), which belongs to the class of snooping protocols. However, in servers with point-to-point connections to the chipset, all the bus transactions usually need to be broadcast to allow for snooping, thus reducing the benefit. These systems employ so-called *Snoop Filters*, which allows to reduce this coherency traffic in given situations.

## New Developments

The next micro-architecture from Intel is the Nehalem architecture. Its main changes are a large L3 cache shared among all four or eight cores on a processor chip. Instead, the unified L2 cache is now private for each core, and reduced in size to 256 kB. Further, all cores (with their L1/L2) can now be driven at different clock rates, and put to sleep independently. The so-called Turbo mode allows to even raise the clock rates of single cores when temperature allows. In effect, this leads to faster program execution when only a few cores are actually used on a chip. Another significant change is the move of memory controllers into the chip, allowing to directly attach main memory. Chips are coupled via a high-speed, point-to-point interconnect, called QPI (Quick-Path Interface). A consequence for multi-chip/socket systems is that distance to memory is different, depending on which core accesses the memory. Up to

the Core Microarchitecture, Intel multiprocessor systems used a Frontside bus, resulting in uniform memory access (UMA). With the introduction of Nehalem, multiprocessor systems now use nonuniform memory access (NUMA), which AMD systems had employed for quite some time. While local memory accesses are faster, remote accesses can become an obstacle to program performance, thus needing new optimization techniques in programs and the operation system. Also, the cache coherence protocol has to be adapted. Intel enhanced MESI by a fifth state (F), which allows to directly forward modified cache lines to other chips without writing to memory (this is similar to the fifth state of the MOESI protocol used by AMD).

For some time, graphics processors have improved quite significantly in computation power, driven by 3D games. Recently, this power is made available to programmers via GPGPU interfaces (General Purpose Graphics Processing Unit). For their purposes, graphics processes contain huge arrays of ALUs, driven in clusters by control units. They can be seen as using an extreme version of the vector extensions of standard processors. Intel recently announced a processor with a large number of simplified cores, but with very wide vector units (64 byte), named Larrabee. Its advantage is that each core is x86-compatible. However, as a core is probably a lot slower than a current Nehalem core, the chip is built as graphics processor. With more

transistor budget available, it can be expected that such simple, but specific cores with wider vector units are mixed with more complex ones, resulting in heterogeneous multicore processors. This also would mean that graphics units are moved into the same chip as the main processor cores, similar to the x87 floating point coprocessor in i486 times.

## Bibliographic Notes and Further Reading

A good introductory book on computer architecture is [1]. A detailed, step-by-step introduction into computer architecture and microprocessor design, using the MIPS ISA, is given in [2]. From the same authors, [3] provides more in-depth reading with practical evaluations of concepts. A good coverage of how to build large parallel machines, again with evaluation of concepts with practical applications, is provided in [4]. For coverage of current microprocessor trends, see [5].

The best reference about the Intel® 64 and IA-32 Instruction Set Architectures, including overviews of the micro-architectures, is the Software Developer's Manual together with the Optimization Reference Manual from Intel Corporation [6, 7], both available for free download from their web site. For a more introductory text on microprocessors, especially also from Intel, see [8].

On the Internet, a lot of technical information for x86 processors can be found on [9], and articles about recent chips, for example, on [10].

## Intel® Parallel Inspector

PAUL PETERSEN

Intel Corporation, Champaign, IL, USA

### Synonyms

Data race detection; Deadlock detection; Illegal memory access

### Definition

Intel® Parallel Inspector is a product that integrates with the Microsoft Parallel Studio to provide support to software developers in analyzing parallel software for problems relating to the correct execution of an application.

### Discussion

#### Introduction

Intel® Parallel Inspector is designed as a component of the Intel® Parallel Studio, a suite of software development tools to aid in the creation of parallel applications. Software development involves many different aspects from the creation of specifications, to writing the implementation code, testing, debugging, and tuning the resulting application. All of these aspects are true when writing any kind of software, with additional challenges arising when writing software which exploits concurrency via threading or parallelism. Parallel Inspector serves as an intelligent assistant to notify the developer about defects in the parallel application that could

cause incorrect behavior. In particular, Parallel Inspector focuses on a few core problems. These are misuse of synchronization which can result in data races or deadlocks, and incorrect memory accesses resulting in illegal or invalid memory references in parallel applications.

## Requirements for Parallel Inspector

Intel® Parallel Inspector works with the Microsoft Visual Studio 2005 or 2008 development environment on the Windows XP, Vista, or Windows 7 operating system. It can either be installed by itself or as part of the Parallel Studio bundle.

Intel® Parallel Inspector operates by analyzing the dynamic behavior of a native code application via dynamic instrumentation. The typical application is written using the C or C++ language. It is preferable to analyze applications that are built with debugging symbols to map the dynamic behavior to the source code. It is also helpful to tailor the inputs driving the test cases to be small and focused on the portions of the applications that the developer wishes to analyze. Using the smallest inputs possible, avoid redundant work during the analysis where similar memory access patterns are repeatedly verified.

## Defects in Parallel Software

The defining characteristic of threaded software is the potential for concurrent access to memory. To be correct, these memory accesses need to follow certain rules:

1. When reading or writing, the memory address must be valid.
2. When reading, contents of the memory address must be initialized.
3. The memory access must be properly synchronized.

Each of these rules is examined in turn to see how Parallel Inspector can assist the software developer.

### Invalid Memory Accesses

First, consider if a memory address is valid. In the memory address space for an application, different parts of the address space are allocated for various purposes. For example, part is allocated for the instructions comprising the code of the application. Part is/Parts are allocated as the stack(s) for the threads. Part is/Parts are allocated for the heap(s) used by the application. Part is/Parts are reserved by the operating system for its

own usage. Typically, other regions of the application's address space are unallocated, and memory references to the unallocated regions of the address space are considered to be illegal. Similarly, requests to write into read-only pages are also illegal (such as attempting to write to the code pages).

### Uninitialized Memory Accesses

Second, consider if it is legal to access a memory address. Writes to any valid memory address are legal even if the memory is uninitialized. However, reads from uninitialized memory addresses are illegal as the value read may be nondeterministic and cause the behavior of the application to be undefined. A specific challenge for uninitialized memory access detection is the reading from uninitialized memory of a value that is ultimately not used. For example, a word containing 4 bytes might only have its lower byte initialized. A common programming pattern would be to load all 4 bytes via a word load instruction, and then mask off all but the lowest byte. By throwing away the high bytes in the mask operation the uninitialized memory cannot affect the behavior of the application, even though it was physically read.

Similarly the same concept can apply to larger structures. Consider a structure containing a "char" variable followed by a "double" variable

```
struct Ex1 {
 char c;
 double d;
};
```

Alignment rules may require that field "d" be aligned on an 8 byte boundary. This forces 7 padding bytes to be inserted after "c", yielding a structure with 16 bytes.

The difficulty arises from structure assignment.

```
struct Ex1 x, y;
y.c = 'a';
y.d = 3.14;
...
x = y;
...
```

Often structure assignment is implemented by copying all 16 bytes, of which 7 of these bytes are uninitialized. Often, heuristics can filter these memory copy operations and avoid issue false-positive reports.

## Synchronization Usage

The last category of problems relates to synchronization of memory accesses.

The best case is where memory is not shared between threads, and thus no synchronization is needed. However, often this is not possible as the shared memory locations are needed for communication of data between threads.

Three cases arise when considering synchronization.

1. Incorrect lock usage can cause deadlock
2. Synchronization is not used, or not used consistently
3. Synchronization is used, but at an incorrect granularity

## Deadlock

Incorrect lock usage can expose the potential for a deadlock at runtime. A deadlock occurs when two or more threads each owns a lock that another thread is attempting to acquire, and will not release its lock until it acquires its next requested lock. This situation forms a cycle in the lock ownership/acquisition graph, as illustrated in the following example:

Thread 1:

```
AcquireLock(A)
AcquireLock(B)
```

...

Thread 2:

```
AcquireLock(B)
AcquireLock(A)
```

...

The lock acquisition graph for Thread 1 is  $A \rightarrow B$ . For Thread 2 it is  $B \rightarrow A$ . Merging these lock graphs graph results in the cycle  $A \rightarrow B \rightarrow A$ , which indicates the potential for deadlock in the application.

## Data Races

The second case is that synchronization is not used, or that it is used inconsistently. An example of this situation is:

Thread 1:

```
...
AcquireLock(A)
X = X + F(1)
ReleaseLock(A)
```

Thread 2:

```
...
X = X + F(1)
```

Thread 3:

```
...
AcquireLock(B)
X = X + F(1)
ReleaseLock(B)
```

In this example, the first update to  $X$  is protected by the lock  $A$ , but the second update to  $X$  is not protected by any lock. Therefore, it is possible that the operations of Thread 1 and Thread 2 interleave in a way that alters the applications behavior. Similarly, Thread 3 has the problem that it is using a different lock than Thread 1, which means that mutual exclusion is not enforced between any of Threads 1, 2, or 3.

## Atomicity Violations

The third case is when synchronization is used at the wrong granularity. In a serial program, all operations between I/O statements appear atomic to an outside observer, since the I/O statements are the only mechanism by which to interact or observe the execution of a serial program. In a multi-threaded program this is not true. The multiple threads that may exist can potentially interact or observe the state of other threads in the application at any point during the execution. Because of this, developers need to be aware of the concept of atomicity. Consider a statement such as:

$X = F(X)$

Let  $X$  be an arbitrary object, and  $F$  be an arbitrary function applied to  $X$ . During this computation, various parts of  $X$  may change to intermediate states that are then used to compute the final value of  $X$ . If no other entity can observe or modify any of these intermediate states, then  $F()$  is an atomic function, and the atomicity of the transformation  $X = F(X)$  has been preserved.

Consider the following example:

```
struct Node {
 struct Node *next;
 double data;
};

Node *head;
int length;
```

```

void Initialize()
{
 head = 0;
 length = 0;
}
void Add(Node *p)
{
 p->next = head;
 head = p;
 length = length + 1;
}
Node *Remove()
{
 Node *p = head;
 length = length - 1;
 head = p->next;
 return p;
}
double GetAverage()
{
 Node *p = head;
 double answer = 0;
 for (int I = 0; I < length; ++I) {
 answer += p->data;
 p = p->next;
 }
 return (sum / length);
}

```

Assume that the application requires that the invariant that “length” is exactly the number of elements in the linked list. The GetAverage() function depends on this to compute the correct answer. Both the Add() and Remove() functions change the value of “length.” If either function is called in parallel with the GetAverage() function, then an inconsistent state of the data structure may be observed.

To fix this, the example must enforce atomicity to maintain the invariant that the value of length is exactly the same as the number of nodes in the list.

Intel® Parallel Inspector is not designed to detect atomicity violations in an otherwise well-synchronized parallel program. Instead, Parallel Inspector detects the lack of synchronization. To reason about atomicity with Parallel Inspector, the recommended approach is to remove synchronization suspected to be at the wrong granularity, find the set of data races this

creates, and then reason about your algorithm to determine if the algorithm is correct if the atomicity region is large enough to enclose all affected memory accesses.

## Intel® Parallel Inspector Defect Model

When Parallel Inspector detects a defect in the parallel software, it records this fact. The record contains the static and dynamic location of the occurrence of the defect as well as supporting information that may be necessary to help the developer understand how the defect occurred or what may be necessary to fix the defect.

Many detected defects may be related to the same root cause in the application. For example, if the developer forgot to synchronize the update to a particular object, then that update may cause a data race with all other uses of that object.

Similarly, if the same object is referenced by several threads, then this set of data races must be fixed by acquiring the same synchronization object to cover all usages of that object.

To aid the user in organizing the defects, Parallel Inspector defines three organizational concepts: an Observation, a Problem, and a Problem Set.

A defect in the application is composed of Observations. An Observation is defined as a fact about an action performed by the application. This may be a memory Read action, a memory Write action, a Lock Acquire action, a Memory allocation action, or possibly a Memory deallocation action. Each Observation has a representative call stack, and specific location (instruction) in the application which triggered this action. Some Observations are fundamental to a defect. For example, in a data-race defect, the memory accesses (either Read or Write) trigger the existence of this defect. Other Observations are incidental. For example, it may be useful to know where the application allocated the object involved in the data race, but typically it is not the allocation which triggered the detection of the defect.

A Problem contains one or more Observations related to the same defect. A Problem also merges all of the dynamic instances of a defect into a single instance of the defect. For example, a utility function may access a shared variable that is unsynchronized, which causes

a data race. This function may be called from many different locations in the application, representing many different dynamic occurrences. This first level of defect organization focuses the user on the source code of the application and collapses all of these dynamic instances into a single Problem.

The second level of organization performed by Parallel Inspector is to organize Problems into Problem Sets. Two Problems are grouped into the same Problem Set when they share a significant Observation. For example, consider Problem 1 that writes to an object at location S1, and reads the object by a different thread at location S2. If another Problem 2 exists that also writes the object at location S1, but reads the object by some other thread at location S3, then Problem 1 and 2 are placed into the same Problem Set. What this indicates is that the pair-wise relationship of a data race between two threads should be extended to a group-wise relationship between a set of threads and a set of memory location. This implies that since S1 is related to S2 and S1 and also related to S3, then it is quite likely that S2 is also related to S3, and needs to be considered when developing the solution to fix the data race.

These three levels of organization of application defects in Parallel Inspector allow the developer to interact with the reported information in appropriate ways.

For example, a “Detail” view is provided that organizes the defects according to the Observations. This allows quick access to any Problem or Problem set based on characteristics of any Observation contained in a Problem Set. For example, the developer may want to know which data races are connected with an object allocated at a specific location in the program. Or, the developer may be concerned about which Observations are reported to be involved with a specific binary module (.DLL or .EXE file) or with a specific function or file. If the developer recently edited these functions or files, or recompiled this module the defect may relate to a modification of the application recently performed by the developer.

## Implementation

Intel® Parallel Inspector is designed to observe an application as it executes. This has the benefit that the tools have accurate information about the state of

the application as it runs, but has the disadvantage of being limited to the subset of the application behavior covered by the workload used during testing. Since Parallel Inspector relies on dynamic program behavior to detect defects, it is primarily a diagnostic tool aiding to pinpoint the root cause of a defect.

Parallel Inspector uses the Pin Dynamic Instrumentation system [6]. This system is a set of APIs which translate and instrument the native assembly language instructions. Pin operates on a trace of instructions translating them with a native-code to native-code JIT compiler, and inserting instrumentation which drives an online analysis engine. This instrumentation observes modification to memory (load or store actions), as well as memory allocation and deallocation, threading and synchronization actions.

Two different analysis engines are included in Parallel Inspector. The Memory Inspection analysis engine maintains a bitmap describing the valid and initialized state of the address space. Allocation actions create valid address regions; write actions create initialized address regions. Subsequent memory accesses are checked against this bitmap to determine if they are invalid or uninitialized. The memory allocation and deallocation operations are matches to help determine which memory regions have never been deallocated, and further analysis is done to determine which memory regions are inaccessible (i.e., a memory leak).

The Thread Inspection analysis engine employs a “happens-before” [4] methodology for determining where a data race may exist in the application. The “happens-before” relationship is computed by observing the synchronization performed by the application. Two threads are ordered by a “happens-before” arc when the second thread’s execution is conditional on the first thread’s execution. For example, the first thread releases a lock, which the second thread subsequently acquires. In this execution of the program, any memory reference that occurs before the first thread releases the lock must “happen-before” any memory reference that occurs after the second thread acquires the lock. Using this methodology, a data race occurs whenever the same memory location is accessed (at least one write) by two threads, and there does not exist a “happens-before” ordering relationship between these two memory accesses.

A special class of memory access is flagged by the Thread Inspector as deserving additional attention. This class of memory accesses is known as “cross thread stack accesses.” When a thread accesses memory belonging to the stack of another thread, typically it does this by dereferencing a pointer published by the thread that owns the stack. The challenge is not only enforcing mutual exclusion to stack locations when they are modified, but the existence of the stack location needs to be maintained during while threads access that stack location. In a strict parent–child relationship, where the parent publishes one of its stack locations to its children, and then waits for the children to terminate, then it is guaranteed that the lifetime of the stack location encloses the lifetime of the remote thread which has obtained a reference to that stack. In any other situation, the developer must be vigilant in understanding the memory reference pattern to determine if it is a legal parallel programming pattern.

Additionally, Thread Inspector determines the existence of actual and potential deadlocks caused by the synchronization executed by the application. A lock hierarchy acquisition graph is inferred from the lock acquire and release actions observed in an applications execution. The analysis engine checks for cycles in this graph to detect if a deadlock exists.

## Bibliographic Notes and Further Reading

The Parallel Inspector is a product in the Intel® Parallel Studio. This product is the evolution of ongoing work, which was initially released from Kuck & Associates, Inc (KAI) as the product Assure, and then subsequently refined and released as the Intel® Thread Checker after the acquisition of KAI by Intel in 2000.

The main evolution of this technology has been to move from source-to-source instrumentation, to static binary instrumentation, to finally the Pin-based dynamic binary instrumentation that is used in the Parallel Inspector.

## Intel® Parallel Studio

PAUL PETERSEN

Intel Corporation, Champaign, IL, USA

## Definition

Intel® Parallel Studio is a product that integrates with Microsoft\* Visual Studio IDE that extends the IDE with facilities to assist in the creation of software for multi-core computers.

## Introduction

Intel® Parallel Studio is a product that encompasses the life cycle of parallel software development. If you are starting from a serial application, the tools provided can generate high performance executables, inform you of where the hotspots exist in your algorithms, and find memory leaks and invalid memory access that may be corrupting your application’s execution. Continuing in the parallel software life cycle, tools exist that assist the user in determining the most appropriate places to introduce parallelism. Once the application

is enabled for parallel execution, the remaining tools in Parallel Studio come into play. Problems unique to parallel programming such as deadlocks, data-races, synchronization overhead, or insufficient concurrency are easily exposed through the parallel analysis tools.

## Requirements for Parallel Studio

Intel® Parallel Studio works with the Microsoft Visual Studio 2005, 2008, or 2010 development environment on the Windows XP, Vista, or Windows 7 operating system.

## Background

*Intel Parallel Studio* is a software development product created by Intel that uses the Microsoft Visual Studio Integrated Development Environment. Its purpose is to enable the development of programs for parallel computing. Parallel programming enables software programs to take advantage of multi-core processors from Intel and other processor vendors.

Parallel Studio consists of four component parts, each of which has a number of features:

- Parallel Composer consists of a high performance C++ compiler, a number of performance libraries (Integrated Performance Primitives), Threading

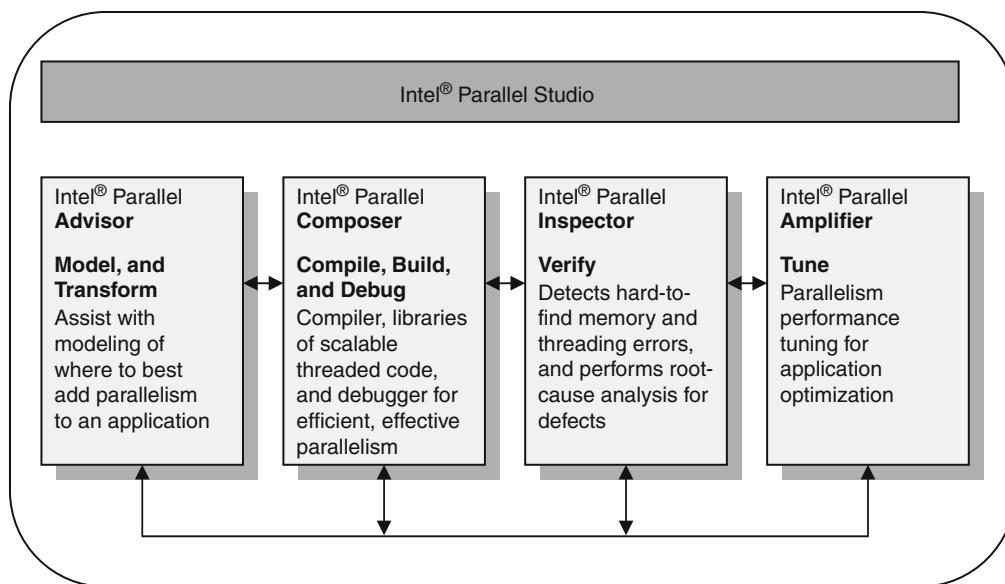

Building Blocks, and an extension to the Visual Studio debugger for parallel programs.

- Parallel Advisor assists the developer in the analysis and modeling of where to best add parallelism to an application.
- Parallel Inspector serves as an intelligent assistant to notify the developer about defects in the parallel application that could cause incorrect behavior. In particular Parallel Inspector focuses on a few core problems. These are misuse of synchronization that can result in data-races or deadlocks, and incorrect memory accesses resulting in illegal or invalid memory references in parallel applications.
- Parallel Amplifier helps the developer to understand the performance implications of their application providing profiling support to determine the hotspots, bottlenecks due to synchronization, and an analysis of the concurrency present in the application.

Parallel Studio is focused on native code development for C/C++ programming.

## Workflow

Parallel software development builds on top of sequential software development in a number of ways. First you must understand the opportunities for

Intel® Parallel Studio. Fig. 1 Intel parallel studio product components

parallelism. Second, you must express the parallelism in the application. Third, you must verify that your expression of parallelism does not have unexpected defects. Finally, you must determine if you are getting the expected benefit from the use of parallelism.

Intel Parallel Studio (Fig. 1) provides the capabilities you need to tackle all four of these areas. Starting with a high performance C/C++ compiler, adding parallelism-specific analysis for opportunities, correctness, and performance gives the developer a head start.

## Intel® Thread Profiler

MARK DEWING, DOUGLAS ARMSTRONG  
Intel Corporation, Champaign, IL, USA

### Definition

The Intel® Thread Profiler is a tool to assist in optimizing multithreaded applications. It shows developers where various performance bottlenecks and impediments to scalability occur in the program.

### Discussion

#### Introduction

Intel® Thread Profiler collects data relevant for multithreaded performance and helps the user understand the cause of various performance problems.

Intel® Thread Profiler can collect data on programs written using OpenMP® or using native threading APIs (Windows® API or POSIX® threads). “\*Other names and brands may be claimed as the property of others”.

### Threading Methodology

Threading for performance is a process with several steps. This process starts with discovering possible parallelism in an existing codebase or algorithm and expressing that parallelism through some threading library or framework (e.g., OpenMP, Intel® Threading Building Blocks, native threading APIs). Next, the threaded code must be debugged and analyzed for correctness with testing and possibly with tool support (e.g., Intel® Parallel Inspector). Then the performance of the code is analyzed and the code tuned. This process is iterative – changes suggested by performance tuning need to be tested for correctness as well.

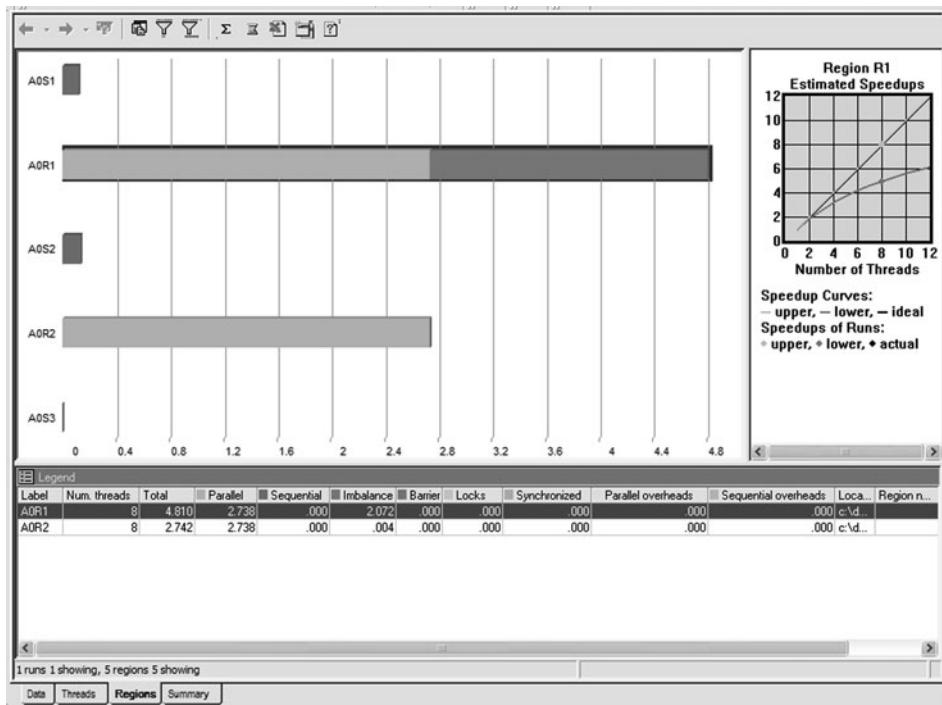

Intel® Thread Profiler can provide assistance in the performance tuning part of the process. A typical usage model is to run the target application under Intel® Thread Profiler and start looking at regions where the concurrency is lower than expected. Next, particular synchronization objects are examined to see which ones are responsible for the most waiting. Finally, the source locations where those objects are used can be examined to understand the root cause of the performance problem.

### Implementation Details

To collect data on OpenMP programs, Intel® Thread Profiler uses a version of the OpenMP runtime library that collects statistics, and writes them to a file. For native threads, binary instrumentation is used to intercept various threading and blocking APIs. A graphical interface integrated into the VTune™ Performance Environment reads the data file and displays it for interactive analysis (VTune is a trademark of Intel Corporation in the USA and other countries).

### Profiling OpenMP

The OpenMP mode of Intel® Thread Profiler displays the amount of time spent in parallel regions and serial regions. It also shows the amount of imbalance in parallel regions, and the amount of overhead due to synchronization and locks. This can be displayed per region, as well as an aggregated summary (Fig. 1).

Intel® Thread Profiler. Fig. 1 OpenMP region view in Thread Profiler

The tabs show a breakdown of the time in categories:

- Summary – time for the whole program
- Regions – time per serial or parallel region
- Threads – time per thread
- Data – grid view of performance data

The screen shot shows the regions view with two parallel regions – one with a large amount of imbalance and one with almost no imbalance.

### Profiling and Tracing Native Threads

When analyzing applications using native threads, different data is collected and displayed to the user, as shown in Fig. 2.

### Timeline Pane

The lower pane in Fig. 2 is the timeline view, where the threads are on the vertical axis and time is on the horizontal. The activity of each thread is shown (either waiting or in a ready-to-run state). Transition lines show connections between threads – where one thread releases a lock and another thread acquires that lock.

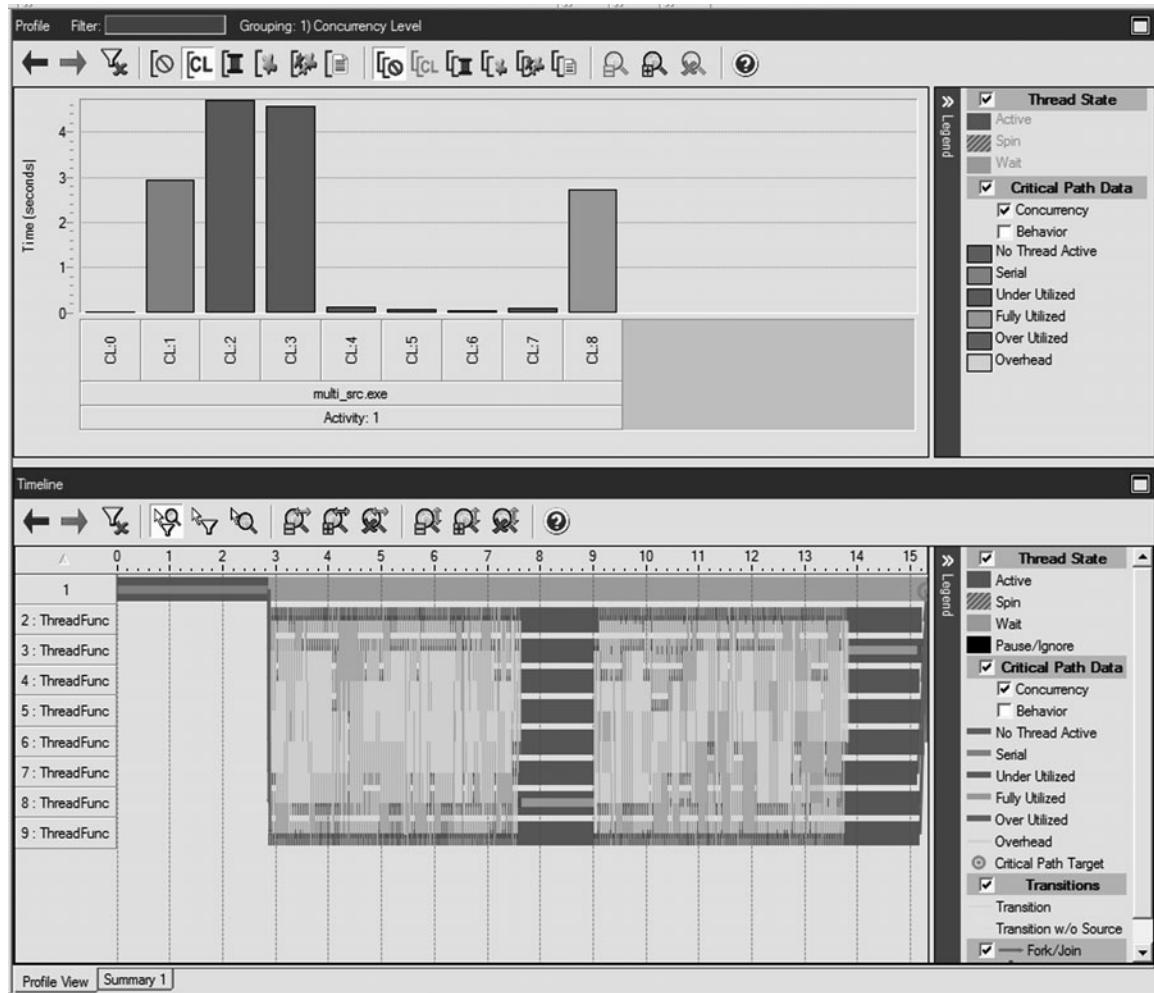

There are several thread states:

- Active – the thread is either running on a core, or is ready to run and is waiting in the run queue.
- Wait – the thread is blocked waiting for some resource to become available (synchronization or I/O).
- Spin – the thread is actively waiting in a synchronization construct. This thread state is only detected in libraries or user codes that have added API calls to inform Thread Profiler of spin waits.

The bars in profile view and line segments in timeline view can also be colored by concurrency and/or behavior.

The concurrency types are:

- No Thread Active – none of the application's threads are active.
- Serial – only a single thread is active.
- Underutilized – the number of active threads is less than the number of cores in the system.
- Fully Utilized – the number of active threads is equal to the number of cores on the machine. This is the ideal case for best utilization of CPU resources.
- Overutilized – there are more active threads than cores on the machine. This can lead to some

Intel® Thread Profiler. Fig. 2 Intel® Thread Profiler display for native threads

performance loss due to excess context switches and thrashing the cache.

The behavior applies to time segments along the critical path

- Critical Path – The thread on the critical path is active, and not holding a resource needed by the next thread on the critical path (compare with “impact time”).
- Blocked on critical path – The thread on the critical path is waiting for an external event – typically a system event (a timer or file I/O) or a user event (mouse or keyboard). (If it were waiting on another thread, that thread would have been on the critical path instead).

- Impact on critical path – The current thread is active, but the next thread on the critical path is waiting. Typically, this means the current thread is holding a lock or other resource while the next thread waits.

### Profile Pane

The upper pane in Fig. 2 is the profile view, which displays wait time and time on the critical path, grouped in various ways – by concurrency, thread, object, object type, or source location. The groupings in more detail are

- None – shows the overall times for the region visible in timeline view
- Concurrency – time a given number of threads are active in the system

- Thread – list of threads created in the process and the amount of time each thread spends active or waiting
- Object Type – waiting caused by objects, grouped by type (all the mutexes in one group, all the critical sections in another, etc)
- Object – waiting caused by individual objects (individual mutexes, critical sections, etc)
- Source Location - time associated with the source location where the wait occurs and the source location where the object is released.

### Source View

The user can navigate to the source code where the wait occurred. The source code where the object is released is also shown.

### Critical Path

The critical path links transitions between threads into a continuous path from the beginning to the end of the program. The critical path is visible in the timeline view, and data aggregated over the critical path is shown in the profile view. If the performance is improved anywhere along the critical path, the program's run time will be reduced. Improving the performance elsewhere is less likely to reduce the program run time (it may affect load or CPU usage, however).

## Tuning Threaded Code

### Imbalance in Parallel Work

Imbalance occurs when one or more threads in a parallel region are idle waiting for other threads in the parallel region to finish working. In the OpenMP

profiler, there is a specific time category for imbalance. In the native threads mode of Intel® Thread Profiler, imbalance can be seen visually in timeline view, or it manifests as underutilized time in the profile view.

The two regions in Fig. 1 are duplicates of the same code and differ only in how the work is scheduled on different cores. The amount of work varies per iteration, and in the first loop, work is assigned statically to different cores. That is, each core executes the same number of loop iterations. The second loop assigns the work dynamically to each core, and results in a much better load balance.

### “Hidden” Synchronization

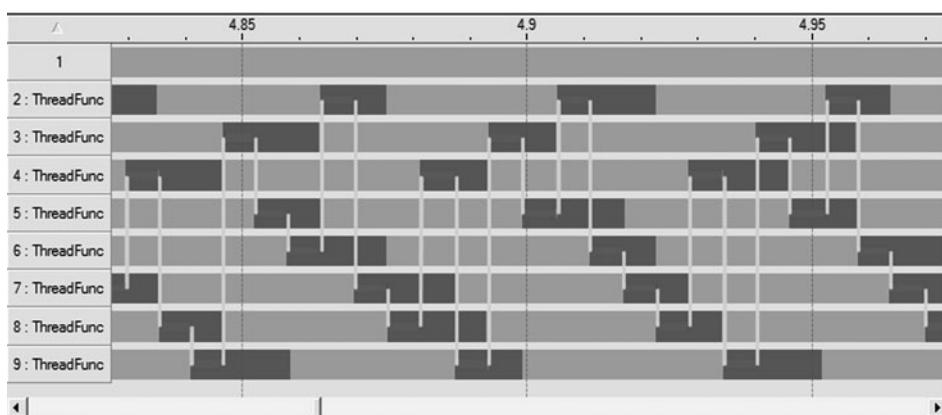

Often the developer is unaware of the parallel behavior of various subsystems and what locks they may hold. Intel® Thread Profiler reveals where these subsystems may be serializing or reducing the concurrency of the higher-level code.

### Excessive Synchronization

If a lock is held and released frequently, the threads may spend an excessive amount of time locking overhead, reducing the amount of time available for actual work.

### Excess Hold Times and Lock Convoys

Threads may hold locks longer than necessary, and this will manifest in underutilized time. This may also lead to a lock convoy, which is easily spotted in the timeline view (Fig. 3).

Intel® Thread Profiler. Fig. 3 Lock convoy in timeline view

### Hot Locks

A hot lock will show up in the object grouping in the profile view – the hot lock will accrue a large amount of waiting time. Further grouping by source location can pinpoint where and how the lock is being used.

### Release History

Intel® Thread Profiler 1.0 was first released in 2003 in conjunction with Intel® Thread Checker for Windows. This version of Intel® Thread Profiler only included support for OpenMP.

Intel® Thread Profiler 2.0 was released in 2004 and added support for native threads. Intel® Thread Profiler 3.0 was released in 2006 and featured an enhanced user interface.

Intel® VTune™ Amplifier XE 2011 was released in 2010, replacing the functionality of Intel® Thread Profiler with a tighter integration of Intel® Thread Profiler and Intel® VTune™ Analyzer capabilities.

### Definition

Intel® Threading Building Blocks (Intel® TBB) is a C++ library for shared-memory parallel programming.

### Discussion

#### Introduction

Intel® Threading Building Blocks (Intel® TBB) is an open-source C++ library for parallel programming of

multi-core processors. It is notable as a commercially supported library for parallel programming targeting mainstream developers. It has won two “Jolt Productivity Awards.” The library has evolved since its initial release in 2006. This entry describes Intel® TBB version 3.0 released in 2010.

The library supports both high-level and low-level specifications of parallel control flow. At the high level are parallel “algorithms,” similar in spirit to ISO C++’s `<algorithm>` library. These range from simple parallel control structures such as parallel iteration to more complex subjects such as parallel sorting. The algorithms may be nested. At a slightly lower level the programmer can specify tasks, which are less structured than the parallel algorithmic operations. For both of these, the run-time deals with mapping the algorithms or tasks onto hardware threads.

For low-level parallel programming, the library provides portable abstractions for threads, mutexes, condition variables, and atomic operations. Since memory allocators are often a significant bottleneck in programs, the library provides a scalable memory allocator.

A key point is most parallelism in Intel® TBB is optional, never mandatory. The programmer specifies *potential* parallelism. The run-time dynamically decides how much potential parallelism becomes real parallelism. For example, the run-time creates no parallelism if only a single thread is available. Consequently, the programmer must not depend on actions running concurrently, otherwise deadlock may ensue. The only mandatory concurrency in Intel® TBB is its implementation of the C++0x class `std::thread`, which is a thin wrapper around an OS thread.

Intel® TBB also provides support for organizing data. It has concurrent containers that can be safely and efficiently operated on by multiple threads. Its abstractions for thread-local storage permit threads to operate on their own private portion of data, while also providing a global view of all of the data.

Intel® TBB supports parallel programming exclusively via library mechanisms, without language extensions. Related approaches such as Cilk (see ►Cilk) and OpenMP (see ►OpenMP) rely on language extensions, which permit more concise syntax. However, the extensions require compiler support. Hence the library approach has an advantage of

not limiting what compiler is used. C++0x lambda functions simplify syntactic issues of the library approach.

## Terminology

The notation **[a,b)** denotes a half-open interval that includes **a** and excludes **b**.

A C++ functor is an object that defines **operator()** as a member. Some examples in this entry create functors via C++0x lambda expressions. The lambda expressions used in this entry start with **[&]**, **[=]**, or **[]**. Below is an example.

```
template<typename F, typename X >
void Apply(F f, X x) {f(x);}
int Foo() {
 int b = 3;
 Apply([&] (int x) {b+=x}, 4);
 return b;
}
```

The lambda expression **[&] (int x) {b+=x;}** returns a function object. The **[&]** specifies that local variables (such as **b**) are captured by reference. Thus, the call to **Apply** updates the variable **b** declared in **Foo**, and **Foo** returns 7.

Evaluation of the lambda expression is similar to invoking the constructor **Functor1(a)**, where class **Functor1** is defined as:

```
class Functor1 {
 B& b_ref;
public:
 void operator()(X x) {b_ref+=x;}
 Functor1(B& b): b_ref(b) {}
};
```

Replacing **[&]** with **[=]** causes local variables to be captured by value. **[]** disallows any capture. A lambda expression can omit the argument list if there are no arguments. If the body of the lambda returns a value, the return type is declared after the parameter list, like this:

```
[](int i)->float {float x=1.0/i; return x;}
```

The return type can be omitted if the body is only a return statement.

Some examples use the C++0x shorthand **auto** for declaring local variables of inferred type. For example

```
auto x = y;
```

declares **x** to be of the same type as **y**.

## Parallel Algorithms

Most of the parallel algorithms in Intel® TBB are C++ templates that act as parallel control structures. These structures compose functors in a particular parallel pattern. The simplest pattern is **parallel\_invoke(f,g)**, which executes functors **f** and **g**, possibly in parallel if resources permit. Extended variants allow more functor arguments.

Parallel loops (See ►Loops, Parallel) are supported by several templates. The basic form **parallel\_for(range, func)** applies functor **func** over an iteration space defined by **range**. For example, the following expression computes **a[i]+=b[i]** for **i** in the half-open interval **[0,n)**:

```
parallel_for(blocked_range<int>(0,n),
[&](blocked_range<int> r) {
 for(int i=r.begin() il=r.end(); ++i)
 a[i] += b[i];
});
```

The **range** argument **blocked\_range<int>(0,n)** describes a one-dimensional iteration space **[0,n)** over type **int**. The **parallel\_for** partitions that space into subranges, and applies the functor to each subrange, in parallel if resources permit.

The **parallel\_for** template operates over any recursively divisible range. Table 1 lists the signatures required of such a range. For a range type **R**, the initialization **R r2(r1,split())** splits **r1** into two pieces. One piece is **r2**. The other piece is **r1**. For instance, if **r1** is a **blocked range** initially representing **[0,8)**, then after **R r2(r1,split())** executes, **r1=[0,4)** and **r2=[4,8)**. The argument **split()** is a dummy argument that distinguishes a splitting constructor from a copy constructor.

**Intel® Threading Building Blocks (TBB). Table 1** Signatures that a recursively divisible range must support

| Signature                | Semantics                               |
|--------------------------|-----------------------------------------|
| <b>R(const R&amp;);</b>  | Copy constructor                        |
| <b>~R();</b>             | Destructor                              |
| <b>R.empty();</b>        | True if range is empty; false otherwise |
| <b>R.is_divisible();</b> | True range can be split into two parts  |
| <b>R(R&amp;, split);</b> | Splitting constructor                   |

Intel® TBB provides **blocked\_range**, **blocked\_range2d**, and **blocked\_range3d** respectively for one-, two-, and three-dimensional ranges. Programmers may define their own ranges. An interesting implementation technique that demonstrates the power of recursive ranges is the internal implementation of template **parallel\_sort(first,last,compare)**. It uses **parallel\_for** over a special range that represents the key sequence. The **parallel\_for** recursively subdivides the key sequence until **is\_divisible()** returns false. Each subdivision invokes the range's splitting constructor, which is defined to do a partitioning step of quicksort. The functor argument to the **parallel\_for** deals with the base case of the recursion. It serially sorts key sequences that are not subdivided. Hence **parallel\_for** sometimes goes far beyond iteration by expressing a parallel divide-and-conquer pattern.

Intel® TBB has a shorthand form for the common case of a one-dimensional space of integral type. The call **parallel\_for(lower,upper,step,func)** is a parallel equivalent of:

```
for(auto i=lower; i<upper; i+=step) func(i);
```

The template **parallel\_do(first,last,func)** has two cases. The first case acts as a parallel variant of **std::for\_each**, and performs the parallel equivalent of:

```
for(auto first i=first; i!=last; ++i) func(*i);
```

The second case acts as a parallel while loop over a work list to be exhausted, but which may have items added to it during the work. This case is distinguished by **func** taking two arguments. The second argument must be of type **parallel\_do\_feeder<T>**, which has a method **add** that feeds another item to the work list. The initial work list is **[first,last)**. For example, let the following structure represent a node in a tree:

```
struct Node {
 int data;
 Node* left;
 Node* right;
};
```

The following code walks such a tree with root node **Root**, adding 1 to each field data.

```
parallel_do(& Root, & Root+1,
[](Node& n, parallel_do_feeder<Node>& f) {
 if(n.left) f.add(*n.left);
```

```
 if(n.right) f.add(*n.right);
 n.data += 1;
});
```

The initial work list consists of **Root**. The functor takes a node and adds its children to the work list. The **parallel\_do** terminates when all work items have been processed.

## Reduction and Scan

The template **parallel\_reduce** performs parallel reduction (See Reductions). It has several forms. The form discussed here is **parallel\_reduce(range,identity,func, reduction)**. The **range** argument is a recursively divisible range. The **identity** argument is the identity element of the reduction operation. The functor **func** has signature **range × value<sub>1</sub> → value<sub>2</sub>**. It should do a reduction over iterations space **range** using **value<sub>1</sub>** as the initial reduction value. The functor **reduction** has signature **value<sub>1</sub> × value<sub>2</sub> → value<sub>3</sub>**. It should reduce **value<sub>1</sub>** and **value<sub>2</sub>** to **value<sub>3</sub>**. The reduction operation must be associative, but does not have to be commutative.

The following example shows **parallel\_reduce** used to reduce the first **n** elements of an array **x** of type **T**. It assumes that **T()** constructs the identity element for **+**.

```
parallel_reduce(blocked_range<int>(0,n),
T(),
[](blocked_range r, T initial) -> T {
 for(int i=r.begin(); i!=r.end(); ++i)
 initial+=x[i];
 return initial;
},
[](T a, T b) {return a+b;}
);
```

Like **parallel\_for**, template **parallel\_reduce** recursively subdivides the range. It uses the functor **func** to evaluate leaves and to perform left-to-right serial evaluation of subranges. It uses the functor **reduction** to merge results from subranges processed in parallel. Overall, it strives to keep each processor busy doing left-to-right evaluation of subranges, using just enough parallel evaluation to keep processors busy [9].

The template **parallel\_scan** computes prefix sum for any associative operation (See ▶ **Prefix**). Because parallel computation of prefix sum requires two passes, but serial evaluation requires only one pass, the template

uses a hybrid algorithm that does parallel evaluation only if idle threads are available [5].

## Partitioning Hints

An optional partitioner argument can be specified as a hint for optimizing execution. The default strategy is **auto\_partitioner**, which applies a heuristic for picking the sizes of the subranges, based on the number of hardware threads and distribution of the work-load [9]. The other two partitioners are **simple\_partitioner** and **affinity\_partitioner**.

Specifying **simple\_partitioner** causes the range to be subdivided as finely as the range argument permits. The following example is similar to the previous example, except that it specifies a grain size of 1,000 for the **blocked\_range** and a **simple\_partitioner**, which causes the **parallel\_for** to subdivide the range into subranges no bigger than 1,000.

```
parallel_for(blocked_range<int>(0,n,1000),
[&] (blocked_range<int> r) {
 for(int i=r.begin(); i!=r.end(); ++i)
 a[i] += b[i];
},
simple_partitioner());
```

Specifying **affinity\_partitioner** hints that performance might benefit from mapping loop iterations to threads similarly to previous executions of the loop or a similar loop. Codes typically benefit from **affinity\_partitioner** when the dataset touched by the parallel loop fits in the aggregate cache of a multi-processor system. The following example uses an **affinity\_partitioner** to hint that the **parallel\_for** should map iterations consistently to threads on each invocation.

```
affinity_partitioner ap;
for(int t=0; t<100; ++t)
 parallel_for(blocked_range<int>(0,n),
 [&] (blocked_range<int> r) {
 for(int i=r.begin(); i!=r.end(); ++i)
 a[i] += b[i];
 },
 ap);
```

The **affinity\_partitioner** object carries information between executions of the **parallel\_for**, and so must stay live between executions. Hence it is declared outside the **t** loop.

## Parallel Pipeline

The **parallel\_pipeline** template executes a linear pipeline of filters. Each filter is a functor. The first filter generates values. Each subsequent filter maps input values to output values. The last filter consumes its input values. The pipeline terminates when all items have been processed.

The filters can be **parallel**, **serial\_out\_of\_order**, or **serial\_in\_order**. The pipeline invokes filters concurrently subject to the following constraints:

- A given serial filter can process only one item at a time.
- Any two **serial\_in\_order** filters process items in the same respective order.

Parallelism is achieved in two ways. First, parallel filters can process any number of items in parallel. Second, different filters can run concurrently.

For instance, a three-stage pipeline might have a **serial\_in\_order** stage for reading chunks of input, a **parallel** stage for processing each chunk independently, and a **serial\_in\_order** stage for writing the output. The chunks will be written in the same order that they are read. For another example, a three-stage pipeline consisting of a **parallel**, **serial\_in\_order**, and a **parallel** stage is isomorphic to a *Doacross* loop (See ▶Loops, Parallel), where the intervening **serial\_in\_order** stage handles the cross-iteration dependency.

## Task Scheduler

The parallel algorithms build upon a task scheduler. The scheduler is non-preemptive and based on work stealing. Tasks may be *spawned* or *enqueued*. Enqueued tasks are used when first-come first-serve behavior is desired, typical of parts of programs that deal with reacting to external events such as user input. Recursively spawned tasks are used to achieve scalability of computations that run to completion.

Typically, a parent task spawns child tasks and then continues when the child tasks finish. The task interface supports two approaches for the waiting. In the *blocking-style* idiom, the parent explicitly waits for the children to complete. In the *continuation-passing* idiom, the parent specifies a continuation task to be executed when the children complete. The continuation-passing idiom is generally more tedious to write, but enables

the same space and time bounds as Cilk (See ►Cilk), because in continuation-passing style, even though tasks may wait on other tasks, no *thread* waits on another thread.

The following code demonstrates the blocking-style idiom. It derives a class **RecursiveTask** from the Intel® TBB base class **tbb::task**, and overrides method **execute()** to specify the actions of the task. The task applies function **Work** across the values in a half-open interval  $[l, u)$  via recursive decomposition.

```
class RecursiveTask: public tbb::task {
 int lower, upper;
 tbb::task* execute() {
 // Override virtual method task::execute()
 if(upper-lower==1) {
 Work(lower);
 } else {
 int midpoint = lower+(upper-lower)/2;
 // 3 = two children + one for the wait.
 set_ref_count(3);
 // Create and spawn two child tasks
 spawn(*new(allocate_child()) Recursive
 Task(lower, midpoint));
 spawn(*new(allocate_child()) Recursive
 Task(midpoint, upper));
 // Wait for my children to complete
 wait_for_all();
 }
 return NULL; // Effect of non-null value
 explained
 later.
}
public:
 // Construct task that evaluates Work(i) for i∈[l,u)
 RecursiveTask(int l, int u): lower(l),
 upper(u) {}
};
```

The **wait\_for\_all** is written separately to simplify exposition. Often the spawning of the last child and waiting are written using the shorthand **spawn\_and\_wait\_for\_all**, which optimizes away some scheduler overhead.

The following code shows how the root task for the parallel recursion is spawned. The net effect of the code is to evaluate **Work(i)** over  $[0,n)$ .

```
void TreeSpawn(int n) {
 if(n>0)
 tbb::task::spawn_root_and_wait(
 *new(task::allocate_root())
 RecursiveTask(0,n));
}
```

Root tasks are always waited on in a blocking manner, so that algorithms can present an ordinary call/return interface to users that does not return until work is completed. However, for efficiency Intel® TBB algorithms often employ continuation-passing style internally below the root task. The following code shows a continuation-passing variant of **RecursiveTask**.

```
class RecursiveTask: public task {
 int lower, upper;
 task* execute() {
 // override virtual method task::execute()
 if(upper-lower==1) {
 Work(lower);
 return NULL;
 } else {
 int midpoint = lower+(upper-lower)/2;
 // Allocate continuation. In this example, the
 // continuation exists only for
 // synchronization, and thus can be a
 // tbb::empty_task.
 task* c = new(allocate_continuation())
 tbb::empty_task;
 // Continuation has two children.
 c->set_ref_count(2);
 // Create right child of c and spawn it.
 spawn(*new(c->allocate_child())
 RecursiveTask(midpoint, upper));
 // Reuse *this as left child of c.
 recycle_as_child_of(*c);
 upper = midpoint;
 // Bypass scheduler - specify *this as next
 // task to run.
 return this;
 }
 }
}
```

```
public:
RecursiveTask(int lower_, int upper_):
 lower(lower_), upper(upper_) {}
};
```

The example shows two common optimizations for recursive spawning. First, the parent recycles itself as its left child, which avoids the overhead of creating another task and copying state from parent to child. Second, the parent does not spawn its left child, but instead returns a pointer to it. By convention, the scheduler executes that task next, skipping the overhead of pushing/popping the deque to be described shortly.

To improve cache reuse, it is sometimes desirable to have a task *y* run on the same thread on which a previous related task *x* ran. The task scheduler interface supports this preference via two methods. One method records where *x* ran, as an abstract **affinity\_id**. The other method lets the programmer specify that the scheduler should try to run *y* in the place with the same **affinity\_id**, unless load balancing requires otherwise. This approach of “replay affinity” does not require knowledge of the machine topology.

The current implementation of the task scheduler uses work stealing. Each thread has both a deque (double-ended queue) of *spawned* tasks and a mailbox of advertisements. The advertisements are for tasks in other deques that have an **affinity\_id** for the owner of the mailbox. A thread spawns a task by pushing it onto its deque. If the task has an **affinity\_id**, then the thread also sends an advertisement to the mailbox for the thread with **affinity\_id**. The threads share a queue-like structure that holds *enqueued* tasks.

A thread chooses the next task to run by the first rule below that applies:

1. Execute the task returned by last executed task.
2. Pop a task from the thread’s deque, choosing the *most recently pushed* task.
3. Dequeue an advertisement from the thread’s mailbox and steal the advertised task.
4. Pop an enqueued task from a global queue-like structure, in approximately first-in first-out order.
5. Randomly choose another thread and pop the *least recently pushed* task from it.

Each rule corresponds to a particular concern. Rule 1 enables tail recursion by tasks. Rule 2 encourages locality. Rule 3 implements “replay affinity.” Rules 4 and 5 balance load.

Rules 2 and 5 are particularly important for nested parallelism. Consider traversing a tree. If done fully parallel, the traversal can become a parallel breadth-first traversal, taking space proportional to the size of the tree. It is better to use just enough of the potential parallelism to keep the hardware threads busy, and let each busy hardware thread do sequential depth-first traversal of some subtree. Rule 2 corresponds to sequential evaluation order. Rule 5 expands actual parallelism just enough to keep an otherwise idle processor busy.

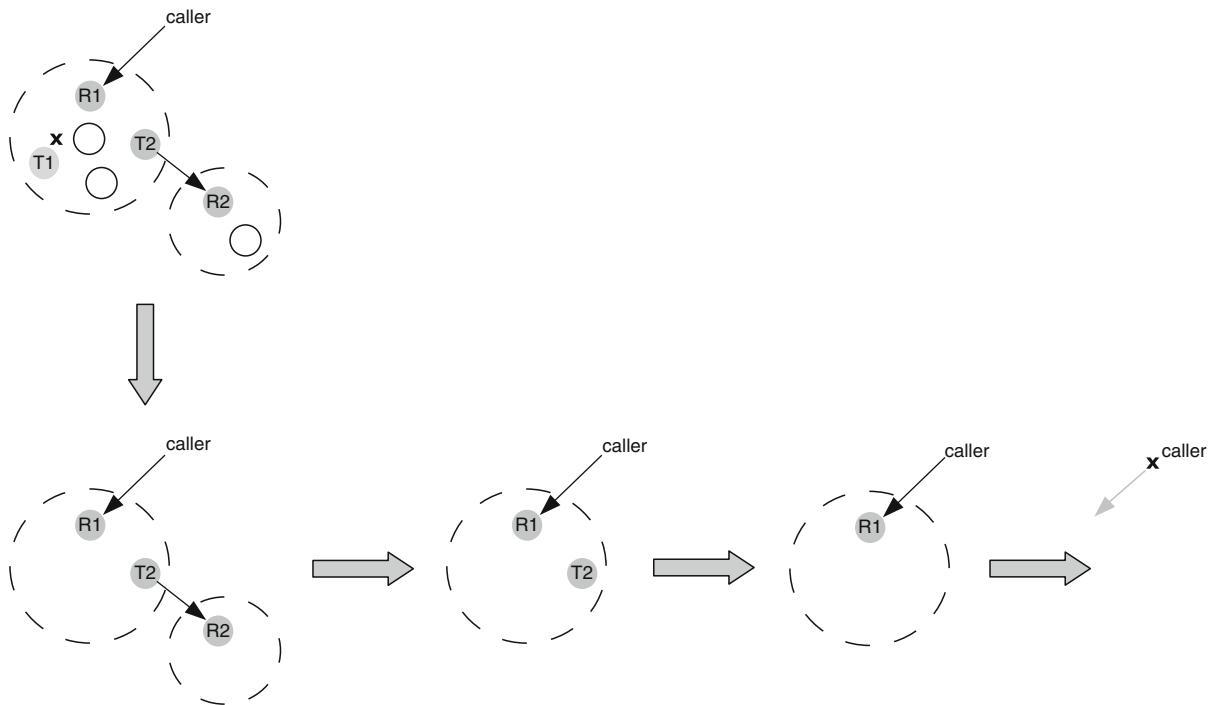

## Exceptions and Cancellation

When a parallel algorithm throws an exception, related work should be canceled and the exception propagated to the thread that initiated the algorithm. Intel® TBB exception handling performs these actions based on **task\_group\_context** nodes. Each task belongs to a **task\_group\_context** node. Typically all tasks of a parallel algorithm instance belong to the same node. The nodes form a tree. The tree of **task\_group\_context** nodes provides a structured summary of the nesting of parallel algorithms.

An algorithm typically creates a **task\_group\_context**, and then invokes **spawn\_root\_and\_wait()** on a root task associated with that **task\_group\_context**. When a running task throws an exception, the following happens:

1. The library temporarily captures the exception.
2. The library cancels the task’s **task\_group\_context** node and its descendent nodes in the tree.
3. The library cancels all tasks in each canceled node. A canceled task skips invoking its **execute()** method unless it is already running, in which case it runs to completion. A task’s destructor always runs, even if it is canceled, thus permitting proper cleanup.
4. After all canceled tasks are destroyed, the library rethrows the exception to the caller that was waiting on the root task.

Figure 1 shows propagation of an exception *x*. The small circles denote tasks. A colored circle denotes a

Intel® Threading Building Blocks (TBB). Fig. 1 Propagation of an exception  $x$  up through a task tree

task that is running. Each large dashed circle denotes a **task\_group\_context** node associated with the tasks inside it. The sequence shows:

1. Task T1's method `execute()` throws exception  $x$ , which is temporarily caught by the library.
2. Tasks are canceled in the **task\_group\_context** containing T1 and its descendant **task\_group\_context**.
3. Task T2 waits for root task R2 to complete.
4. Root task R1 waits for task T2 to complete.
5. The library rethrows  $x$  to the caller of `spawn_root_and_wait(R1)`.

The waiting in steps 3 and 4 are necessary because the only implicit cancellation point is just before task execution begins. To improve response time to cancellation, a task can explicitly poll its **task\_group\_context** and return early.

A **task\_group\_context** also can be used to explicitly cancel a parallel algorithm, from either inside or outside the algorithm. Thus, the **task\_group\_context** tree provides a structured way to process cancellation and exception handling, even though the underlying

task graphs may have much less structure and in the case of continuation-passing style, are decoupled from the thread stacks.

## Task Groups

Intel® TBB provides a higher-level task interface **task\_group** that simplifies the writing of blocking-style tasking, particularly in conjunction with C++0x lambda expressions. The following example uses **task\_group** to execute `Work(i)` for  $i \in [\text{lower}, \text{upper}]$ .

```
void Recurse(int lower, int upper) {
 if(upper<=lower) {
 // Do nothing
 } else if(upper-lower==1)
 Work(lower);
 else {
 int midpoint = lower+(upper-lower)/2;
 tbb::task_group g;
 g.run([&] {Recurse(midpoint,upper);});
 g.run_and_wait([&] {Recurse(lower,
 midpoint);})
 }
}
```

## Containers

Sometimes threads must inspect and modify a common container of data. The containers provided by the C++ standard library generally do not permit concurrent modification, and thus actions on them must be serialized. This serialization can become an impediment to scalability. Intel® TBB provides five containers that permit concurrent inspection and modification. The containers are independent of the Intel® TBB task scheduler. They may be used in conjunction with any threading package.

A **concurrent\_queue** is an unbounded queue that permits multiple producers and consumers to operate on the same queue. There is no support for blocking pop operations. Consumers use **try\_pop**, which returns a failure status if the queue is empty.

A **concurrent\_bounded\_queue** adds support for blocking and putting an upper bound on the queue size. The blocking push operation waits if the queue is full. The blocking pop operation waits if it is empty.

A **concurrent\_vector** is a vector that supports concurrent access and growing. For example, multiple threads can execute **v.push\_back(item)** on the same **concurrent\_vector v** without corrupting it. The growth operations do not move existing items, so unlike for **std::vector**, it is safe to access existing elements while the vector is growing. Besides **push\_back**, there are two other growth operations:

- **grow\_by(n)** appends n consecutive elements.
- **grow\_to\_at\_least(n)** appends zero or more consecutive elements to make the vector at least size **n**.

All growth operations return an iterator pointing to the first element appended. In the case where **grow\_to\_at\_least(n)** appends no elements, it returns an iterator pointing to just beyond the nth element.

A **concurrent\_unordered\_map** is a hash table of **(key,value)** pairs that supports concurrent **insert** and **find** operations, along with safe concurrent traversal during these operations. The interface closely resembles the C++0x **unordered\_map** interface.

A **concurrent\_hash\_map** is a thread-safe hash table of **(key,value)** pairs that supports concurrent **insert**, **find**, and **erase** operations, but not concurrent traversal. A fundamental problem of concurrent **find** and **erase** operations on the same key is that they may race in

a way such that the **find** operation returns a reference to an item that is promptly destroyed by the **erase** operation. Class **concurrent\_hash\_map** addresses the problem by combining lookup with locking. The find and insert operations return the found **(key,value)** pair via an **accessor** object. The accessor acts as a pointer to the item with an implicit lock on it. An **accessor** implies a writer lock. A **const\_accessor** implies a reader lock. Concurrent erasure of an item waits until the item has no accessors pointing to it.

## Thread Local Storage

Intel® TBB abstracts thread-local storage via container-like objects that have a separate element per thread. Method **local()** returns a reference to a thread's element, which is created lazily upon first access by its associated thread. Copying such a container copies all of its elements, retaining the element to thread mapping.

There are two such container classes. The more general class is **enumerable\_thread\_specific**. The example below shows how it can be used for reduction.

```
typedef enumerable_thread_specific<double> ets_type;
ets_type local_sums;
parallel_for(0, n, [&](int i) {
 local_sums.local() += a[i];
});
double global_sum = 0;
for(ets_type::const_iterator i=result.begin();
 i!=result.end(); ++i)
 global_sum += *i;
```

Alternatively, the final reduction can be written more concisely using method **combine**:

```
double global_sum = local_sums.combine
 (std::plus<double>());
```

Class **combinable<T>** is similar, but omits the iterator support. It exists for compatibility with Microsoft's Parallel Patterns Library.

## Memory Allocator

Because malloc scales poorly on some systems, Intel® TBB provides a scalable memory allocator. It also provides an allocator for cache-aligned allocations. All the allocators have interfaces similar to the

**C++ std::allocator.** The library also provides a C level interface that is analogous to the traditional malloc interface. Intel® TBB provides support for automatically replacing calls to the system-defined allocators with calls to the scalable allocator.

The implementation of the scalable allocator uses techniques similar to Hoard [2]. Each thread maintains its own size-segregated lists of free memory blocks. If a thread frees a block that was allocated by another thread, the freeing thread sends the block back to the originating thread.

## Mutexes

Intel® TBB provides a variety of mutex classes, which all implement a common set of signatures for ordinary mutual exclusion. The common set of signatures permits code to be parameterized with respect to the mutex type. The different types are tailored to different semantic or performance needs; for example, efficiency under light contention versus fairness under heavy contention. Most of the mutex classes have corresponding reader-writer variants that provide for shared/exclusive locking.

All of the mutex classes support a locking pattern where lock acquisition is represented by construction of a **scoped\_lock** object as shown below:

```
std::list<std::string> myList;
tbb::mutex MyMutex;
void PrependElement(std::string x) {
 tbb::mutex::scoped_lock lock(MyMutex);
 myList.push_front(x); // protected by lock on
 mutex.
}
```

Destruction of the **scoped\_lock** object causes the lock to be released. The pattern has the advantage that the programmer cannot forget to release the lock, and the lock is released even if **push\_front** throws an exception.

A subset of the mutex classes support an unscoped locking interface that follows C++0x conventions [6].

## Atomic Operations

Intel® TBB provides template class **atomic<T>** for atomic operations. Type T can be any integral, enum, or pointer type. The class supports atomic read, write, fetch-and-add, exchange, and compare-and-swap. Overloaded operators provide an intuitive interface for

fetch-and-add. For example, the following code atomically decrements RefCount and executes Foo() if it became zero.

```
extern atomic<int> RefCount;
if(--RefCount==0) Foo();
```

The Intel® TBB memory model is acquire-release consistency. Atomic reads have acquire semantics. Atomic writes have release semantics. (See ▶Memory Models). The read-modify-write operations (fetch-and-add, exchange, compare-and-swap) are sequentially consistent and (unlike C++0x sequentially consistent atomics) act as memory fences with respect to other memory operations. The read-modify-write operations take an optional argument that can specify weaker ordering.

## Future Directions

The immediate future direction of Intel® TBB is driven by the C++0x draft. Intel® TBB works with standard C++98 compilers, without special support, except that it currently depends upon vendor extensions for atomic operations and memory consistency rules because C++98 lacks a memory model for multi-threading. The C++0x draft addresses this issue. C++98 prevents propagation of an exception across threads. Intel® TBB works around this limitation by propagating an approximation of the original exception. Intel® TBB implementations built on top of C++0x can propagate the original exception across threads.

C++0x also introduces lambda expressions, which were not present when Intel® TBB was initially designed. Interfaces in Intel® TBB have been evolving to work better with lambda expressions. For example, TBB 2.2, introduced overloads of **parallel\_reduce** that specifically target ease of use with lambda expressions.

Intel® TBB has been evolving to support a subset of interfaces that are compatible with Microsoft's Parallel Patterns Library (PPL). Examples of existing PPL-compatible interfaces are **parallel\_invoke**, **task\_group**, as well as the short forms of **parallel\_for**.

## Bibliographic Notes and Further Reading

Intel® TBB continually evolves. The most up-to-date description is its reference manual [5]. The corresponding tutorial [4] describes use cases for various features.

The work-stealing approach to task scheduling is adapted from Cilk [3]. (See ►Cilk). There are important differences. In Cilk, the spawning thread immediately executes the child, and the parent is stolen. In Intel® TBB, a thread that spawns a child continues execution, while the spawned child may be stolen. The Cilk semantics are simulated via continuation-passing style. Where blocking style is used, Cilk guarantees on space and time do not apply. The algorithm templates in TBB generally use continuation-passing style internally, with a single blocking-style task at the root.

The mechanism for `auto_partitioner` does introspection on stealing [9]. The mechanism for `affinity_partitioner` [9] is derived from a locality-guided work-stealing technique described by Acar, Blelloch, and Blumofe [1].

## Definition

High-performance computing architectures utilize interconnection networks as the communication substrate between the processor cores, memory modules, and I/O devices.

## Discussion

### Introduction

In their most general form, interconnection networks are a central component of all computing and communication systems from the internal interconnects of chip-scale embedded architectures to geographic-scale systems such as wide area

networks and the Internet. This section focuses on interconnection networks as they are used in multiprocessor and multicore systems. Specifically, the section addresses basic systems concepts and principles for interconnecting processors, cores, and memory modules. These concepts and principles are not exclusive to this application domain and in fact have also found application in networks used in storage systems, system area networks, and local area networks, albeit with distinct engineering manifestations tailored to their particular domains.

Interconnection networks have their roots in telephone switching networks and packet switching data networks and, in fact, the earliest multiprocessor networks were adaptations of those networks. They have since evolved to incorporate new principles and concepts that accommodate the distinct engineering and performance constraints of multiprocessor and multicore architectures. In particular, the lack of standards such as that found in the wide-area and local-area communities created opportunities for meeting performance goals via customized solutions, which in turn has been largely responsible for the diversity of implementations. However, the shared goal of high-performance multiprocessor communication has led to a common set of principles and concepts organized around a network stack that can be viewed as being comprised of the following layers: *routing layer*, *switching layer*, *flow control layer*, and *physical layer*. These layers collectively operate to realize network performance and correctness properties, for example, deadlock freedom. The physical layer comprises signaling techniques for synchronized transfer of data across links. Switching techniques determine *when* and *how* messages are forwarded through the network. Specifically, these techniques determine the granularity and timing with which resources such as buffers and switch ports within a router are requested and released. For example, in packet switching a packet is forwarded only after it has been received in its entirety at a router whereas in virtual cut through switching bytes of a packet can be forwarded once routing information is available and the corresponding output port is free. Forwarding and reception are overlapped. The design of switching techniques is closely coupled to the behavior of flow control protocols, which ensure the availability of buffering resources as packets traverse the network.

Finally, routing algorithms determine the path taken by a message through the network.

This section describes basic interconnection network concepts covering topology, routing, correctness, and common metrics. The discussion includes the routing layer and periodically exposes dependencies on the lower level layers particularly with respect to deadlock freedom.

## Topology

Routing of communication between nodes is the most basic property of an interconnection network and is intimately tied to the pattern of interconnections between nodes where a node may be a processor, a core, a memory module, or an integrated processor-memory module. Such an interconnection pattern is referred to as the *topology* of the network and defines the set of available paths between communicating nodes. A node may be a source or destination of a message that is encapsulated in one or more packets each of which is comprised of a *header* that contains routing and control information and an optional *body* that contains data. A crossbar switch provides a direct connection between any pair of network nodes. It is also the most expensive interconnect in terms of hardware and power. Thus, as system size grows we encounter a variety of topologies that represent various performance and cost trade-offs. The most common topologies can be broadly classified into shared medium, direct, indirect, and hybrid.

## Shared Medium Networks

The bus is the most common shared medium network and the first widely used interconnect in multiprocessor architectures. A bus can have several hundred signals organized as address, data, and control. Only one node is allowed to transmit at a time as determined by the *arbitration policy* that arbitrates between concurrent requests for the bus.

Such shared medium buses do have several advantages for low node count systems. They provide an efficient broadcast medium in support of one-to-all or one-to-many communication patterns. The shared bus also serves to serialize all traffic between nodes. When used as a processor-memory interconnect, this property is exploited in cache-based multiprocessors to support coherence protocols for shared memory multiprocessors [13]. Routing on the

bus is straightforward since all devices snoop the address lines. However, if the bus is used to connect devices of differing speeds, such as processors to memory, bus utilizations can degrade rapidly if a transaction (e.g., reading from memory) holds the bus for the duration of the transaction. As processor and memory speed disparities grew, low utilizations led to *split phase transactions* where requests and responses are split into two separate transactions. As a result, multiple memory transactions can be interleaved on the bus increasing bus utilizations.

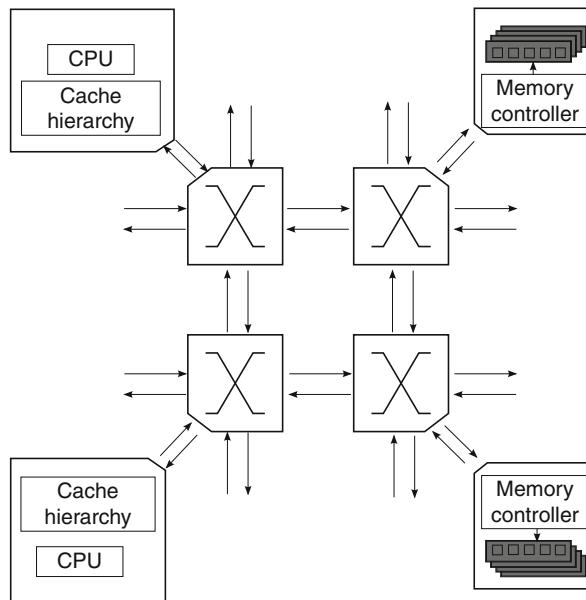

Physical constraints limit bus lengths and consequently system sizes. This has also become true for chip multiprocessors, and thus the use of buses can be expected to be limited to smaller sized systems at future technology nodes.

### Direct Networks

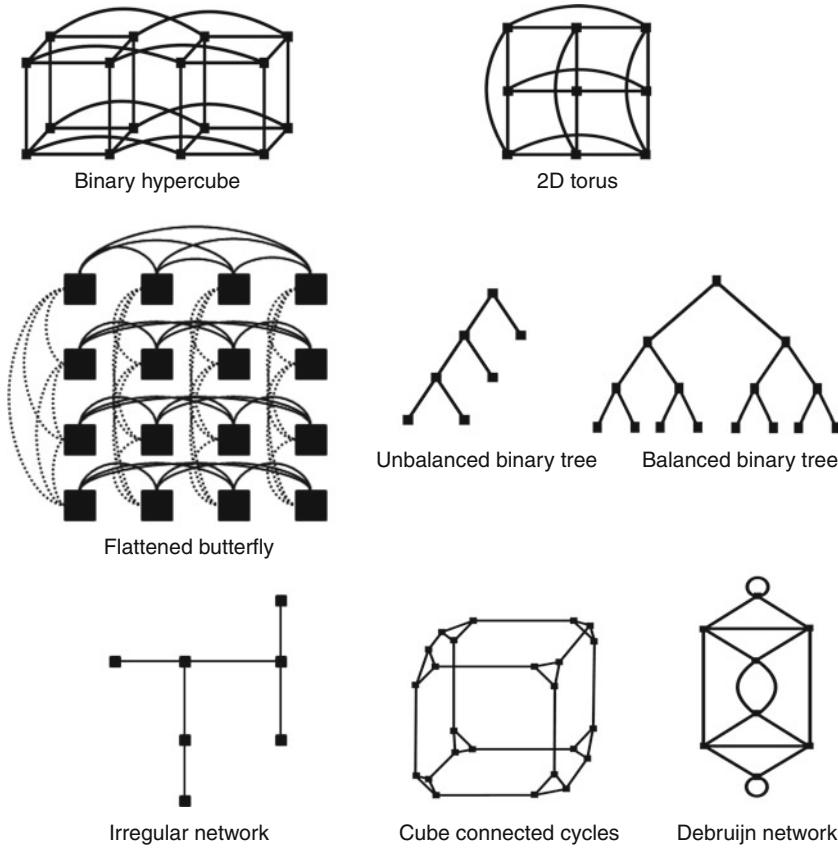

To achieve scalability beyond that which is feasible with shared medium networks, nodes are interconnected by *point-to-point links*. A node includes a router whose input and output links are connected to routers at some set of *neighboring nodes* producing a direct network. An example of a processor node in a 2D mesh network is illustrated in Fig. 1 where one of the router links connects within the local node. Each unidirectional link realizes the *injection* and *ejection* channels.

The topology refers to the overall interconnection pattern between nodes (actually between the routers to which the node is connected). A common topology, particularly for on-chip networks, is a 2D mesh as shown in Fig. 1. Formally, an  $n$ -dimensional mesh has  $k_0 \times k_1 \times \dots \times k_{n-2} \times k_{n-1}$  nodes, where  $k_i$  is the number of nodes along dimension  $i$  and is referred to as the *radix* for dimension  $i$ , and where  $k_i \geq 2$  and  $0 \leq i \leq n-1$ . Each node  $X$  is identified by  $n$  coordinates,  $(x_{n-1}, x_{n-2}, \dots, x_1, x_0)$ , where  $0 \leq x_i \leq k_i - 1$  for  $0 \leq i \leq n - 1$ . Two nodes are connected if their coordinates differ by 1 in only one dimension. Except for nodes on the boundary, all nodes are directly connected to  $2n$  other nodes. Thus, we can have a  $3 \times 4$  mesh where each interior node is connected to four other nodes or a  $6 \times 4 \times 8$  3D mesh where each interior node is connected to six other nodes. Now, messages between a pair of nonadjacent nodes are routed through the intermediate routers.

A symmetric generalization of the mesh is a  $k$ -ary  $n$ -cube [4]. Unlike the mesh, nodes at the edge have a link that “wraps around” the dimensions as shown in Fig. 2 for the 3-ary 2-cube. Now all nodes have the same number of neighbors. Formally, a  $k$ -ary  $n$ -cube has  $k_0 \times k_1 \times \dots \times k_{n-2} \times k_{n-1}$  nodes,  $k_i$  nodes along each dimension  $i$  and two nodes  $X$  and  $Y$  are neighbors if and only if  $y_i = x_i$  for all  $i$ ,  $0 \leq i \leq n - 1$ , except for dimension  $j$ , where  $y_j = (x_j \pm 1) \bmod k$ . Every node has

**Interconnection Networks. Fig. 1** An example of network nodes

**Interconnection Networks.** Fig. 2 Example direct network topologies

$2n$  neighbors. When  $n = 1$ , the  $k$ -ary  $n$ -cube collapses to a bidirectional *ring* with  $k_0$  nodes. When the radix in all dimensions are equal to  $k$ , we have  $k^n$  nodes. When  $k = 2$ , the topology becomes the binary *hypercube* or binary  $n$ -cube as shown in Fig. 2 which illustrates a 16-node binary hypercube.

A generalization of the  $k$ -ary  $n$ -cube is the *generalized hypercube* where rather than being connected to the immediate neighbors in each dimension, each node is connected to every node in each dimension. In graph theoretic terms, as we proceed from meshes through  $k$ -ary  $n$ -cubes to generalized hypercubes, additional links are added creating a denser interconnect. From a practical standpoint, as additional links are created, feasible channel widths change since the number of I/Os at an individual router have some maximum value. Finally, in all of the cases above, we note that the radix in each dimension can be distinct. These networks are often referred to as *orthogonal networks*

recognizing the independence of the routing behavior in each dimension (see ►Routing (Including Deadlock Avoidance)).

The landscape of direct interconnection network topologies is only limited by the imagination and many variants have been proposed and will no doubt continue to be proposed to match engineering constraints as technologies evolve. The preceding are the most common classes of networks used in current generation systems. Figure 2 illustrates some other common examples from the current time frame. A 2D flattened butterfly topology used in on-chip networks is equivalent to a 2D generalized hypercube. Various forms of balanced and unbalanced trees have been proposed motivated by the logarithmic distance properties between nodes. Others such as de Bruijn networks [16], star networks [2], and cube connected cycles [15] present different trade-offs between network diameter (longest path between nodes) and wiring

density. We can anticipate other direct networks to evolve in the future.

A final observation is that all of the topologies in the preceding discussion exhibit some form of regularity in structure, the edge routers in the mesh notwithstanding. A final class of networks that can be distinguished are irregular networks. Rather than a mathematical description, such networks are typically represented as graphs of interconnections and can be constructed to form any type of topology. An example is shown in Fig. 2. These networks are usually motivated by packaging constraints or customization, for example a specific topology in embedded systems where the topology is customized to the specific communication interactions between nodes. As a result of their irregularity these networks rely on distinct classes of routing techniques that are described in Routing.

### Indirect Networks

In general, direct topologies support interconnections where some routers may simply serve as connections to other routers and are not attached to any node such as a processor, core, or memory. These are the class of indirect networks. Like direct topologies, these may be organized into regular or irregular configurations.

A large class of regular indirect networks are multistage interconnection networks (MINs) an example of which is illustrated in Fig. 3. Nodes are connected to the inputs and outputs of the network. Each  $2 \times 2$  router – typically referred to as a switch in these topologies – can route a packet from one of its input ports to one of its output ports. There are  $N = 2^n$  input ports,  $N = 2^n$  output ports, and  $\log_2 N$  stages of switches with  $N/2$  switches in each stage. The interconnections between stages of switches are important – they ensure that a single path exists between every input port and every output port. In particular, consider the interconnection between stages 1 and 2 in Fig. 3. The connections can be described by the function

$$\sigma(x_{n-1}x_{n-2}\dots x_1x_0) = x_{n-2}\dots x_1x_0x_{n-1}$$

For example, output 5 of stage 0 is connected to input 3 of the next stage of switches (as shown in Fig. 3) and similarly output 6 is connected to input 5. This connection can be thought of as analogous

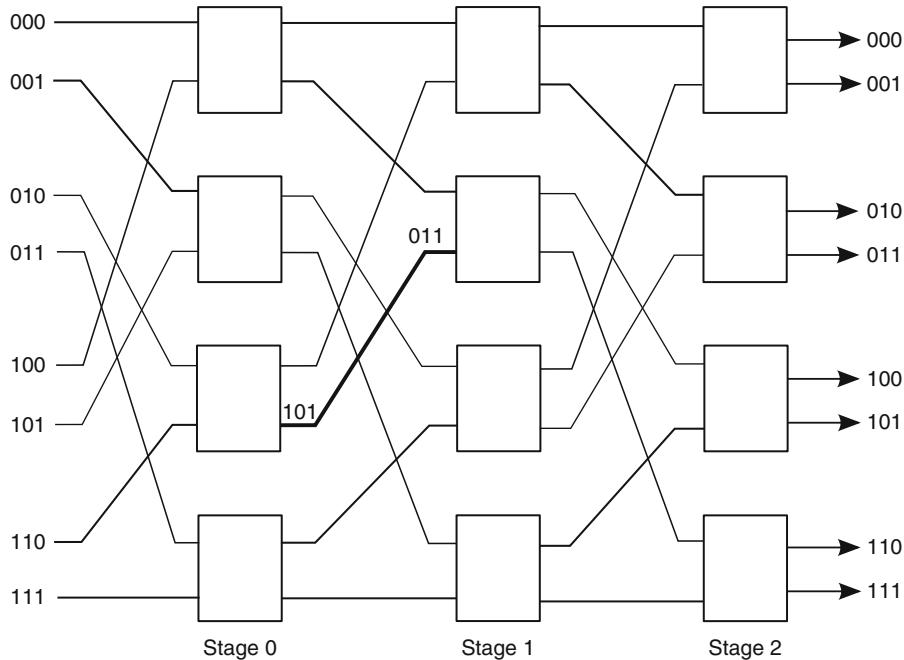

to perfectly shuffling a deck of  $N$  cards, where the deck is cut into two halves and shuffled perfectly, that is, the inputs are shuffled to the outputs. This function is referred to as the *shuffle* function and the network in the figure is the well-known Omega network. The preceding is a compact way of expressing the connections between stages. Note that every output (of a stage) is connected to exactly one input (of the next stage of switches), and therefore these connections can be represented as a *permutation* of the inputs. Consequently, such networks are referred to as *permutation networks*. In general, such networks can be constructed with  $t \times t$  switches and correspondingly  $n = \log_2 N$  stages for connecting  $t^n$  nodes.

Not all stages need to have the same interconnect pattern. For example, consider the following interconnect function.

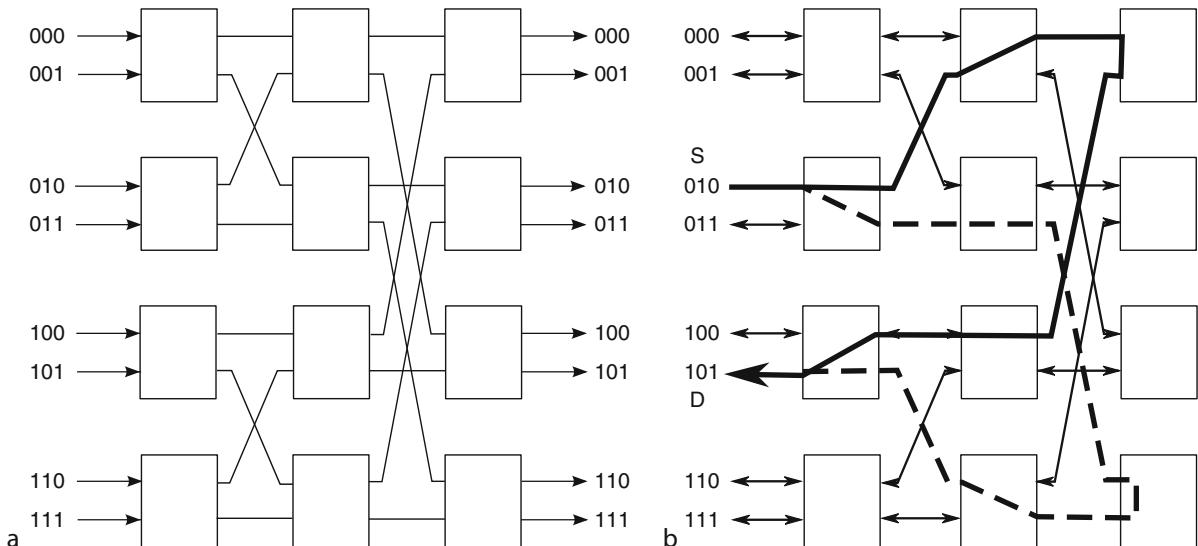

$$\beta_i(x_{n-1}\dots x_{i+1}x_ix_{i-1}\dots x_1x_0) = x_{n-1}\dots x_{i+1}x_0x_{i-1}\dots x_1x_i$$

The preceding function refers to Butterfly function forming the corresponding network of the same name illustrated in Fig. 4a. Note each stage uses a distinct butterfly ensuring every input has a path to every output. Many such MINs have been defined based on different permutation functions (see [11, 19] for a sampling). Perhaps, the oldest and best known among these is the Clos Network [3]. The Clos network is derived from a recursive decomposition of the crossbar with the first level decomposition shown in Fig. 5a. A crossbar is decomposed into a 3-stage network. Consider a network with  $N = r \times n$  inputs. The first stage comprises of  $r, n \times m$  switches while the center stage comprises  $m, r \times r$  switches. The last stage comprises  $r, m \times n$  switches. Each switch at the first stage has a connection to every switch in the middle stage. Each switch in the center stage has a connection to every switch at the last stage. Thus, there are  $m$  paths between every input and output. Each of the individual switches can be further and recursively decomposed with  $n = m = 2$  and  $r = N/2$  until the network is reduced to  $(2\log_2 N) - 1$  stages of  $2 \times 2$  switches. This network is known as the Benes network.

The MINs are characterized based on their ability to simultaneously establish connections between inputs and outputs. If a path through the MIN prevents other paths between free inputs and outputs from being set up, they are referred to as *blocking networks*. MINs

**Interconnection Networks.** Fig. 3 A MIN with a shuffle interconnection between stages

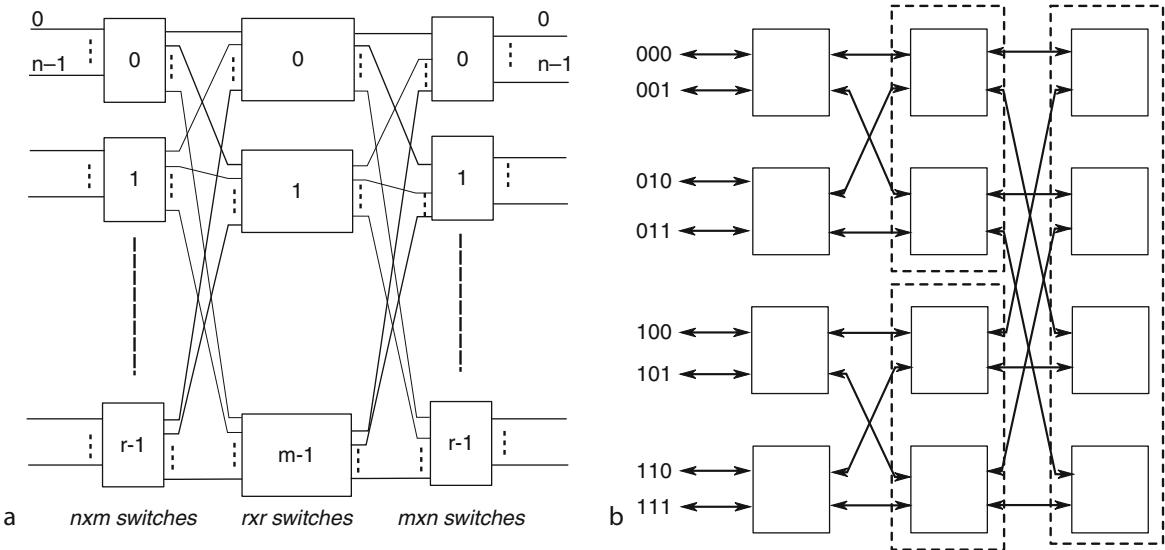

**Interconnection Networks.** Fig. 4 Some Example MINs. (a) The butterfly network. (b) A bidirectional MIN network

for which any free input can be connected to any free output are referred to as *non-blocking* while MINs where any free input can be connected to any free output by rearranging (rerouting) existing paths are referred to as *rearrangeable*. The preceding MINs with  $\log_2 N$  stages are blocking. Note that adding extra stages

introduces multiple paths between inputs and outputs until the network becomes rearrangeable and eventually non-blocking. Clos networks are non-blocking when  $m \geq 2n - 1$  and rearrangeable when  $m \geq n$ .

Finally, the preceding discussion was based on MINs with unidirectional links routing packets from input to

**Interconnection Networks. Fig. 5** Some additional MINs. (a) Crossbar decomposition of the clos network. (b) An example fat tree

output. However, MINs can operate with bidirectional links and packets can be routed to “any” output port of an intermediate switch leading to routing paths shown in Fig. 4b. Such MINs are referred to as *bidirectional MINs*. A careful look at the structure of bidirectional MINs will reveal that there exist multiple paths between any source–destination pair, an example of which is shown in the figure.

A fat tree is an indirect network that is topologically a balanced binary tree topology with the modification that the bandwidth of the links increases as one gets closer to the root (hence the label “fat”) [14]. This is typically achieved by adding more links in parallel closer to the root. Routing is straightforward in a fat tree – a message is routed up to the nearest common ancestor and then down to the destination. Thus, local communication is restricted to sub-trees. Fat trees are universal in the sense that it is the most efficient network for a given amount of hardware (see [14] for definitions of efficiency and universality). A butterfly BMIN with turnaround routing can be viewed as a *fat tree* – consider the dashed boxes of Fig. 5b as single internal switches in a fat tree. In this case, it can be viewed as having four  $2 \times 2$  switches in the first stage, two  $4 \times 4$  switches in the second stage, and a single  $8 \times 8$  switch in the last stage (the root of the tree). Modern fat tree topologies have evolved into a parametric family

as a function of (a) the number of levels in the tree, (b) the number of switches at each level, and (c) the switch sizes.

As with direct networks, the preceding MINs are considered regular, and it is possible to consider a range of irregular indirect networks of arbitrary topologies with nodes connected to an arbitrary subset of switches. As before, this has a clear impact on the routing protocols.

### Hybrid Networks

As the name suggests, hybrid networks are customized networks that couple various topological concepts described so far. For example, we might have a mesh of clusters where nodes within a cluster are interconnected by a high-speed bus. Or, we may have a hierarchy of ring interconnections. Hybrid networks are often motivated by the target packaging environment and incorporation of new technologies. For example, continued progress in optical communication, especially silicon nanophotonics, will lead to networks where interconnects and topologies are optimized for a combination of optical and electrical signaling.

### Routing

The routing algorithm establishes a path through the network and can be distinguished by the number

of candidate paths that can be produced between a source and destination. *Deterministic* routing protocols provide a single path between every source–destination pair. *Oblivious* routing algorithms produce routes independent of the state of the network, for example independent of local congestion. While deterministic routing algorithms are oblivious, the converse may not be true. For example, the source may cycle through alternative (deterministic) paths to the destination for successive packets in an attempt to balance network traffic across all links while not being influenced by the current state of any router. Another example is Valiant's two-phase routing protocol [20] where a packet is first transmitted to a randomly chosen node and then routed deterministically to the destination. *Adaptive* routing algorithms operate in response to network conditions in making routing decisions at each router by selecting from a set of alternative output ports at intermediate routers and thereby exposing multiple alternative paths to a destination. All of the preceding routing algorithms may cause a packet to follow a *minimal* path to the destination or permit *non-minimal* paths.

Implementations of routing algorithms admit to several alternatives. In *distributed routing*, each router implements a routing function that provides an output port(s) for each packet based on some combination of destination and/or input channel and/or source. Several implementations of distributed routing are feasible including table look-up or finite state machine implementations. In *source routing*, the source node prepends an encoding of the entire path to the destination, for example, as a sequence of output ports at each intermediate router. Each router along the path simply queries this header to determine the local output port along which to forward the packet. Source routing is invariably deterministic.

Many refined characterizations of routing algorithms have also emerged over the years. In *multiphase* routing algorithms, packets employ different routing algorithms during different phases of transmission. In *optimistic routing* algorithms, packets can freely choose any path to the destination since deadlock freedom is ensured via recovery rather than avoidance (see ►Deadlocks). Alternatively, in *conservative routing* algorithms, packets advance only when progress to the destination along the selected path is

assured. Principle features of routing algorithms and an accompanying taxonomy can be found in [11].

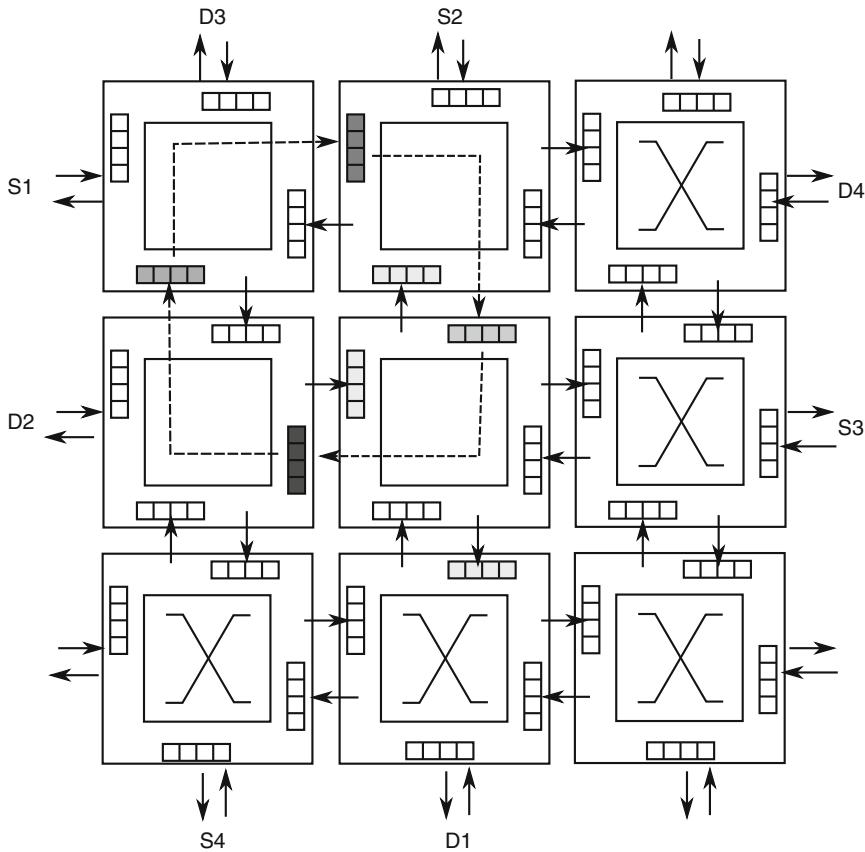

## Deadlock and Livelock

For any given topology, the routing algorithms must realize deadlock-free and livelock-free operation. *Deadlock* refers to the network state where some set of messages are indefinitely blocked waiting on resources held by each other. *Livelock* refers to a packet state, where a packet is routed through the network indefinitely and is never delivered. The presence of faulty components can lead to both deadlock and livelock behavior if mechanisms to prevent them are not implemented.

An example of a deadlocked configuration of messages is shown in Fig. 6 where messages are being transmitted between sources  $S_i$  and destinations  $D_i$  in a 2D mesh using a deterministic shortest path routing and input buffered switches (nodes attached to each router are not shown). Every message is waiting on a buffer used by another message producing a cycle of dependencies where each message is transitively waiting on itself. When routing is adaptive more complex configurations of deadlocked messages can occur where each message is blocked waiting on multiple buffers occupied by multiple messages and the set of messages cannot make progress since each message is transitively waiting on itself along all feasible output ports at the intermediate router.

*Deadlock avoidance* mechanisms are designed such that packets request and wait for resources (e.g., buffers) in such a way as to avoid the formation of deadlocked configurations of messages or otherwise guarantee progress. Routing algorithms for a topology are designed in conjunction with switching techniques to avoid deadlock. The most commonly employed principle, which is also common to deadlock avoidance in operating systems, is to provide a global ordering of resources and for all packets to request resources in this order. Specific applications of this principle are topology specific and are described in ►Routing (Including Deadlock Avoidance).

In contrast, *deadlock recovery* mechanisms promote optimistic routing of messages in the absence of any deadlock avoidance rules [1]. Deadlocked configurations of messages are detected and recovery mechanisms are invoked that reestablish forward

**Interconnection Networks. Fig. 6** An instance of deadlock

progress of packets. The application of deadlock recovery is motivated in network configurations where the probability of deadlock occurrence is very low. This is often the case in adaptively routed networks with large numbers of virtual channels.

All deadlock freedom proofs rely on the *consumption assumption* – messages reaching a destination are eventually consumed. However, the end points can introduce dependencies between incoming packet channels and outgoing packet channels since there may be dependencies between message types, for example processing of a message may lead to the injection of new messages. Consequently, it is possible to introduce a dependency between injection and ejection buffers external to the networks and which is not addressed by routing restrictions in the network. This can potentially introduce cyclic dependencies and therefore deadlock referred to as *protocol* or *message-dependent* deadlock [18]. For example, in shared memory systems

message traffic consists of request packets (for cache lines) that produce response traffic (cache lines). Traffic is often separated into two virtual networks – the request network and response network. Thus, protocol handlers at the end points can ensure that each network satisfies the consumption assumption and that the end point is never indefinitely blocked waiting on injection (full) or ejection (empty) channels.

### Deadlock-Free Routing

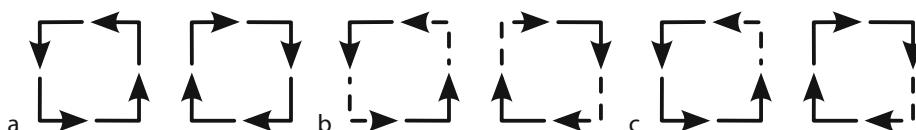

The literature on packet data networks is rich with techniques for deadlock-free routing (avoidance). This section will be focused on principles and common techniques that are utilized in multiprocessor interconnection networks that in one form or another enforce ordering constraints to ensure deadlock freedom.

The simplest example of deadlock free routing is in 2D meshes using X-Y routing where a packet is routed in the X dimension eliminating the X-offset (find the right column) before routing in the Y dimension (eliminate the Y-offset) – also known as *dimension order routing*. This avoids deadlocked configurations since no message traversing the Y dimension can request a channel in the X dimension and create a cycle of dependencies as illustrated in Figure 6. This deadlock-free routing algorithm is naturally extended to  $n$  dimensions where all packets follow the same order of dimensions in eliminating offsets in each dimension. The *Turn Model* generalizes dimension order restrictions on routing by observing that packets must be prevented from moving from one class of channels to another, that is, performing a *turn* [12]. In dimension order routing in 2D meshes packets are prevented from turning from the Y dimension to the X dimension. Many Turn-based deterministic and adaptive routing algorithms have been developed in the literature. One of the principle attractions of the Turn Model is that it can be applied to networks without virtual channels. Figure 7a shows all possible turns for a 2D mesh. Figure 7b shows those turns (dashed arrows) that are restricted for X-Y routing. Note that two turns are restricted in each cycle. However, restricting the use of a single turn in each cycle is sufficient to avoid deadlock. An example is illustrated in Figure 7c.

Deadlock-free routing in irregular networks can be achieved with similar ordering constraints. For example, a distinguished node can be identified in the network (e.g., the root of a spanning tree). A labeling algorithm labels all channels as either being *up* and directed toward the root or *down* and being directed away from the root. Packet routing is now constrained to use all up channels followed by all down channels. A packet cannot turn from a down channel to an up channel avoiding the creation of cyclic dependencies [17].

The wrap-around links in multidimensional tori introduce hardware cycles within a dimension and therefore dimension order routing is not deadlock free (consider the case where each node in a row is simultaneously transmitting to a destination  $h$ -hops away in the same row). For deterministic routing the work of Dally and Seitz [6] showed that the necessary and sufficient condition for deadlock-free routing is an acyclic channel dependency graph – intuitively if a packet can be routed from channel A to channel B, there is a dependency from A to B. Acyclic dependency graphs are achieved in tori with the presence of two virtual channels per physical channel – say VC0 and VC1 – and placing restrictions on how these channels may be used. A single link in each dimension is chosen (sometimes called the dateline link). The routing algorithm constrains the packets being routed across this link to use one virtual channel class. Coupled with the routing rules across other links, cycles in the channel dependency graph and hence deadlock is avoided. The requirement of acyclic channel dependency graphs can be implemented in many ways by creatively restricting the use of virtual channels in regular and irregular networks.

The theory of deadlock free adaptive routing protocols was developed by Duato [7, 8]. Intuitively, cycles may exist in the channel dependency graph as long as there exists an acyclic subgraph that enables all messages to be routed between any source destination pair – sometimes referred to as an *escape path* or *escape channel* at a router. Virtual channels provide a natural medium for implementing adaptive routing. In the case of tori, each physical link supports three virtual channels – VC0, VC1, and VC2. The first two provide the acyclic subgraph necessary for deadlock free routing. VC2 is the adaptive channel that can be used by a packet to cross any physical link to the destination. The theory has been developed for wormhole, packet, and virtual cut-through implementations [7–10]. In general,

**Interconnection Networks. Fig. 7** Possible and restricted turns in a 2D mesh. (a) Possible turns in a 2D mesh; (b) Restricted turns for X-Y routing; (c) Minimum turn restrictions for deadlock freedom

by suitably specifying routing restrictions, adaptive routing protocols can be developed for regular and irregular networks.

## Metrics

The construction of an interconnection network is a process of trade-offs between various network design parameters such as topology, channel widths, and switch degree and the physical constraints of the target implementation environment such as on-chip vs. in-rack vs. inter-rack. The consequences of the choice of network parameters are captured in several common metrics.

A practical constraint encountered by interconnection networks is the wiring density. Since networks must be implemented in three dimensions, for an  $N$  node network the available wiring space can be seen as growing as  $O(N^{\frac{2}{3}})$  which corresponds to the area of the surface of a 3D cube containing the  $N$  nodes. Network traffic can grow as  $O(N)$ . As system sizes are scaled, wiring limits are eventually encountered. A common metric to capture wiring limits is the *bisection width* of a network defined as the minimum number of wires that must be cut when the network is divided into two equal sets of nodes. The intuition is that in the worst case, every node on one side of the minimum cut will be communicating with every node on the other side of the cut maximally stressing the communication bandwidth of the network. For regular topologies such as  $k$ -ary  $n$ -cubes the minimum bisection width is orthogonal to the dimension with the largest radix. For irregular topologies, the min-cut defines the bisection width. Bisection bandwidth is usually computed as the bandwidth across these wires implicitly considering only data signals. The bisection widths of several topologies where each link between adjacent nodes is  $W$  bits wide are listed in [Table 1](#).

**Interconnection Networks. Table 1** Examples of bisection width and node size of some common net-works ( $t \times t$  switches are assumed in the MIN)

| Network               | Bisection width | Node size |
|-----------------------|-----------------|-----------|
| $k$ -ary $n$ -cube    | $2Wk^{n-1}$     | $2Wn$     |
| Binary $n$ -cube      | $\frac{NW}{2}$  | $nW$      |
| $n$ -dimensional mesh | $Wk^{n-1}$      | $2Wn$     |
| MIN                   | $NW$            | $2tW$     |

A second physical constraint is the number of data signals on a router referred to as the *node degree*, *node size*, or *pin-out*. The importance of node degree stems from the fact that it is a practical limit on routers. Further, the topology, bisection width, and node degree are closely related. Consider the implementation of a  $k$ -ary  $n$ -cube with the bisection width constrained to be  $N$  bits. The maximum channel width determined by this bisection width is  $W$  bits and is given by

$$\text{Bisection width} = 2Wk^{n-1} = N \Rightarrow W = \frac{k}{2} \quad (1)$$

The channel width directly impacts message latency and hence performance. The specific relationships between channel widths, node degree, and bisection bandwidth vary significantly whether the network is implemented on-chip, intra-rack, or inter-rack. These metrics also provide a uniform basis for comparison between various topologies.

## Bibliographic Notes and Further Reading

Each of the major topics discussed in this section have been subjected to a rich and diverse development. Entries can be found in the encyclopedia for all levels of the interconnection network stack. At the lowest level, the entry on *Flow Control* elaborates the issues and solutions for managing buffer resources as packets progress through a network. One level up, *Switching Techniques* are closely coupled with flow control and interact with higher-level routing protocols that are covered in the entry on *Routing (Including Deadlock Avoidance)* to determine no-load latency properties of an interconnection network. However, workloads can place highly nonuniform demands on the network. The entry on *Congestion Management* introduces a variety of techniques for managing such nonuniform demands and enhancing performance. A very important special case of traffic patterns is collective communication, and various approaches toward support for such communication patterns can be found in the entry on *Network Support for Collective Communication*. High-performance network designs are especially challenging when the network must be resilient to

faults. Basic issues and approaches can be found in the entry on *Fault Tolerant Networks*. Finally, the injection and ejection interfaces to the network must be designed to deliver network performance to the end point hosts. Basic architectural and operational principles are covered in *Network Interface*.

A combined coverage of fundamental architectural, theoretical, and system concepts and a distillation of key concepts can also be found in two texts [5, 11]. Advanced treatments can be found in papers in most major systems and computer architecture conferences with the texts contributing references to many seminal papers in the field.

## Synonyms

High-performance I/O

## Definition

Parallel I/O refers to input/output operations where multiple processes working together in executing a parallel application concurrently access secondary storage devices to exchange data between the main memory and files. The discussion in this entry will

be focused on parallel I/O in the context of HPC (High Performance Computing), especially scientific computing on large-scale parallel machines.

## Introduction

I/O is an integral part of computing, scientific and commercial both alike. For parallel scientific applications, the purpose of their execution is to generate data through simulation, or to analyze data collected from observation instruments or computer simulations (which usually will in turn produce results stored in data files). With today's supercomputers, 100,000s of processes may work in parallel in executing a single parallel program and accessing the secondary storage system. Unlike other environments with high I/O *concurrency*, such as commercial settings where a large number of client requests are processed by web server clusters or data centers, the HPC parallel I/O workloads are generated from much more tightly coupled/synchronized computation and often demand high data bandwidth in addition to low access latency. Moreover, parallel I/O plays an important role in HPC fault tolerance – by providing efficient checkpointing and restart operations.

Parallel I/O faces tremendous performance and scalability challenges in the current era of Peta-scale computing. First, the well-known performance gap between the computing components (CPU and memory) and the secondary storage devices (hard disks) keeps widening. Although disk speed has also been continuously growing in the past decades, hard disks appear slower and slower. Second, such performance gap is worsened by the limitation in parallelism. On state-of-the-art supercomputers, there are typically orders-of-magnitude more I/O client nodes compared to I/O server nodes, creating complex resource sharing and interference problems when data travel from individual compute nodes' memory to shared interconnections, I/O servers, and storage devices. In particular, this challenge is intensified by the trend of having more CPU cores within each compute node, when the clock rate improvement predicted by the Moore's law cannot sustain due to semiconductor and heat management limitations. Such increased computation parallelism aggravates the I/O intensity and contention levels, making careful I/O

subsystem design crucial to delivering a balanced overall performance.

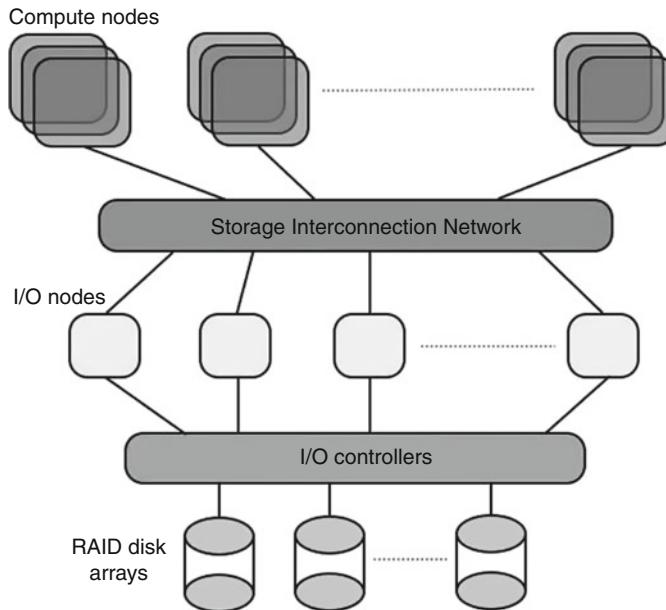

## Hardware Environments

Parallel I/O, in a more general sense, can be carried out in most distributed storage systems, such as in typical commercial/R&D settings, when storage and I/O hardware are shared by multiple users or client applications. Examples include the NAS (Network Attached Storage) and SAN (Storage-Area Networks) environments.

In the context of HPC, where the term “parallel I/O” is mostly used, there are several common hardware and networking features in addition to distributed accesses to shared storage devices. HPC I/O environments, designed for efficient file accesses performed by closely synchronized parallel applications (especially parallel simulations), often possess highly homogeneous hardware at both the client and server sides, as well as strictly hierarchical and symmetrical network structure.

[Figure 1](#) demonstrates a representative hardware and interconnection architecture designed for high-performance parallel I/O. Such an I/O environment can be viewed as a multilevel client-server architecture. On today's supercomputers (see configurations of state-of-the-art machines on the Top500 list [39]), the client side consists of 10,000s or more *compute nodes*, where users run their parallel programs, typically in batch mode. These programs issue I/O requests through the client layer of the parallel file system, which also resides on the compute nodes. Each node is equipped with its own main memory, shared by multiple cores. Smaller clusters may have node-attached local secondary storage (hard disks), while such a configuration has become rare on supercomputers these days.

The nodes are connected with each other through one or more interconnection networks (such as InfiniBand or Myrinet), to communicate with each other. Message passing has been the dominant inter-process communication scheme in the past 2 decades and currently remains the main stream. The majority of parallel applications today adopts the MPI (Message Passing Interface) [21, 22] programming model. Also connected to the compute nodes are *I/O nodes*, which are I/O servers handling client I/O requests and run the server

I/O. Fig. 1 Sample High Performance Computing (HPC) I/O hardware architecture

layer of the parallel file system. With modern supercomputers, it is not rare that there are redundant interconnection networks among nodes (typically with different types of topology), for better performance and fault tolerance. One of these networks can potentially be assigned as the main I/O interconnection.

On supercomputers these days, the ratio of compute to I/O nodes often varies between dozens to hundreds. Unlike in the case of compute nodes, the existence and operation of I/O nodes are typically transparent to application programmers. However, the combination of parallel I/O libraries (such as MPI-IO) and parallel file systems, both to be discussed in the next section, allows user programs to perform parallel I/O and access shared files via the I/O nodes implicitly through MPI interfaces.

While small or medium clusters often have disks directly attached to the I/O nodes, on large-scale supercomputers they are connected with another interconnection network, to form a SAN. A group of controllers can be placed between the I/O node layer and the disk layer, connecting hundreds or more I/O nodes to 10,000+ hard disks. For performance and fault tolerance, these disks are usually organized into RAID [31] groups. Data striping is performed at the file system level, and further at the storage device level.

## Parallel I/O Software

### Overview of Parallel Application Execution and I/O Scenario

On today's typical HPC platforms, parallel I/O is carried out in multiple stages of parallel jobs. Such jobs are executed mostly in batch mode, submitted through job scripts and managed by batch job schedulers/managers such as LSF, PBS, MOAB, and LoadLeveler. Jobs submitted wait in the job queue until dispatched by the scheduler, to execute on the requested number of processors/cores. Usually such a partition of computation hardware (compute nodes, including CPUs and memory, and in some cases local secondary storage resources such as hard disks and nonvolatile memory devices) is occupied by the job until it finishes or its execution time has exceeded the maximum specified in the job script. On the other hand, concurrent jobs on a parallel computer need to compete with each other in using shared resources, such as the interconnection networks and the share/parallel file system.

With parallel simulations, the dominant type of applications running on 100s to 100,000s processor cores, the execution of a job typically goes through many computation timesteps in an iterative manner. Often there is certain correspondence between a

computation timestep with a physical timestep, therefore the simulation computes the development of the object or phenomenon being studied along the time dimension. With most simulation codes, the execution alternates between *computation phases* and *I/O phases*, by having one I/O timestep every  $n$  computation timesteps. Application developers or users can configure the frequency of such periodic I/O operations by adjusting  $n$ .

There are two major types of data written during a parallel simulation run: *checkpointing data* that save the current status of the computation, so that the computation can be restarted after a crash, a failure, or at a given intermediate point of simulation, and *result data* that save an intermediate “snapshot” of the simulation, for future analysis and visualization. Concatenating multiple snapshots generated by an application run allows scientists to view a movie demonstrating the process being simulated. In contrast, often no more than two consecutive checkpoints are needed for fault-tolerance purposes. Obviously, in choosing a desired periodic I/O frequency, users have to consider the trade-off between I/O cost and resolution. More frequent I/O steps generate more detailed view of the simulation and allow for less redundant recomputation in case of hardware/software failures, but will cost more time spent on I/O during the job run and result in larger result datasets that need to be stored, migrated, and processed. In most cases, application users tune the I/O frequency so that the visible time spent on I/O operations within a run is under a certain budget, e.g., 5–10% of the total parallel execution time (wall time).

In addition to periodic checkpointing and result data output, applications may write out miscellaneous data to assist book-keeping, debugging, and performance diagnosis/analysis. Such data include application-level logs and library-level profiling data and traces. Meanwhile, for most simulation codes the demand for input is relatively small: simulation jobs typically only read input data (from files describing the initial simulation state or a certain checkpoint) during the start or restart process, to initialize data structures before the first timestep. Therefore, simulation codes are often considered write-intensive, with the exception of *out-of-core* applications, where the aggregate memory is not large enough to accommodate the entire data

footprint, requiring applications to repeatedly swap data between the main memory and the secondary storage. Non-simulation applications (such as analytics and parallel data base search codes), on the other hand, may have larger portions of input in their I/O workloads.

Besides the I/O needs during the execution of a job, staging operations are needed to move input data to and move output data from a supercomputer center. The high-performance file systems at these centers are “scratch space” for jobs’ transient use instead of long-term storage. With parallel data transfer tools such as GridFTP, input staging and output offloading can also be carried out with multiple streams accessing files simultaneously.

## HPC I/O Access Patterns

HPC applications have traditionally been using several modes for performing I/O. One brute force approach is to have every process communicate their data to/from a root process (typically process 0), which is in charge of all file I/O. This approach is simple and can easily coordinate data to/from multiple processes while accessing files with traditional, single-process I/O interfaces. The problem is also obvious: parallel I/O is not used and the I/O process is serialized through the root process, which quickly becomes the I/O bottleneck even in a midsize cluster.

Another rather straight-forward alternative to the above approach is to have each process perform their file I/O independently, to/from separate files. This approach is also easy to implement, and in many cases results in good performance in terms of the aggregate I/O throughput. By accessing nonoverlapping sets of files, many parallel processes can go ahead with I/O without coordinating with each other to decide their data’s global offsets or synchronizing through file locks. Within each file, accesses can also be largely sequential. However, this approach brings the need of creating, managing, and using a large number of small files. Such a management overhead is prohibiting for long-running, large-scale applications, which easily generate millions of files if independent file I/O is used. Also, this approach makes it more challenging to restart an application with a different number of processes.

Considering the limitations of the above two methods, many large-scale applications with significant

periodic I/O requirement choose to go with the “true parallel I/O” mode, where many processes collaboratively access one or more shared files during each I/O phase. This is often done via parallel I/O libraries (see section “Parallel I/O Libraries” below). This approach combines the benefits of the first two methods: a small number of “global” files plus concurrent file I/O accesses.

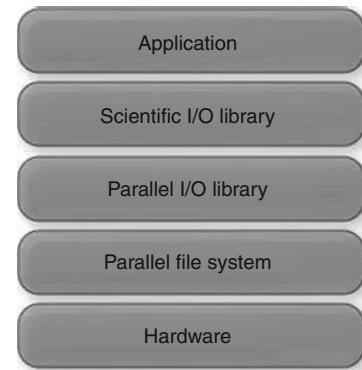

Such shared-file accesses create more interesting I/O patterns, as many processes need to map their in-memory data partitions to on-disk file range partitions, to store the global data object in layouts that facilities future restart or analysis. Therefore, the access pattern heavily depends on the domain decomposition method adopted by the parallel computation model. For regular applications that work on multidimensional arrays, commonly seen patterns are similar to HPF (High Performance Fortran) [11], such as BLOCK and CYCLIC. Fine-granule interleaving pattern maybe created by corresponding strided data distribution, or a mismatch between in-memory and on-disk data layouts. For example, a 2-D array distributed to  $p$  processes in column-major blocks may produce such an interleaving pattern when the shared array needs to be written out to disk in row-major order. Such finely interleaved accesses can be aggregated and reorganized by the parallel I/O libraries, though, to alleviate the I/O performance concern.

### Parallel I/O Software Stack

Between a parallel application and the storage media, parallel I/O requests usually have to go through a multilayer I/O software stack, across the user and the kernel space. Figure 2 illustrates such a deep I/O stack and the software layers will be discussed in the following sections. Please note that performing parallel I/O does not require all layers to be included. For example, off-the-shelf clusters often do not have parallel file systems, and applications may choose not to use high-level scientific data libraries or parallel I/O libraries.

### Parallel File Systems

Parallel file systems aim to bring to parallel computer users a file system view that is similar to traditional serial file systems on a single computer: a unified, logical storage space. It hides from programmers

I/O. Fig. 2 Sample HPC I/O stack

and users the fact that physical storage spaces are attached to distributed I/O servers, which are in turn interconnected to the compute nodes where the application programs run. Currently, parallel file systems are installed on supercomputers and medium/large clusters, while small clusters often use distributed file systems such as NFS [29].

In addition to the routine features of distributed file systems, such as file and directory management, request routing, and disk space management, parallel file systems have features and strategies that are designed to fit parallel I/O demands. One important feature is file striping, which partitions file into chunks and distribute them across I/O servers and further across disks. With intelligent striping strategies, a parallel file system can achieve reasonable I/O load balance for both large and small file accesses, as well as system extensibility when new servers and disks are added. In addition, parallel file systems take into account the HPC I/O workload (multiple parallel jobs running concurrently) in making design choices regarding file block size, metadata server configuration, distributed lock management, caching/prefetching policies, fault-tolerance mechanisms, etc.

As of now, the most commonly used parallel file systems include the proprietary GPFS [33] (available on IBM systems), and two open-source systems: Lustre [8], and PVFS [5].

### POSIX I/O

File systems used in HPC environments usually support I/O accesses via the well-known POSIX (IEEE

Portable Operating System Interface for Computing Environments) interfaces. POSIX interfaces can be used at different levels in a parallel program's execution: they can be directly called by the programmer to carry out I/O operations, and they are used eventually by higher level I/O middleware (such as parallel I/O libraries) to access disk files. With the former approach, these familiar interfaces (such as `open`, `close`, `read`, and `write`) allow programs extended from sequential codes to easily run on parallel file systems. By having multiple processes carry out I/O simultaneously, “parallel I/O” can be achieved simply through POSIX interfaces. However, they do not assist parallel program developers in achieving high-performance I/O, especially to perform coordinated accesses to shared files with high I/O concurrency [15]. Also, strict enforcement of POSIX consistency may prevent applications from applying performance optimizations.

## Parallel I/O Libraries

Parallel I/O libraries act as middleware between the underlying parallel file system (accessed via POSIX/POSIX-like I/O interfaces) and the parallel application. Most importantly, parallel I/O libraries provide applications with convenient interfaces to easily access shared files concurrently, as well as performance optimizations that often dramatically improve applications' parallel I/O efficiency.

For ease of use, parallel I/O libraries supply users with file I/O interfaces to simultaneously open/close shared files and share common file pointers, as well as to conduct both *individual* and collective I/O. In particular, collective I/O [3, 13, 27, 34, 38] allows processes to collaborate in reading/writing their portions of data from/to shared files, using data distribution descriptions that map naturally to the domain decomposition methods used widely in parallel simulation codes. For example, a parallel program that distribute a large 3-D double array across 256 processes in  $8 \times 8 \times 8$  grids can conveniently write out their sub-arrays into the global array, stored in row-major order in a shared file. With parallel I/O libraries, this can be done with a single collective I/O call (which also forces implicit synchronization in a way similar to a barrier call). The complicated data reorganization and correspondent inter-process communication are

therefore hidden from the programmer. There are also interfaces for programmers to define more sophisticated or irregular data distribution, such as with indirection arrays.

Several collective I/O architectures have been proposed in the past, including DDIO (Disk Directed I/O) [13] and SDIO (Server Directed I/O) [34]. The current prevalent architecture is 2PIO (Two Phase I/O) [3], where each I/O operation is separated into communication phases and I/O phases, for performing inter-process data exchange/reorganization and file I/O, respectively.

Mechanisms such as collective I/O are also important performance optimizations, for example, aggregating small, noncontiguous I/O requests into large, contiguous ones. The resulting long, sequential accesses are favored by hard disks, the dominant storage media used in secondary storage. Also, avoiding finely interleaved accesses alleviates the false sharing problem, as well as the consequent expensive locking/synchronization costs. In addition, parallel I/O libraries employ other performance optimizations, such as I/O aggregation (which reduces the number of processes that make I/O calls, which helps to reduce I/O contention in the face of large-scale runs where thousands or more processes are used to execute a parallel application), data sieving (which avoids small, non-contiguous I/O by in-memory data manipulations, either “picking out” useful data segments or masking holes in output through read-modify-write operations), and I/O hints (which pass information from the application to help the parallel I/O library in configuring its internal settings, such as available buffer size, aggregation parameters, and file consistency requirements).

To this date, the most popular parallel I/O libraries follow the MPI-IO specification, as a part of the MPI-2 Standard [23]. MPI-IO specifies the semantics of MPI-IO interfaces, which carry a unified style with familiar MPI calls for inter-process communication. While MPI-IO has been implemented with several MPI distributions, the most widely used and studied implementation is ROMIO [38], developed at the Argonne National Laboratory, as a part of MPICH, a popular open-source MPI library. ROMIO adopts the 2PIO design and adopts many collective I/O optimizations mentioned above.

## Scientific Data Format Libraries

Parallel I/O libraries such as ROMIO provide application programmers with the convenience and performance for coordinated, efficient multi-process I/O operations. However, many scientists running large-scale simulations and performing subsequent analysis/visualization of the computation results do not read/write data in plain binary formats. Instead, they often use high-level I/O libraries to create and access data in special scientific data formats. These file formats bring several important features. First, they produce self-explanatory and self-contained files that encompass both raw datasets (most commonly multidimensional arrays) and their accompanying metadata items. Such metadata describe attributes associated with the raw datasets, such as variable name, unit, type, array dimension and size, and other information needed to interpret and analyze the data. Second, they facilitate binary portability through automatic file conversion when the files are moved between architectures using different floating point presentation. This is important as scientific data files and programs need to be designed to survive generations of diverse HPC platforms. Finally, such data formats often support good file extensibility, allowing files to grow easily when datasets are expanded or more datasets are stored within a file.

Different scientific communities have different preferences over format choices, but more and more scientists and their applications converge to two most popular formats these days, HDF [12] and netCDF [24]. Both formats possess the aforementioned advantages, at the cost of performance: file access latency and bandwidth are often significantly inferior compared to those with binary files. In recent years, both formats have added support for parallel accesses, by developing parallel access interfaces on top of the MPI-IO parallel I/O library.

## Parallel I/O Today

Due to the unsolved and incoming challenges of delivering scalable, high-speed parallel I/O on large-scale supercomputers, there continue to be research and development efforts on parallel I/O system design and optimizations. In particular, the recent trend is going toward more integrated explorations and development, where application developers/users, I/O

middleware designers, supercomputer center managers and system administrators, file system designers, and finally supercomputer vendors gather together to participate in next-generation HPC I/O subsystem design.

One example of such coordinated design is the recent ADIOS parallel I/O middleware [17], which was developed jointly between Oak Ridge National Laboratory and Georgia Tech through tight interaction with state-of-the-art parallel scientific simulations. ADIOS is able to facilitate convenient result/checkpoint data output through intuitive group-based interfaces, with the help of an auxiliary XML configuration file. Also, ADIOS can perform aggressive asynchronous I/O as well as data staging operations [40]. This allows analytics tasks typically performed as post-processing steps to be carried out efficiently on the fly along the data output pathway, avoiding the need for multiple rounds of input and output. Another example is the close collaboration among designers across the many layers in the deep HPC I/O stack, such as the Lustre Center of Excellence that connects vendors and file system designers directly to supercomputing centers and application users.

Recently researchers and developers are also working on streamlining parallel I/O operations during parallel job runs with other pre-job and post-job data activities, such as data staging/offloading to/from supercomputing centers, long-area data migration, and data analytics. The traditional “in-job” parallel I/O becomes one link in the end-to-end scientific data workflow, while other components of the workflow have also been increasingly exploiting parallelism of various forms. Ongoing work is examining mechanisms and tools to allow part of these data processing/analysis tasks into the “in-job” data pathway. For example, long-desired features such as in-situ visualization not only completes important data post-processing, but also enables valuable runtime job steering capabilities.

Parallel I/O beyond the environment of supercomputing centers can potentially get more help from ongoing efforts such as the creation of pNFS (parallel NFS). There are also efforts underway to improve software reuse and data sharing, for example, through efforts to make popular scientific data formats such as netCDF and HDF more compatible with each other.

## Future Directions

Parallel I/O faces new challenges as well as new opportunities in the coming years, when supercomputing is moving from Peta-scale to Exa-scale and beyond.

With next-generation supercomputers, the computation parallelism will continue to rise and intensify the pressure on the I/O subsystem. The unprecedented high degree of I/O parallelism will be reflected in the number of processes making I/O calls and sharing files, the number of metadata operations to be processed concurrently, the number of disks and disk controllers, and the number/volume of data files.

On larger systems, parallel I/O challenges will be highlighted in several aspects. First, the increasing number of cores per node demands more scalable interconnection and storage device layers. Also, it is not clear whether the memory capacity and bandwidth would become a severe problem again, when shared among dozens or more cores within the same node. If true, this will make it harder to apply optimizations developed in the past decade to exploit unused memory to perform asynchronous I/O or intelligent client-side caching/prefetching. Second, with millions of disks to manage, software and hardware reliability will continue to be a problem in maintaining the overall system availability and usability. In particular, it is predicted that with extreme-scale systems, disk recovery through RAID coding will become a constant event and requires careful handling to avoid overall parallel I/O speed degradation. More elaborate metadata server and I/O node fall-over schemes may be needed too. Third, the large amount of data produced on extreme-scale systems need to be managed and processed. In particular, timely data movement and analysis tools will be crucial in the end-to-end scientific computing cycle. Finally, with the increasing system scale and complexity, it becomes ever more challenging to monitor and analyze parallel I/O performance. Effective benchmarking, tracing, and profiling mechanisms are needed for researchers to provision resources for large centers' storage subsystem, and to understand, configure, and optimize its performance in everyday operations. Performance visualization and automatic analysis/debugging tools will also facilitate the identification and solving of I/O

problems, particularly in the direction of cross-layer trace correlation and causal study.

One side problem of the increasing scale of supercomputers is that it becomes harder and harder for academic researchers to deploy and evaluate their parallel I/O design or improvements on production-scale platforms. In particular, server-side and kernel-level modifications often have to be constrained to experiments on small or medium research clusters, where the configuration and bottlenecks are drastically different from large-scale machines. The advances in cloud computing and virtual machine technologies, though, may enable these researchers to emulate supercomputer environments and perform large-scale experiments.

Meanwhile, there are also emerging opportunities for new practice or even paradigm shifts in parallel I/O systems and software in the future years and decades. One ongoing exploration is examining the feasibility and methodology for incorporating new storage devices into the HPC I/O hierarchy, as destination storage devices or intermediate caching layers. Examples of such devices of interest include Solid State Drives (SSDs) and phase-changing memory. These nonvolatile memory devices provide a compromise between capacity and speed between the main memory and secondary storage. Also, free of moving parts, these devices offer more reliable and energy-efficient I/O solutions compared to hard disks. However, there are unique challenges associated with deploying these new devices as the current I/O stack is designed based on hard disks' operation characteristics. Also, for HPC I/O, the write durability of devices such as SSDs may make their deployment costly, considering the write-intensive workloads on supercomputers. Scientific data centers, in this sense, may be better candidates for employing such read-friendly storage media for fast parallel I/O.

## Bibliographic Notes and Further Reading

For interested readers, John May authored a comprehensive book on parallel I/O for HPC [20], published in 2001. It gives a detailed overview of

HPC I/O hardware and software layers, as well as detailed discussions on standard parallel I/O interfaces (MPI-IO) and high-level scientific data libraries (netCDF and HDF5). A more recent overview of an HPC storage system instance is given by researchers at Oak Ridge National Laboratory [30], which describe the hardware, network, and software settings of the Spider parallel file system that is deployed at their computing center. Spider connects the storage hardware on several computing platforms centered around Jaguar, the Cray system that ranks as the world's largest supercomputer as of early 2010.

There have been several studies that investigate HPC I/O characteristics. In particular, a series of investigations on this topic were published in the 1990s [9, 10, 14, 35]. A recent study on Peta-scale I/O workloads was conducted by Argonne National Laboratory researchers [6].

A large amount of work has been conducted in parallel I/O performance optimization, especially on improving the performance of collective I/O. These optimizations include automatic I/O library parameter tuning [7], buffering/caching techniques [16, 18], file domain partitioning methods and handling of irregular/noncontiguous access patterns [4, 28, 37], exploiting overlap between computation and I/O [19, 23], and application-specific optimizations [26, 32].

The John May book mentioned above also discussed two specific uses of parallel I/O beside job input and result output: I/O in parallel out-of-core applications (to swap data between memory and disk due to limited main memory space), and checkpointing (to write out data periodically for fault tolerance and future restart). Several studies focused on parallel I/O for out-of-core codes (e.g., [25, 36]). Due to the increasing system size and per-node memory capacity, out-of-core applications are less common these days. For checkpointing, application-level parallel checkpointing has mostly shared characteristics with result output, though recent studies have explored new ways of performing checkpointing (such as in-memory checkpointing through file system interfaces [1] and checkpointing-specific storage design [2]).

### Definition

JANUS is a massively parallel application-driven machine, developed in the years 2006–2008 to support Monte Carlo simulations of spin-glass systems, a compute-intensive application in statistical physics. JANUS – fully based on FPGA technology – is a large array of processing elements that work under the supervision of a traditional host-machine; they are firmware-configured on-the-fly to run an application code developed in a hardware description language. Each processing element, when configured for spin-glass simulations, implements a massively-parallel architecture, midway between a graphic processing unit and a many-core CPU, in which several hundreds small processing cores concurrently run a SIMD application. For the specific application for which it was developed, JANUS offered approximately a 1,000 $\times$  performance gain over systems available at the time it was brought on line.

### Discussion

#### Overview

Application-driven computing systems have been used in many cases in computational physics in the last 20 years. These systems have been extremely successful in diverse compute-intensive areas, such as condensed matter simulations [1], Lattice QCD [2–4], and the simulation of gravitational systems [5]. The main reason for these successes has invariably been that the architectural requirements for the algorithms relevant for those problems were – at the time these machines were developed – at strong variance with those targeted by off-the-shelf CPUs or systems, so tailoring the architecture

to the algorithm yielded huge performance gains over commercial state-of-the art solutions. JANUS belongs to this class of machines: it was developed in the years 2006–2008, in order to simulate the behavior of glassy materials in condensed matter physics with Monte Carlo techniques; it has delivered – for that specific problem – performances more than three orders of magnitudes higher than possible with traditional systems available at the time it was developed. JANUS was developed by a collaboration of Italian and Spanish Universities (Università di Roma “La Sapienza,” Università di Ferrara, Universidad de Zaragoza, Universidad Complutense de Madrid, Universidad de Extremadura, and Instituto de Biocomputacion y Fisica de Sistemas Complejos (BIFI) in Zaragoza). The team had a strong and complementary background in the areas of physics of complex systems and in dedicated computer systems for lattice QCD.

A major challenge in condensed matter physics is the understanding of glassy behavior [6]. Glasses are materials of the greatest industrial relevance (aviation, pharmaceuticals, automotive, etc.) that do not reach thermal equilibrium in human lifetimes. This sluggish dynamics is a major problem for the experimental and theoretical investigation of glassy behavior, placing numerical simulations at the center of the stage. Glasses pose a formidable challenge to state-of-the-art computers: studying the surprisingly complex behavior governed by deceptively simple dynamics equations still requires inordinately long execution times.

Spin glasses (SG) are widely used theoretical models of disordered magnetic alloys widely regarded as prototypical glassy systems [7, 8]; the investigation of these systems today is largely based on Monte Carlo simulations (see e.g., [9] for a comprehensive review). The associated computational challenge is huge; in many SG models, the dynamical variables – so-called spins – are discrete and sit at the nodes of discrete  $d$ -dimensional lattices. In order to make contact with experiments, it is necessary to follow the evolution of a

large enough 3D lattice, say  $80^3$  sites, for time periods of the order of 1 s. Since one Monte Carlo step – the update of all the  $80^3$  spins in the lattice – roughly corresponds to  $10^{-12}$  s, some  $10^{12}$  such steps are needed, that is,  $10^{18}$  spin updates. Statistics on several ( $\approx 10^2$ ) copies of the system has to be collected, adding up to  $\approx 10^{20}$  Monte Carlo spin updates. Performing this simulation program in a reasonable time frame (say, less than 1 year) requires a computer system able to update on average one spin in approximately 1 ps. At the time JANUS was proposed, clever use of traditional systems allowed to reach simulation performances several hundred times lower.

In order to bridge this huge gap, a large amount of parallelism is available and easily identified in the associated algorithms (see later for some details); the JANUS architecture has been designed to carefully exploit at large fraction thereof, basically handling at the same time spin variables sitting at non-neighboring sites of the lattice. Each JANUS processor is able to process almost 1,000 spins in parallel; this immediately causes a major memory access bottleneck that has been circumvented by appropriate memory organization and access strategies and – at the technological level – by the use of embedded memory. Altogether, an intra-node degree of parallelism of order  $1,000 \times$  is compounded by a further factor ( $100 \times$ ) by trivially processing in parallel a corresponding number of copies of the system, so the required system-level performance has been reached.

Implementing this large degree of parallelism has been technologically possible because the data-path associated to the handling of each spin has limited logical complexity, being based on logic operations and integer arithmetics (as opposed to floating-point arithmetics) and because control can be readily shared across collaborating data-paths.

JANUS is fully based on Field Programmable Gate Array (FPGA) technology. FPGAs are inherently slow and trade flexibility with complexity (under general terms, any system of  $n$  gates can be emulated by an FPGA of complexity  $n \log_2 n$ , and  $\log_2 n$  is a “large” number when  $n \approx 10^6 - 10^7$ ). These disadvantages are offset by more dramatic speedup factors allowed by architectural flexibility. Also, development time of an FPGA-based system is short. Early attempts in this

direction had been made several years before by a subset of the JANUS team within the SUE project [10]. An ASIC approach, that would obviously further boost performance, was not considered by the JANUS developers as the longer development times and larger development costs made it a nonviable option.

## Spin Glasses

Basic ingredients of spin glasses (SG) are frustration and randomness (see Fig. 1). The dynamical variables, the spins, represent atomic magnetic moments (the elementary magnets whose combined effects make up the magnetism of the sample as a whole). Spins sit at the nodes of a crystal lattice (Fig. 1 – left), and take only two values,  $\sigma_i = \pm 1$ , corresponding to two possible orientations for the atomic magnet.

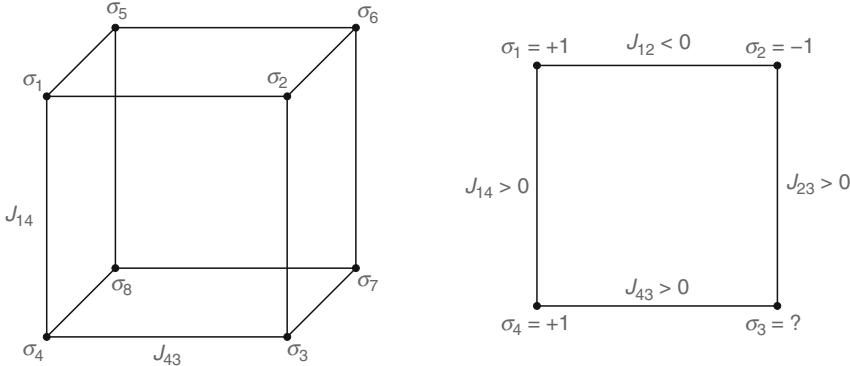

Depending on material details that wildly change from site to site, a pair of neighboring spins may lower their energy if they take the same value (and have therefore a tendency to do so). In this case, the *coupling constant*  $J_{ij}$ , a number assigned to the lattice link that joins spins  $\sigma_i$  and  $\sigma_j$ , is positive. However, it could happen with roughly the same probability that the two neighboring spins prefer to anti-align (in this case,  $J_{ij} < 0$ ).

A lattice link is *satisfied* if the two associated neighboring spins are in the energetically favored configuration. In spin glasses, positive and negative coupling constants occur with the same frequency, as the spatial distribution of positive or negative  $J_{ij}$  in the lattice links is random; this causes *frustration*. Frustration means that it is impossible to find an assignment for the spin values,  $\sigma_i$ , such that all links are satisfied (the concept is sketched in Fig. 1 – right, and explained in more details in the caption). For any closed lattice circuit such that the product of its links is negative, it is impossible to find an assignment that satisfies every link. In spin glasses, the probability that a given circuit is frustrated is 50%.

In a typical SG model, the Edwards–Anderson model [11], the energy of a configuration (i.e., a particular assignment of all spin-values) is given by the Hamiltonian function

$$H = - \sum_{\langle ij \rangle} \sigma_i J_{ij} \sigma_j, \quad (1)$$

where summation is taken on all pairs of nearest neighbor sites on the lattice. The coupling constants  $J_{ij}$  are

**JANUS FPGA-Based Machine. Fig. 1** *Left:* The spin-glass lattice is obtained by periodically repeating the unit cell. Dynamical variables, the spins, take values  $\sigma_i = \pm 1$ . Each pair of neighboring spins have either a tendency to take the same value or the opposite one. This is controlled by a coupling constant ( $J_{ij}$ ) attached to the lattice link joining the two spins.  $J_{43} < 0$  implies that the link is satisfied if  $\sigma_4 \cdot \sigma_3 < 0$  while  $J_{43} > 0$  demands that  $\sigma_4 \cdot \sigma_3 > 0$ . *Right* (frustration example): Consider the front plaquette of the cell at left, for the given values of the couplings, and try to find an assignment of the four spins such that all four links are satisfied. If one starts with  $\sigma_1 = +1$  and goes around the plaquette clockwise,  $J_{12} < 0$  requires that  $\sigma_2 = -1$  and then  $J_{23} > 0$  implies  $\sigma_3 = -1$ . On the other hand, going anticlockwise,  $\sigma_4 = +1$  (because  $J_{14} > 0$ ) and also  $\sigma_3 = +1$ , since  $J_{43} > 0$ ! Nothing changes if the initial guess is  $\sigma_1 = -1$ : also in this case conflicting assignments for  $\sigma_3$  are reached

chosen randomly to be  $\pm 1$  with 50% probability, and are kept fixed. A given assignment of the  $\{J_{ij}\}$  is called a *sample*. Some of the physical properties (such as internal energy density, magnetic susceptibility, etc.) do not depend on the particular choice for  $\{J_{ij}\}$  in the limit of large lattices. However, for the relatively small simulated systems it is useful to average the results obtained on several samples, that is, on different assignments of the  $\{J_{ij}\}$ .

It turns out that frustration makes it hard to answer even the simplest questions about the model. In three dimensions, experiments and simulations provide evidence that a spin-glass ordered phase is reached below a critical temperature  $T_c$ . In the cold phase ( $T < T_c$ ) the spins *freeze* in some disordered pattern, presumably related to the configuration of minimal energy.

For temperatures (not necessarily much) smaller than  $T_c$  spin dynamics becomes exceedingly slow. In a typical experiment one quickly cools a spin glass below  $T_c$ , then waits to observe the system evolution. As time goes on, the size of the domains where the spins coherently order in the (unknown to us) spin-glass pattern, grows slowly. Domain growth is sluggish: even after 8 h of this process, for a typical spin-glass material at a

temperature  $T = 0.72T_c$ , the domain size is only around 40 lattice spacings.

The smallness of the spin-glass ordered domains precludes the experimental study of equilibrium properties in spin glasses, as equilibration would require a domain size of the order of  $\sim 10^8$  lattice spacings. The good news is that an opportunity window opens for numerical simulations. In fact, in order to understand experimental systems, it is sufficient to simulate lattices not much larger than the typical domain size. This is the physics motivation behind the development of JANUS.

### Monte Carlo Simulations of Spin Glasses

Spin glasses are studied numerically with Monte Carlo techniques that ensure that the system configurations  $C$  are sampled according to the Boltzmann probability distribution

$$P(C) \propto e^{-\frac{H(C)}{T}}, \quad (2)$$

describing the equilibrium distribution of configurations for a system at constant temperature  $T$ .

One typical Monte Carlo algorithm is the Heat Bath algorithm, which assumes that at any time any spin has to be in thermal equilibrium with its surrounding

environment, meaning that the probability for a spin to take value +1 or -1 is determined only by its nearest neighbors, follows the Boltzmann distribution; the energy of a spin at site  $k$  of a 3D lattice of linear size  $L$  is

$$E(\sigma_k) = -\sigma_k \sum_{\langle km \rangle} J_{km} \sigma_m, \quad (3)$$

where the sum runs over the six nearest neighbors of site  $k$ . One can derive that the probability follows the Boltzmann distribution: in particular, the probability for the spin to be +1 is

$$\begin{aligned} P(\sigma_k = +1) &= \frac{e^{-E(\sigma_k=+1)/T}}{e^{-E(\sigma_k=+1)/T} + e^{-E(\sigma_k=-1)/T}} \\ &= \frac{e^{\phi_k/T}}{e^{\phi_k/T} + e^{-\phi_k/T}}, \end{aligned} \quad (4)$$

$$\phi_k = \sum_{\langle km \rangle} J_{km} \sigma_m, \quad (5)$$

where  $\phi_k$  is usually referred to as the *local field* acting on site  $k$ .

At the computational level, the corresponding algorithm takes the following steps:

1. Pick one site  $k$  at random.
2. Compute the local field  $\phi_k$  (Eq. 5).
3. Assign to  $\sigma_k$  the value +1 with probability  $P(\sigma_k = +1)$  as in Eq. 4; this can be done by generating a random number  $R$ , uniformly distributed in  $[0, 1]$ , and setting  $\sigma_k = 1$  if  $R < P(\sigma_k = 1)$ , as given by Eq. 4, and  $\sigma_k = -1$  otherwise.
4. Go back to step 1.

A full Monte Carlo step consists in the iteration of the above scheme for  $L^3$  times. Many Monte Carlo steps evolve the system toward statistical equilibrium.

Physical spin variables can be mapped into bits by the following transformations

$$\begin{aligned} \sigma_k &\rightarrow S_k = (1 + \sigma_k)/2, \\ J_{km} &\rightarrow \hat{J}_{km} = (1 + J_{km})/2, \\ \phi_k &\rightarrow F_k = \sum_{\langle km \rangle} \hat{J}_{km} \oplus S_m = (6 - \phi_k)/2, \end{aligned} \quad (6)$$

( $\oplus$  is the exclusive-or operation) so several (not all) steps in the algorithm involve logic (as opposed to arithmetic) operations.

The procedure is easily programmed for a computer; some comments are in order:

1. High-quality random numbers are necessary to avoid dangerous spurious spatial correlations

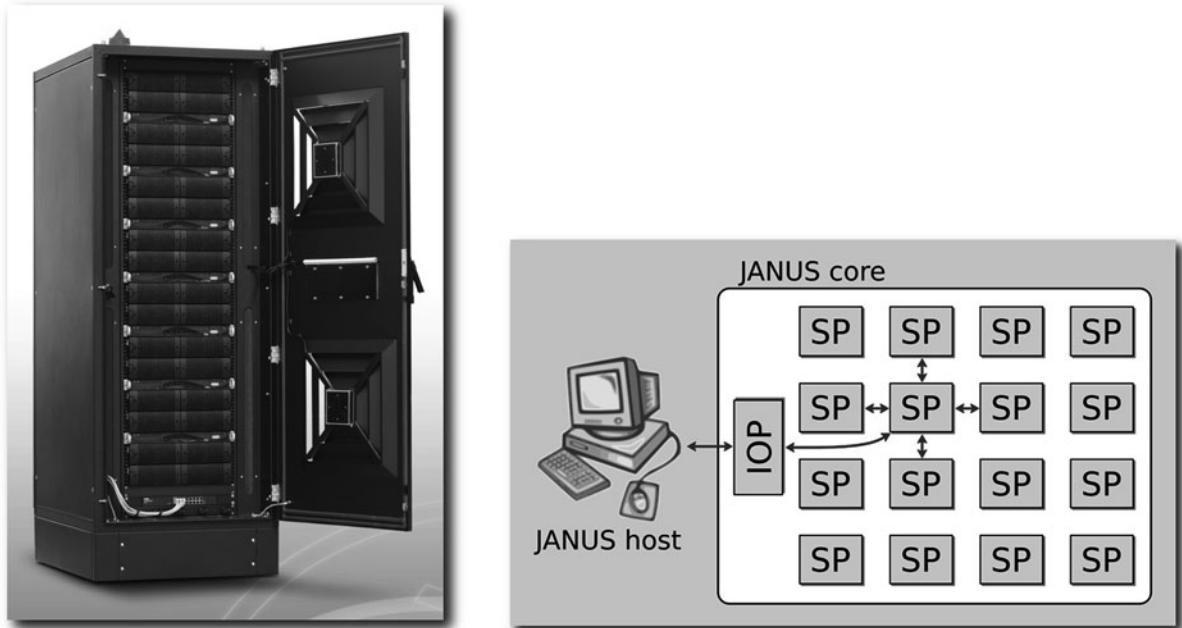

between lattice sites, as well as temporal correlations in the sequence of generated spin configurations.

2. The local field  $\phi_k$  can take only the seven even integer values in the range  $[-6, 6]$ , so probabilities  $P(\sigma_k = +1) = f(\phi_k)$  may be stored in a small look-up table.
3. The kernel of the program is the computation of the local field  $\phi_k$ , involving just a few arithmetic operations on discrete variable data.
4. Under physically reasonable assumptions, the simulation retains the desired properties even if Monte Carlo steps are implemented by visiting each lattice site exactly once, in any deterministic order, provided no two interacting spins are handled at the same time.
5. Several sets of couplings  $\{J_{km}\}$  (i.e., several *different samples* of the system) need to be generated; an independent simulation has to be performed for every sample, in order to generate properly averaged results.
6. One usually studies the property of a spin-glass system by comparing two or more statistically independent simulations of the *same sample*, starting from uncorrelated initial spin configurations (the two copies of a sample are usually referred to as *replicas*).

The last three points identify the parallelism available in the computation, which can be trivially exposed for points 5 and 6 above. For point 4 a more accurate analysis is required. In fact, one labels all sites of the lattice as *black* or *white* in a checkerboard scheme: all black sites have their neighbors in the white site set, and *vice versa*: one can then in principle perform the three steps of the algorithm on all white or black sites in parallel. These remarks identify the available parallelism in the algorithm. The next section describes the architecture that JANUS adopts in order to exploit as much as possible of this opportunity.

## JANUS: The Architecture

JANUS is a heterogeneous massively parallel system built on a set of FPGA-based reconfigurable computing cores connected to a host-system of standard processors. Each JANUS-core contains 16 so-called simulation processors (SP) and 1 input/output processor (IOP). The SPs are logically arranged at the vertexes of a 2D mesh and have direct low-latency high-bandwidth

**JANUS FPGA-Based Machine.** Fig. 2 *Left:* The JANUS system installed at BIFI, Zaragoza (Spain) has 16 JANUS-cores and 8 JANUS-hosts. *Right:* Simple block diagram of a minimal JANUS system, with one JANUS-host and one JANUS-core

communication links with nearest neighbors in a toroidal topology. Each SP is also directly connected with the IOP, while the latter communicates with an element of the host-system, as shown in the right side of Fig. 2. SPs and IOPs are based on Virtex4-LX200 FPGAs manufactured by Xilinx, that – at the time the system was developed – were the densest FPGA devices available from industry. The largest available JANUS machine (installed at BIFI – Zaragoza, since early 2008) has eight hosts (with a disk-system of 4 TBytes) and 16 JANUS-cores (Fig. 2, left side). More details on this machine are in [12–14].

The IOP handles the JANUS-host I/O interface, providing functionalities needed to configure the SPs for any specific computational task, to move data sets across the system and to control SP operations. The IOP processor exchanges data with the JANUS-host on two Gigabit-Ethernet channels, running a standard raw-Ethernet communication protocol. This means that JANUS can only be used in a very loosely-coupled mode with its host, as the JANUS-host bandwidth is rather low and the associated latency is large.

The SP is the computational element of the JANUS system. It contains uncommitted logic that can be configured via the IOP as needed to run

computing-intensive kernels. The SPs of each JANUS-core can be configured to run in parallel 16 independent programs, or to run 1 single program partitioned among the 16 FPGAs, exchanging data as appropriate across the nearest-neighbor toroidal network.

JANUS is programmed developing two different programs: a standard C program running on the host system that typically builds on a low-level communication library to exchange data to and from the SPs, and a code (written in a hardware description language, such as VHDL) defining the application running on the SPs.

In this approach, the FPGAs must be carefully configured and optimized for application requirements. Tailoring any specific application to JANUS is a lengthy and complex procedure, hopefully rewarded by huge performance gains. Obviously, high level programming frameworks able to automatically split an application between standard and reconfigurable processors and to generate VHDL code for the configurable segment would be welcome for this machine, but the tools currently available typically do not deliver the level of optimization needed for the high performance application run by JANUS; all application codes executed by JANUS so far have been handcrafted in VHDL.

It is critical for any successful JANUS implementation that as much as possible internal resources of the FPGA are exploited in a coordinated way (see [15] for a detailed description). It turned out that the underlying architecture of the Virtex4 FPGAs is almost optimal for the mix of computational operations involved in SG simulations, while other applications that were tried on the machine, especially in the area of optimization, e.g. graph coloring, did not have a comparable impact. So, JANUS, that had been advertised in earlier publications as a potentially general-purpose reconfigurable architecture, has been extensively used only for SG simulations.

Here just a few highlights of the architecture configured inside each SP node are given. The first issue that had to be addressed is memory organization, a potential performance bottleneck. LX200 FPGA devices come with many small embedded RAM blocks, which may be combined and stacked to naturally reproduce a 3D array of bits representing the 3D spin lattice. Memory banks embedded in the FPGA device are large enough to store the full simulation data structure, that – in turn – makes huge memory bandwidth possible. If one considers an SG simulation on a lattice of the size discussed earlier ( $80^3$  sites) one standard JANUS implementation configures embedded memory blocks with 80 bit width to represent the linear size of the spin lattice: 10 such memories with 10 bit addressing are enough to store the whole lattice. Addressing all memories with the same given address  $z$  allows to fetch or write a  $80 \times 10$  portion of an entire  $80^2$  lattice plane corresponding to spins with Cartesian coordinates ( $0 < x < 79, 0 < y < 9, z$ ). The next portion of the same plane is addressed by  $z + 80$ , referring to spins with coordinates ( $0 < x < 79, 10 < y < 19, z$ ), and so on. It is useful for performance to simulate two real replicas, so a good strategy allocates one such structure for *black* spins of replica 1 and *white* ones of replica 2. A further structure is allocated for white and black spins of replicas 1 and 2 respectively. A similar storage strategy applies to the read-only storage blocks associated to the  $J_{ij}$ .

After initialization, this firmware-enabled machinery fetches all neighbor spins (addresses  $z, z+1, z-1, z+80, z-80$ ) of an entire portion of plane of spins (identified by a single memory address  $z$ ) and feeds them to the update logic. The latter returns the processed (updated) portion of spins to be uploaded to memory

at the same given address. Altogether, 800 spins are updated simultaneously, so the update logic is made up by 800 identical update cells. Each cell receives the 6 nearest neighbor bits, 6 coupling bits, and one 32-bit random number; it then computes the local field, which is an address to a probability look-up table; the random number is then compared to the extracted probability value and the updated spin is output. Look-up tables are small 32-bit wide memories instantiated as *distributed RAM*. There is one such table for each update cell. Random number generators – one to each update cell – are implemented as 32-bit Parisi-Rapuano generators [16], requiring one add and one bit-wise xor-operation for each random value.

The typical number of 800 updates per clock cycle is a trade-off between the constraints of allowed RAM-blocks configurations and available logic resources for the update machinery. This internal architecture is very similar in structure to modern graphics processing units (GPUs) or many-core CPUs: there is a large number of independent computational data paths that are fed by memory available on board. The specific application can be arranged as just one large SIMD thread, so control is shared by all data paths. This saves precious logic that is allocated to more data path instantiations; furthermore the logical complexity of each data path is significantly smaller than typical CPUs: these two points are the key to the huge performances of this system.

Total resource occupation for the design is 75% of RAM-blocks (total available RAM is  $\approx 672$  KBytes for each FPGA) and 85% of logic. The system runs at a conservative clock frequency of 62.5 MHz. At this frequency, power consumption for each SP is  $\approx 35W$ . It is interesting to note that the FPGA would operate correctly at a much higher clock rate, and the current upper limit in frequency is set by the performance of the forced-air cooling systems, a reminder that power management is becoming more and more a key performance bottleneck in high performance computing.

## JANUS Performance

JANUS performance can be assessed in at least two different ways:

- The number of effective operations per second
- The speed-up factor (mostly in wall clock time, but also on other relevant metrics) with respect to pro-

cessor clusters or “arbitrary” size (i.e., assuming that, for the given simulation, the optimal number of processor is actually deployed)

Let us first consider the number of effective operations performed by second. At each clock cycle (clock frequency is 62.5 MHz), each SP processor updates 800 spins. On a traditional architecture, this would imply at least the following instructions for each spin:

- Six loads
- *1 sum (32 bits)*
- *2 xor (32 bits)*
- *6 sum (3 bits)*
- *6 xor (3 bits)*
- *1 load LUT*
- *1 comp (32 bits)*
- Six updates of address pointers (1 mult, 1 sum )
- One store
- Jump condition

If one wants to count only algorithm-relevant operation, all load/store and address instructions must not be counted; also, the 6 xor and sum operations on short operands may be considered equivalent to one standard arithmetic operation. All in all, there are seven equivalent instructions for each spin update (shown in italic in the list above). This translates into a processing power of  $7 \times 800 \times 62.5 \times 10^6$  operations per second, which is 350.0 Giga-ops. The largest JANUS machine operates 256 processors in parallel, so it performs at the level of 89.6 Tera-ops.

It is also interesting to compare JANUS performances with those obtained on commercial CPUs, where spin-glass simulations had been performed earlier.

The main reason why SG simulations are not very fast on traditional CPUs is that the natural physical variables for the problems are bits, while CPU architectures are based on long (e.g., 32–64 bit) words. A widely used trick to boost performance (usually called multi-spin coding) uses the bits of the CPU word to code the same spin of a matching number of systems, treated in parallel by the algorithm. Using this technique, carefully optimized codes running on high-end CPUs available in 2006–2008 were able to handle on average one spin

in slightly less than 1 ns. By contrast, the JANUS implementation performs at 0.020 ns/spin. This means that  $10^{12}$  Monte Carlo steps for a system of  $80^3$  sites take approximately 100 days wall clock time, while a similar simulation on PCs would take of the order of 10 years: in conclusion, JANUS has made it possible for the first time to stretch SG simulations to experimentally relevant time scales [17]. JANUS has excellent performance also from the point of view of power requirements: each node uses  $\approx 35\text{W}$  of power, which translates into  $\approx 10$  Giga-ops/W.

## Future Directions

JANUS has marked a new standard in the simulation of complex discrete systems by allowing studies that would take years on traditional computers. The system has a very large sustained performance, an outstanding price–performance ratio, and an equally good power–performance ratio. Physics results obtained analyzing simulation results delivered by JANUS have been published in several journals, and the system is still on line, with no plans to phase it out in the near future.

From the point of view of a computer system, JANUS has shown the potential performance impact of reconfigurable computing and of many core architectures.

- From the former point of view, JANUS strongly leveraged on the very regular structure of the target algorithm: a highly optimized code carefully matching the low-level underlying FPGA architecture was developed in less than three months with reasonable human effort; on the other hand attempts with automatic VHDL generators (starting, e.g., from C programs) yielded no more than a few percent of the performance of the handcrafted code, even in JANUS almost ideal conditions: clearly, reconfigurable computing will not have a significant impact till this gap is substantially narrowed.
- As a prototypical many-core system, JANUS can be seen as an extreme version of the architecture adopted in very recent years by General Purpose GPUs (GP-GPUs); in both cases a very large number of computational threads is handled by a large set of computing cores, clustered in SIMD-controlled partitions. JANUS pushes to the extreme this trend

by making the cores very simple and by arranging just one SIMD partition. Huge performance are expected by this architecture, but memory access becomes rapidly the critical bottleneck. JANUS has solved this problem using a large number of embedded memory banks and carefully arranging data structures on them.

As a technological trend, GPGPU in the near future will probably still boost performance for floating-point based performance. JANUS is still on the leading edge for the specific mix of logic/integer-arithmetic operations associated to spin-glass systems.

## Bibliographic Notes and Further Reading

A comprehensive review on the class of physics problems at the basis of the development of JANUS can be found in [6], while [9] describes the relevant algorithms. A discussion of application-driven systems developed over the years for theoretical physics applications is available in the papers [2, 3, 5]. A recent special issue of Computing in Science and Engineering has covered this area in details [18].

## Java

### ► Deterministic Parallel Java

## JavaParty

MICHAEL PHILIPPSEN

University of Erlangen-Nuremberg, Erlangen, Germany

## Definition

While Java offers both a means for programming threads on a shared-memory parallel machine and a means for programming remote method invocations in a wide-area distributed memory environment, it lacks support for NUMA-architectures or clusters, that is, architectures where locality matters because of nonuniform access times. Java also lacks support for a more data-parallel programming style.

JavaParty fills this gap by providing language extensions that add both *remote objects* and *collectively replicated objects*. The former allow the programmer to express knowledge about the locality of both the application's objects and threads in an abstract way, that is, without requiring code for low-level object placement, for explicit replication and (cache) coherency, or for low-level details of explicit message passing. The latter provide a means for working elegantly on all objects of an irregular data structure in parallel.

The beauty of JavaParty is twofold. First, the flavor of all the added language features fits nicely into Java. Second, since a preprocessor transforms the language extensions back into regular Java code, JavaParty programs run anywhere, that is, for running JavaParty

programs it is sufficient to start a regular JVM (Java Virtual Machine) for example on each (multi-core) node of a cluster.

## Discussion

### Remote Objects

#### The Concept

JavaParty class definitions may have a new label `remote` that is implemented either as a new modifier or as an annotation. An instance of a class with label `remote` is a *remote object*. It appears like regular Java objects, but they may live in remote address spaces, that is, by making a class `remote` the programmer explicitly expresses that it is acceptable if access to its instance variables or invocation of its methods may be slower than accesses to regular (local) Java objects. A remote thread is tied to an object in Java. The thread will be spawned on the remote node that hosts the thread object. JavaParty extends Java's object model to a distributed object model. Conceptually, a remote object is implemented by a local proxy object (stub) that forwards all accesses to a remote JVM that hosts the remote object. The proxy objects are generated automatically by the preprocessor, see below; they are transparent to the JavaParty programmer.

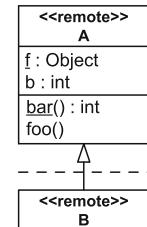

In JavaParty, garbage collection of remote objects works like that for regular (local) Java objects. Remote objects are also transparent with respect to synchronization, that is, a thread that holds a lock on a remote object may enter another synchronized method of that object even if the flow of execution has moved between different address spaces and JVMs. Static fields of a regular (local) Java class exist only once for all objects of that class. The same holds for static fields of a remote JavaParty class: all accesses to its static fields appear like in regular Java although the static fields can reside on a cluster node that may be different from the node that allocates the instance fields of a remote object. Conceptually, the static fields of a remote object are reached through another (automatically generated) proxy object that is also transparent for the programmer.

#### Transformation

From the two `remote` JavaParty classes shown in Fig. 1, the JavaParty preprocessor generates several pure Java

```
remote class A {
 static Object f;
 int b;
 static int bar() {...}
 void foo() {...}
}

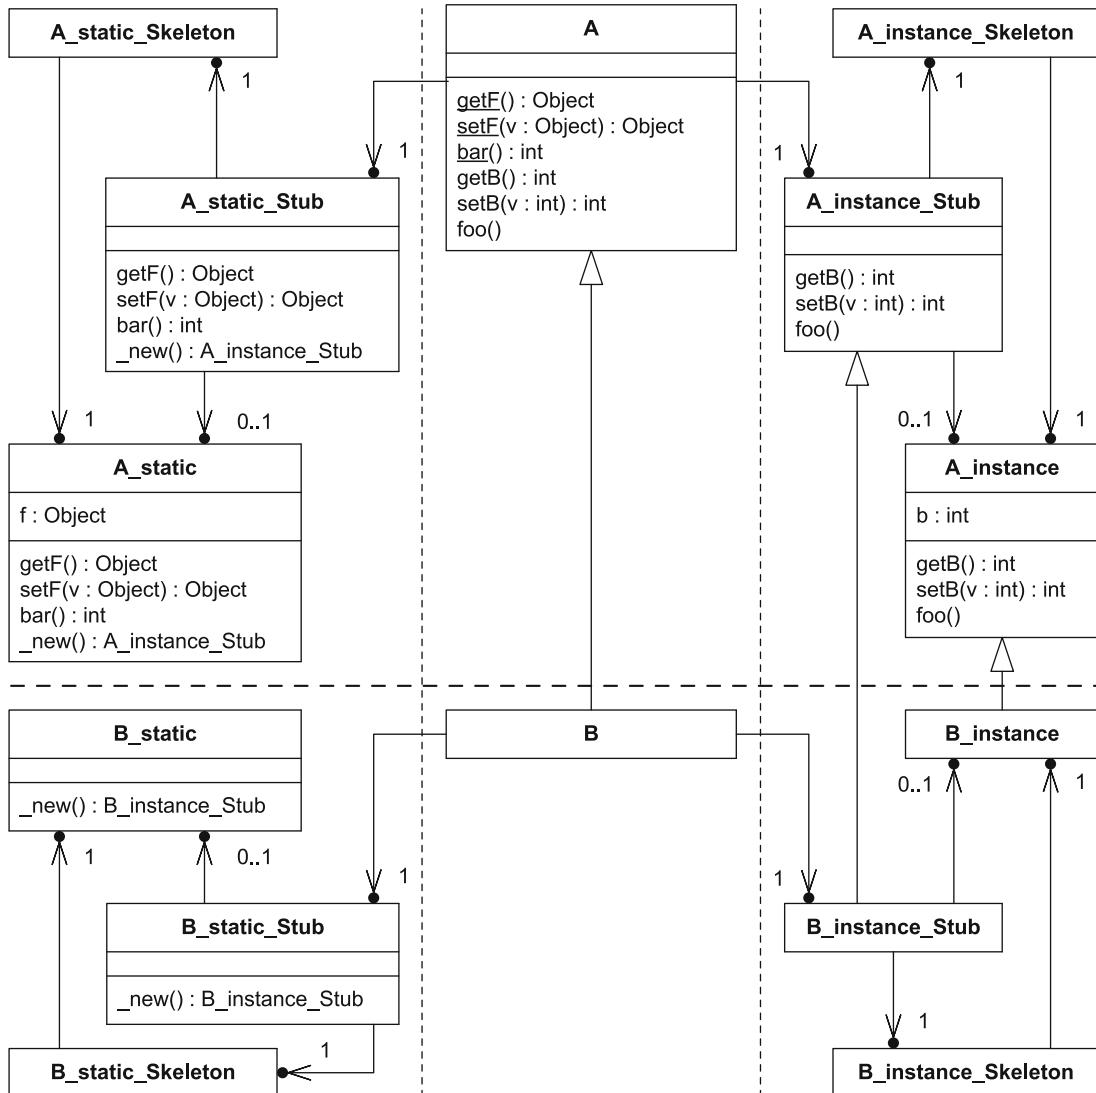

remote class B extends A {...}
```

**JavaParty, Fig. 1** Two `remote` JavaParty classes before transformation

classes. The left column of Fig. 2 depicts the classes that implement static/class fields and static/class methods, that is, you will find implementations for `f` and `bar` in `A_static`. All the instance fields and methods are implemented in class `A_instance` in the right column. On both sides, variables are replaced by setter and getter methods. At runtime, there might be several instances of class `A_instance`, one for each object of type `A` that the application creates. Since all objects might live on remote nodes, JavaParty also generates a stub and a skeleton (interface) for each of the two classes, so that it fits to Java's RMI implementation of remote methods. To create an instance of `A_instance` on a remote node, we need some way of calling a constructor on that node. Since Java's RMI does not allow this, JavaParty generates an extra method `_new` (for each of `A`'s constructors) that is called instead and that returns a reference to a remote object (or to its proxy to be more specific). Hence, at runtime there is one object of type `A_static` on each node, just to provide the constructors for creating all the necessary `A_instance` objects. But only one of these class objects actually implements the static fields and methods of `A`.

In addition to the classes that implement the instance parts and those that implement the static parts, a `remote` JavaParty class is replaced by a so-called handle class. The handle classes for the above example are shown in the middle column of Fig. 2. These classes provide the original constructors (that will call the `_new` methods), they bundle the references to the two remote objects of types `A_static` and `A_instance`, they deal with exceptions that might be caused by remote method invocations, they hide migrating remote objects, they shortcut methods calls if a potentially remote object happens to reside on

**JavaParty. Fig. 2** Simplified result of JavaParty's remote class transformation

the same node, they are used for `instanceOf` type comparisons, etc. For details and other aspects of the transformation, for example, exception handling, some additional methods, name mangling, the transformations within non-remote classes that access remote classes, etc., please check the bibliographic notes.

### Copy Semantics for Local Object Arguments in Remote Method Invocations

The main difference between regular/local Java objects and remote objects is the way arguments are passed.

For method invocations on local objects, Java copies references to local objects that are passed as arguments. In contrast, for a method invocation of a remote JavaParty object, the complete local object referred to and all the regular/local Java objects that can be reached transitively from that object are copied and shipped. This is of course necessary if the remote object resides on a different node of a cluster on which the addressed local objects are not present. For consistency, object cloning is performed even if a remote object happens to reside locally in the same JVM. There is no semantic difference for primitive type arguments. References to remote

objects are treated as such, that is, remote objects are not copied if references to them are passed along in method invocations.

## Object Distribution

The JavaParty runtime system uses heuristics to decide on which actual node of a cluster to allocate a newly created remote object and on which cluster node to execute a newly spawned remote thread. These heuristics may be guided by the results of a previous static analysis. The runtime system can automatically and transparently migrate remote objects to improve access times. If needed, the programmer can use library calls to select specific cluster nodes, to pin remote objects, or to tie a set of remote objects together so that the automatic (or manual) migration affects all of them at once. The flow of execution automatically follows the data which are being manipulated, that is, a thread executes an object's method on the node that hosts the object. Explicit or manual migration of thread objects can be used to enhance locality, since thread objects that reside at the place of the accessed objects will be faster.

## Collectively Replicated Objects

JavaParty adds `replicated` as another new class modifier/annotation for replicated objects. Whereas a remote object conceptually resides on a single remote node, a copy of a replicated object resides on *every* remote node (unless the degree of replication is restricted). Whereas a remote object is accessed remotely through a proxy object, a replicated object can only be accessed locally since it is implemented by one regular (local) Java object on each node. There is no proxy object for remotely accessing a replicated object. When an object of a replicated class is created, as its initial distribution, a copy of it with all its instance variables is created on every node of the underlying parallel computing system. Threads access this copy, called *replica*, locally on their node as they would access regular (local) Java objects, that is, there is no runtime overhead in accessing a replica.

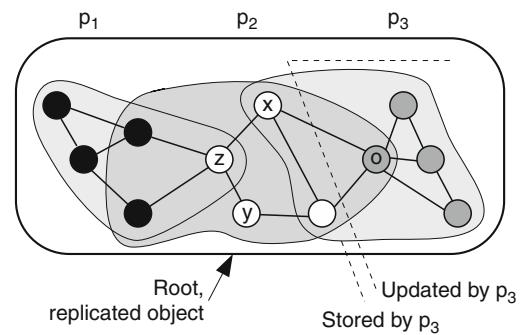

As mentioned above, JavaParty transitively clones the whole graph of referred to objects when a local argument object is shipped in a remote method invocation. Similarly, all the objects transitively referred-to from a replicated object are cloned and also exist on every node. Consider a replicated object that holds references

to a graph of local objects. Then conceptually, a copy of this object graph exists on every node.

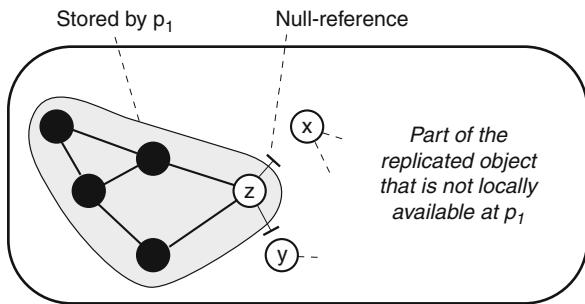

The JavaParty runtime system can choose to use a partial replication and to cut out those parts of the object graph that are not used on a particular node. This can be done automatically based on some static analysis. Alternatively, the JavaParty programmer can again use library calls to indicate cutoff objects. As an example consider the situation depicted in Fig. 3.

Here, three threads  $p_1 - p_3$  work on a replicated object graph, one thread per cluster node. Although conceptually a copy of the whole object graph is stored on all three nodes, each of the worker threads updates only a few objects (the black, white, or gray circles, respectively) based on some information in neighboring objects. A full replication that stores the whole object graph per JVM is not required. A partial replication is sufficient and more efficient with respect to memory consumption. It suffices that each JVM only keeps copies of those objects that are shown in the shaded areas. For instance, on the first JVM, where thread  $p_1$  is executed, it is sufficient to keep the part of the wire frame shown in Fig. 4.

As will be discussed below, JavaParty automatically keeps replicas in a consistent state, that is, a deep comparison of all the local objects that can be reached through the replicated object's fields must show identical values in the fields of primitive types. References to local objects may, however, be set to `null` on some nodes due to the decision to only partially replicate the data, while on other nodes the graph traversal will reach regular objects. For the example object graph, the JVM of  $p_1$  could store only a part of the replicated

**JavaParty. Fig. 3** Replicated data structure

**JavaParty. Fig. 4** Replica of node  $p_1$  in case of partial replication

object graph. Figure 4 illustrates the null references at the cutoff object  $z$ .

### Memory Model

Similar to Java where a thread is only guaranteed to see the changes made by different threads if both threads have been subject to an explicit mutual synchronization, nodes can work on their replica in isolation, that is, without an explicit synchronization no other node is ever guaranteed to see a change.

With replicated objects, a single type of synchronization that guarantees exclusive access to an object is no longer sufficient since the main reason for replication is to allow concurrent access to locally available replicas (with as little overhead as possible). Hence, JavaParty adds a concurrent read, exclusive write (CREW) locking for replicated objects:

```
shared synchronized(p) { //reader
 ...
 //read access to replica
}
...
exclusive synchronized(p) { //writer
 ...
 //update replica and notify
 ...
 //about change
}
```

This language extension allows concurrent threads in a *shared block* as long as there is no thread in an *exclusive block* at the same time. Synchronized methods can also be flagged as *shared* or *exclusive*. As usual, at some point in time, after a modifying thread leaves the exclusively locked block and before another thread enters some synchronized block on the same object, all changes must be made available to the second thread.

At the end of the exclusive block, changes are broadcast to all nodes that hold copies of the replicated object, so that other threads see the updated values, that is, a consistent state, as soon as they enter another synchronized block.

The JavaParty compiler generates code for the necessary consistency messages. This code extends Java's regular memory model to a distributed environment. In regular Java, changes made by one thread in a synchronized block are only guaranteed to be visible to another thread if the later enters a synchronized block itself. Java's `wait` and `notify` are also transformed into communication operations so that they work on replicated objects as expected even though the signaling needs to span node boundaries.

### Bulk Synchronous Collective Synchronization

JavaParty's replicated objects are called collectively replicated objects because there is a third flavor of synchronization, called *collective synchronization*. It is indicated by means of the modifier `collective`. In contrast to shared and exclusive synchronization, on every node that carries a replica exactly one thread must enter a collectively synchronized block of code. Together these threads form a *collective* that cooperatively work on the replicated state. In the above example, three threads will enter a collectively synchronized block of code to work on the replicated object graph, each on its portion of the replicated state, to collectively perform an updating step. After acquiring a collective lock, each thread is allowed to modify its portion of the replicated object's state, while concurrently, other threads modify their portions. Within the synchronized block, that is, while working on its portion of the replicated data, a thread does not see the updates performed by other threads. Only at the synchronization barrier of lock release (but not earlier), all the modifications are merged and are then made available on all the nodes. Conceptually, the end of a collective block is a synchronization barrier combined with an all-to-all broadcast that brings replicated objects back into a consistent state.

In the above example, both threads  $p_1$  and  $p_2$  can access the white object  $z$  – each thread on its own node. If either thread changes some fields of  $z$  within a collectively synchronized block, the other threads will not

see these changes immediately. Due to the bulk synchronous paradigm, the modifications are only shipped when all nodes leave the collective block. If both  $p_1$  and  $p_2$  have modified different instance fields of  $z$  concurrently, only the modified fields are exchanged. It is in general considered to be a program error if the modified portions of the replicated state overlap, that is, if both  $p_1$  and  $p_2$  alter the same instance field of  $z$  to different values. In this case it is unspecified which of the two values survives. JavaParty also provides a means of specifying merging routines that handle such concurrent updates of a single instance variable.

A naive implementation of a collective synchronization could broadcast all-to-all, diff and merge the replicated data structure. However, an efficient implementation, only ships the modified instance fields, and only ships them to those nodes that actually store the objects in case of partial replication.

## Bibliographic Notes and Further Reading

Many parallel object-oriented languages have been proposed in the past, see for example [1, 5]. JavaParty extends Java with a remote object model for distributed environments with nonuniform memory access and adds collective replication for data-parallel computation on irregular data structures in the style of bulk synchronous parallelism (BSP [8]). JavaParty runs on top of a set of regular Java virtual machines (JVMs). Alternatively, a JavaParty implementation could target a VM that spans a cluster and combines local memories into a virtual huge address space, see for example [9].

The most cited paper on JavaParty [7] covers the technical details of the transformation of remote classes into regular Java classes plus proxies and RMI invocations. There are several papers on implementation aspects that are essential to make JavaParty run fast. The most important ones are the following: The fast remote method invocation and object serialization, that is, the Karlsruhe RMI drop-in replacement for Java's remote method invocation KaRMI, is presented in [6]. Locality optimization and automatic placement

of threads and objects to reduce communication costs is addressed in [2]. JavaParty's distributed garbage collector is covered in [4]. How collective replication, especially the collective update operation at the end of collective synchronization blocks, can be implemented efficiently is covered in [3].

## Job Scheduling

ROLF RIESEN<sup>1</sup>, ARTHUR B. MACCABE<sup>2</sup>

<sup>1</sup>IBM Research, Dublin, Ireland

<sup>2</sup>Oak Ridge National Laboratory, Oak Ridge, TN, USA

## Synonyms

[Node allocation](#); [Processor allocation](#)

## Definition

A parallel job scheduler allocates nodes for parallel jobs and coordinates the order in which jobs are run. With

enough resources available, a system can execute multiple parallel jobs simultaneously, while other jobs are enqueued and wait for nodes to become available. The job scheduler manages the queues of waiting jobs and oversees node allocation. The goals of a scheduler are to optimize throughput of a system (number of jobs completed per time unit), provide response time guarantees (finish a job by a deadline), and keep utilization of compute resources high.

## Discussion

### Introduction

Users of a parallel system submit their jobs by specifying which application they would like to run and how many nodes they need. It is then the task of the job scheduler to find and allocate the appropriate number of nodes. This is different from a sequential system where the Operating System (OS) is responsible for scheduling processes and assignment of them to processor cores. The difference is that sequential processes are pursuing independent goals and are not working together, in parallel, to complete a common task. There is some cost associated with moving a process to another processor core, but in general the OS can assign processes to the least busy core without much concern for other processes.

Parallel jobs have different requirements, and they often run on multicomputers where each node, consisting of one or more processors and memory, runs its own copy of the OS. Parallel jobs cannot make progress until all processes of the job are assigned to CPUs. Only when these processes execute concurrently, are the resources used efficiently and the job finishes as quickly as possible. For example, if one process in a parallel job is waiting for data from another process, it cannot continue until the other process has run and computed the result that is needed by the first process. For that reason, it is important that a parallel scheduling system allocates and schedules all processors that are part of the same job, at the same time. Although a parallel job scheduler has to coordinate with the OSs running on each node, it is usually an independent software component that is not built into the OS kernel.

A node in a parallel system consists of one or more processors, each with one or more CPU cores. These cores share a network interface to communicate with

processes running on cores of other nodes. Some job schedulers allocate individual cores, but it is more common to allocate all cores on a node as a unit.

A job scheduling system, in coordination with the local OSs, ensures that a node and its processor cores are not overburdened, by limiting the number of processes assigned to each node at any given time. Therefore, a parallel job sometimes has to wait until enough nodes are available to run it. The job scheduler maintains queues to keep track of waiting jobs. When a job finishes, the nodes it was using are released and the scheduler selects the next job to run. Since each job needs a different number of nodes, assigning the available nodes to the waiting jobs is not trivial. It is sometimes necessary to leave nodes unallocated and combine them with nodes that become available later, so a larger job can run.

Managing the running and waiting jobs is done with several goals in mind. The highest priority goal is often throughput. The number of jobs a system can process in a unit of time is its throughput. On some systems, at least for some of the jobs, response time is more important. A simulation that predicts tomorrow's weather needs to finish in time for today's news. If its execution is delayed for too long, it will not meet its deadline. Another aspect of scheduling is resource utilization. Nodes should not be idle while there are still jobs to complete.

There are two main aspects to parallel job scheduling. First, the job scheduler needs to decide when a particular job needs to run. In addition to ensuring that enough nodes are available, possibly by reserving them, the scheduler may also take into consideration the priority of a job and how long it has been in the queue. The second part of scheduling is node allocation. When there are more nodes available than needed by the next job, the scheduler needs to decide which nodes should be allocated. In heterogeneous systems, node allocation may need to take into account available processor speeds and type, as well as memory sizes and other specific resources, and match them with the requirements of a job. Even in homogeneous systems, where all nodes have the same capabilities, the allocation strategy is important because it impacts performance of the system. Nodes that are located physically close to each other have lower communication latencies, and it is less likely that other messages and I/O traffic traversing the

system will delay messages between these nodes. The following sections discuss scheduling and allocation in more detail.

## Scheduling

When nodes become available, the scheduler needs to pick which job to run next. The easiest way to do that is to simply pick the next job in the queue. If that job needs more nodes than are currently available, the scheduler waits until more of the currently running jobs finish and enough nodes become available. This is called First-Come First-Serve (FCFS) scheduling.

FCFS is inefficient because it leaves nodes idle, while smaller jobs further back in the queue could be run. A method called *backfill* solves that problem. When nodes are available, but the next job in the queue is too big to fit, the scheduler searches further back into the queue to find a job that can be run on the available nodes. This can lead to *starvation* of bigger jobs, if only a few nodes are available at a time. Smaller jobs in the queue must be prevented from always bypassing the larger jobs. Methods to prevent starvation usually assign a priority to each job, or use multiple queues with different priorities. While jobs are waiting to run, their priority is increased periodically or they are moved to higher priority queues.

Another method to prevent starvation is reservation. When larger jobs are enqueued, they are allowed to reserve nodes. When these nodes become available, they remain idle or are used for short running jobs only. When all reserved nodes are ready, the larger job runs.

Both backfill and reservation work better, if the job scheduler knows how long an application will use its nodes. That knowledge makes it possible to run some shorter and smaller jobs, while the system is waiting for the remaining nodes to become available to run the larger job. This makes scheduling decisions much more complex, but utilizes the nodes of a system better. Calculating an optimal solution for large numbers of nodes and jobs is extremely time consuming. Therefore, heuristics are used to compute good approximations in an acceptable amount of time.

Scheduling systems that depend on knowing how long an application needs its nodes terminate applications that do not finish within their allocated time. The scheduler sends a signal to the application a few seconds before it removes the job from the system. This

gives applications a chance to save their current state and intermediate results to disk. They can be restarted later at which time they read their saved state and resume from where they were interrupted.

Predicting how long an application will run is difficult. Most job schedulers rely on the user to supply that information. Even for experienced users, this is not always an easy estimate since the running time of most applications is highly input dependent. Users therefore have a tendency to overestimate the time their applications need on the system to ensure that they finish before the scheduler terminates them. It turns out that overestimating is not necessarily bad. Since nodes become available sooner than the scheduler anticipated, it can often run some short jobs until the next scheduled job needs these nodes. Researchers investigating this phenomena have reported that accurate estimates help users because their jobs are serviced more predictably and faster by the job scheduler, but overestimating does not hurt the system, since it can backfill short-duration availabilities.

For some applications and workloads, it is possible to automatically calculate the expected running time. For other applications, it is possible to look at historical information and estimate the running time. Several sophisticated methods have been proposed, but most commercial systems rely on user estimates.

## Node Allocation

Scheduling, discussed in the previous section, is used to decide which job to run when. Once a job has been selected to run, node allocation decides on which nodes this job should run. In a multicomputer, the allocation granularity is usually a node, not individual processor. If a user requests 64 processors and there are four processors per node, then the allocator would assign 16 nodes to that job.

The network topology connecting the nodes arranges them in a geometric pattern such as 2-D or 3-D meshes, hypercubes, or trees. When allocating nodes, it is important to place processes that communicate frequently with each other on nearby nodes. If frequently communicating processes are placed far apart from each other in the network topology, then their communication costs increase. Furthermore, since the links in the network paths between the nodes are shared with

other communication flows, further slowdowns occur due to contention in the network.

While placing the processes of a parallel job in a contiguous region of the network topology is desirable, it is not always possible. The coming and going of differently sized jobs causes fragmentation that leads to the situation where enough nodes are available to run a particular job, but they are scattered throughout the system. Using the nodes anyway leads to poor communication performance, while waiting for more nodes to become available leads to poor system utilization and throughput.

Another complicating factor is that the allocator does not know which processes of an application will communicate with each other once the job starts executing. Each process of a message-passing application receives a rank number at the start of execution. The allocator assumes that processes with similar rank numbers will be the ones communicating with each other most frequently. This assumption is based on the observation that simulations of physical systems often map processes in a 2-D or 3-D layout. In many simulations, physical properties of one region are computed based on the conditions in the surrounding regions. That means information has to flow among processors assigned to neighboring regions.

Unfortunately, when application programmers write their code, they cannot know how their processes will be assigned to nodes, especially if their programs will run on different network topologies and machine sizes. Therefore, programmers often make the assumption that nearby ranks are also near each other in the network. If a program logically arranges its processes in a  $4 \times 4$  grid, the allocator only knows that this application requires 16 processors to run. It is tempting to assume that allocating nodes in a square is best, but that strategy fails for nonsquare numbers of nodes, cannot always be done given the available nodes, and may be a mismatch with the logical ordering the application uses.

In many systems, the scheduler and allocator are separate components. The scheduler receives information about the number of available nodes and uses that to dispatch jobs. The allocator must find nodes for that job, even if that leads to higher fragmentation and decreased application performance. It is beneficial to combine these two functions and allowing the allocator to delay a job until a more favorable configuration

of nodes becomes available. That requires a more complex scheduler, and ways to assure fairness and prevent starvation.

In large-scale, high-performance systems, migration of running processes is considered to be too complex and has too much overhead to be used to achieve better node allocations. Complicating allocation further is that in some systems the nodes are not homogeneous. Matching job requirements with nodes that have different memory sizes and CPUs further complicates node allocation. Often, same node types are grouped and served by separate queues in the scheduler.

## Space and Time-Sharing

Node allocation discussed so far implicitly assumed *space-sharing*, where each processor is allocated to a single job. There might be multiple jobs currently running on a machine, but each job has its own set of processors allocated to it. On nonparallel systems, *time-sharing*, where multiple processes run for short slices of time on a single processor, is more common.

Space-sharing improves the performance of parallel applications. When the individual processes of a parallel application communicate with each other, they often depend on a quick response time for data requests, so they can continue with their computations. If process A is waiting for information from process B, but B is not currently running, then A will be blocked and it may lose its time slice before the response from B arrives. When the data finally does arrive, A may not be running anymore and will not be able to process the data and respond right away. This in turn may delay B, while it is waiting for a response from A.

This problems gets worse the more processes depend on each other's responses. The solution in high-performance systems is space-sharing. Once allocated to their nodes, the processes of a parallel application will not be preempted by other parallel jobs. This improves responsiveness among the processes of a parallel job and lets it finish more quickly.

A method called *gang-scheduling* can help with synchronizing processes of the same job. The idea is to coordinate processors and make sure that context-switches from one job to another occur at exactly the same time on all processors. That way processors can be time-shared among several jobs, but all the processes of one job run during the same time slices. This prevents

blocking when processes of the same job communicate with each other.

Gang-scheduling is not very common because it requires hardware support or very coarse time slices. IBM's Blue Gene machines have a built-in synchronization network that makes gang-scheduling feasible. Gang-scheduling can reduce OS noise: All OS housekeeping tasks are done at the same time on all processors and no application process gets delayed waiting for another process whose OS is busy.

## Future Directions

Desktop computers and even laptops are now parallel systems. With the number of cores increasing for the foreseeable future, the parallelism available in these systems will soon rival many clusters in use today. While scheduling in a shared-memory system is easier, for example, process migration is less difficult, the amount of parallelism and the need for data locality will pose challenges for which traditional OSs have not been designed, but which have been explored in the parallel job scheduling community for many years.

One of the many new challenges in this area to be considered is the following. In the future, the cores inside a multicore CPU will be connected by a Network on Chip (NoC). Each core in use generates heat and raises the temperature in adjacent cores. It is therefore beneficial to distribute the cores that are currently active in a way such that the overall temperature of the chip is minimized. This adds another dimension to the already complex problem of allocation.

## Bibliographic Notes and Further Reading

The International Workshop on Job Scheduling Strategies for Parallel Processing (JSSPP) has been held annually for more than 15 years and is a rich source of information on the topic of parallel scheduling and processor allocation [2]. Over the years the field has evolved. In the introduction to two of the JSSPP workshops, Feitelson et al. document some of the

changes that have occurred [3, 4], while [5] looks at some of the challenges ahead.

Knowing the expected running time of an application is important for job scheduling. Whether user estimates are accurate has been explored in [8], and using historical information to automate runtime prediction has been looked at in [13].

Some common batch scheduling systems in use are: Platform Computing's Load Sharing Facility (LSF) [16], the Portable Batch System (PBS) [6], and a Simple Linux Utility for Resource Management (SLURM) [7, 14].

Topology aware processor allocation and the effect of contiguous or noncontiguous allocation have been most recently studied in [12], while communication awareness is discussed in [1]. Innovative use of (one-dimensional) space-filling curves to allocate processors to improve communication efficiency is explored in [9] and [1]. Making the allocator temperature-aware has been suggested in [10]. The tradeoffs of space- and time-sharing as well as combining several of these methods to improve utilization are discussed in [15].

An excellent description of the architectural and software components of a large-scale parallel system, and how they interact, is contained in [11]. That paper provides a sense of what is required to integrate node scheduling and allocation into a complex parallel system.

## LAPACK

JACK DONGARRA, PIOTR LUSZCZEK  
University of Tennessee, Knoxville, TN, USA

### Definition

LAPACK is a library of Fortran 77 subroutines for solving most commonly occurring problems in dense matrix computations. It has been designed to be efficient on a wide range of modern high-performance computers. The name LAPACK is an acronym for Linear Algebra PACKage. LAPACK can solve systems of linear equations, linear least squares problems, eigenvalue problems, and singular value problems. LAPACK can also handle many associated computations such as matrix factorizations or estimating condition numbers.

### Discussion

LAPACK contains *driver routines* for solving standard types of problems, *computational routines* to perform a distinct computational task, and *auxiliary routines* to perform a certain subtask or common low-level computation. Each driver routine typically calls a sequence of computational routines. Taken as a whole, the computational routines can perform a wider range of tasks than are covered by the driver routines. Many of the auxiliary routines may be of use to numerical analysts or software

developers, so the Fortran source for these routines has been documented with the same level of detail used for the LAPACK routines and driver routines.

LAPACK is designed to give high efficiency performance on vector processors, high-performance “super-scalar” workstations, and shared memory multiprocessors. It can also be used satisfactorily on all types of scalar machines (PCs, workstations, and mainframes). A distributed memory version of LAPACK, ScaLAPACK [1], has been developed for other types of parallel architectures (e.g., massively parallel SIMD machines, or distributed memory machines).

LAPACK has been designed to supersede LINPACK [2] and EISPACK [3, 4] principally by restructuring the software to achieve much greater efficiency, where possible, on modern high-performance computers, and also by adding extra functionality, by using some new or improved algorithms, and by integrating the two sets of algorithms into a unified package.

LAPACK routines are written so that as much as possible of the computation is performed by calls to the Basic Linear Algebra Subprograms (BLAS) [5–7]. Highly efficient machine-specific implementations of the BLAS are available for many modern high-performance computers. The BLAS enable LAPACK routines to achieve high performance with portable code.

The complete LAPACK package or individual routines from LAPACK are freely available on Netlib [8] and can be obtained via the World Wide Web or anonymous ftp. The LAPACK homepage can be accessed via the following URL address: <http://www.netlib.org/lapack/>.

LAPACK90 is a Fortran 90 interface to the Fortran 77 LAPACK library. LAPACK++ is an object-oriented C++ extension to the LAPACK library. The CLAPACK library was built using a Fortran to C conversion utility called f2c [9]. The J LAPACK project provides the LAPACK and BLAS numerical subroutines translated

from their Fortran 77 source into class files, executable by the Java Virtual Machine (JVM) and suitable for use by Java programmers. The ScaLAPACK (or Scalable LAPACK) [1] library includes a subset of LAPACK routines redesigned for distributed memory message-passing MIMD computers and networks of workstations supporting PVM and/or MPI.

Two types of driver routines are provided for solving systems of linear equations: simple and expert. Different driver routines are provided to take advantage of special properties or storage schemes of the system matrix. Supported matrix types and storage schemes include: general, general band, general tridiagonal, symmetric/Hermitian, positive definite, symmetric/Hermitian, positive definite (packed storage), positive definite band, positive definite tridiagonal, indefinite, complex symmetric, and indefinite (packed storage).

## Latency Hiding

Latency hiding improves machine utilization by enabling the execution of useful operations by a device while it is waiting for a communication operation or memory access to complete. Prefetching, context switching, and instruction-level parallelism are mechanisms for latency hiding.

## Layout, Array

PAUL FEAUTRIER  
Ecole Normale Supérieure de Lyon, Lyon, France

## Definitions

A high-performance architecture needs a fast processor, but a fast processor is useless if a memory subsystem does not provide data at the rate of several words per clock cycle. Run-of-the-mill memory chips in today technology have a latency of the order of ten to a hundred processor cycles, far more than the necessary performance. The usual method for increasing the memory

bandwidth as seen by the processor is to implement a cache, i.e., a small but fast memory which is geared to hold frequently used data. Caches work best when used by programs with almost random but nonuniform addressing patterns. However, high-performance applications, like linear algebra or signal processing, have a tendency to use very regular addressing patterns, which degrade cache performance. In linear algebra codes, and also in stream processing, one finds long sequences of accesses to regularly increasing addresses. In image processing, a template moves regularly across a pixel array.

To take advantage of these regularities, in fine-grain parallel architectures, like SIMD or vector processors, the memory is divided into several independent banks. Addresses are evenly scattered among the banks. If  $B$  is the number of banks, then word  $x$  is located in bank  $x \bmod B$  at displacement  $x \div B$ . The low-order bits of  $x$  (the byte displacement) do not participate in the computation. In this way, words in consecutive addresses are located in distinct banks, and can, with the proper interface hardware, be accessed in parallel. A problem arises when the requested words are not at consecutive addresses. *Array layouts* were invented to allow efficient access to various *templates*.

## Discussion

### Parallel Memory Access

There are many ways of taking advantage of such a memory architecture. One possibility is for the processors to access in one memory cycle the  $B$  words which are necessary for a piece of computation, and then to cooperate in computing the result. Consider, for instance, the problem of summing the elements of a vector. One reads  $B$  words, adds them to an accumulator, and proceeds to the next  $B$  words.

Another organization is possible if the program operations can be executed in parallel, and if the data for each operation are regularly located in memory. Consider, for instance, the problem of computing the weighted sum of three rows in a TV image (downsampling). One possibility is to read three words in the same column and do the computation. But since it is likely that  $B$  is much larger than three, the memory subsystem will be under-utilized. The other possibility is to read  $B$  words in the first row,  $B$  words in the second row, and so on, do the summation, and store  $B$  words of the

result. This method is more efficient, but places more constraints on the target application.

### Templates and Template Size

In both situations, the memory is addressed through *templates*, i.e., finite sets of cells which can move across an array. Consider for instance a vector:

```
float A[100].
```

The template  $(0, 1, 2, 3)$  represents four consecutive words. If located (or *anchored*) at position  $i$ , it covers elements  $A[i]$ ,  $A[i+1]$ ,  $A[i+2]$  and  $A[i+3]$  of vector  $A$ . But the most interesting case is that of a two-dimensional array, which may be a matrix or an image. The template  $((0,0), (0,1), (1,0), (1,1))$  represents a two-by-two square block. If anchored at position  $(i,j)$  in a matrix  $M$ , it covers elements  $M[i][j]$ ,  $M[i][j+1]$ ,  $M[i+1][j]$ , and  $M[i+1][j+1]$ . The first template is one dimensional, and the second one is two dimensional. One may consider templates of arbitrary dimensions, but these two are the most important cases.

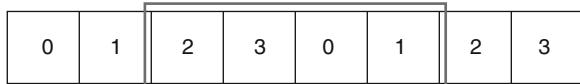

The basic problem is to distribute arrays among the available memory banks in such a way that access to all elements of the selected template(s) takes only one memory cycle. It follows that the size of a template is at most equal to the number of banks,  $B$ . As has been seen before, memory usage is optimized when templates have exactly  $B$  cells; this is the only choice that is discussed here.

Observe also that, as the previous example has shown, there may be many template selections for a given program. The problem of selecting the best one will not be discussed here.

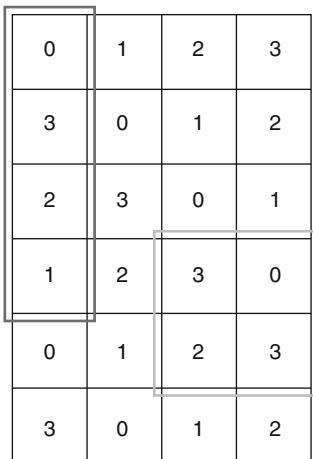

### Layouts

A layout is an assignment of bank numbers to array cells. A template can be viewed as a stencil that moves across an array and shows bank numbers through its openings. A layout is *valid* for a template position if all shown bank numbers are distinct. In Fig. 1, the layout is valid for all positions of the solid template. In Fig. 2, the layout is valid for all positions of the solid template, and valid for no position of the dashed template.

The reader may have noticed that the information given by array layouts such as Fig. 1 or 2 is not complete. One must also know at which address each cell is located in its bank. This information can always be retrieved

Layout, Array. Fig. 1 A vector layout

Layout, Array. Fig. 2 A matrix layout

from the layout. Simply order the array cells and allocate each cell to the first free word in its bank. For Fig. 2, the bank address is found equal to the row number. This scheme imposes two constraints on a layout:

- Array cells must be evenly distributed among banks.
- The correspondance between cells and bank addresses cannot be too complex, since each processor must know and use it.

Depending on the application, one may want that a layout be valid at some positions in the array, or at every possible position. For instance, in linear algebra, it is enough to move the template in such a way that each entry is covered once and only once. One says that the template tessellates or *tiles* the array domain. Once a tiling has been found one simply numbers each square of the template from 0 to  $B - 1$ , and reproduces this assignment (perhaps after a permutation) at all positions of the tile. This insures that the array cells are evenly distributed among the banks. In other applications, like image processing, the template must be moved at every position in the array. Imagine for instance that a smoothing operator must be applied at all pixels of an image. In fact, the two situations are

equivalent: If a template tiles an array and if block numbers are assigned as explained above, then the layout is valid for every position. For a proof, see [4].

## Skewing Schemes: Vector Processing

Consider the following example:

```
for(i=0; i< n; i=i+1)
 X[i] = Y[i] + Z[i],
```

to be run on a SIMD architecture with  $B$  processing elements. If the layout of  $Y$  is such that  $Y[i]$  is stored in bank  $i \bmod B$  at address  $i \div B$ ,  $B$  elements of  $Y$  can be fetched in one memory cycle. After another fetch of  $B$  words of  $Z$ , the SIMD processor can execute  $B$  addition in parallel. Another memory cycle is needed to store the  $B$  results. Note that this scheme has the added advantage that all groups of  $B$  words are at the same address in each bank, thus fitting nicely in the SIMD paradigm.

Suppose now that the above loop is altered to read:

```
for(i=0; i< n; i=i+1)
 X[d*i] = Y[d*i] + Z[d*i],
```

where  $d$  is a constant (the step). The block number  $d \cdot i \bmod B$  is equal to  $d \cdot i - k \cdot B$  for some  $k$ , and hence is a multiple of the greatest common divisor (gcd)  $g$  of  $d$  and  $B$ . It follows that only  $B/g$  words can be fetched in one cycle, and the performance is divided by  $g$ . Since  $B$  is usually a power of 2 in order to simplify the computation of  $x \bmod B$  and  $x \div B$ , a loss of performance will be incurred whenever  $d$  is even. One can always invent layouts that support non-unit step accesses. For instance, if  $d = 2$ , assign cell  $i$  to bank  $(i \div 2) \bmod B$ . However, in many algorithms that use non-unit steps, like the Fast Fourier Transform,  $d$  is a variable. It is not possible to accomodate all its possible values without costly remapping.

## Skewing Schemes: Matrix Processing

In C, the canonical method for storing a matrix is to concatenate its rows in the order of their subscripts. If the matrix is of size  $M \times N$ , the displacement of element  $(i, j)$  is  $N \cdot i + j$ . In Fortran, the convention is reversed, but the conclusions are the same, *mutatis mutandis*. One may assume that the row length  $N$  is a multiple of  $B$ , by padding if necessary; hence, all matrices may be assumed to have size  $M \times B$ . As a consequence, element  $(i, j)$  is allocated to bank  $j \bmod B$ .

|            |     |     |     |            |            |            |            |
|------------|-----|-----|-----|------------|------------|------------|------------|
| <b>0,0</b> | 0,1 | 0,2 | 0,3 | <b>0,0</b> | 0,1        | 0,2        | 0,3        |
| <b>1,0</b> | 1,1 | 1,2 | 1,3 | 1,3        | <b>1,0</b> | 1,1        | 1,2        |
| <b>2,0</b> | 2,1 | 2,2 | 2,3 | 2,2        | 2,3        | <b>2,0</b> | 2,1        |
| <b>3,0</b> | 3,1 | 3,2 | 3,3 | 3,1        | 3,2        | 3,3        | <b>3,0</b> |

$B = 4, S = 0$ : four cycles are needed to access column 0  
a

$B = 4, S = 1$ : column 0 can be accessed in one cycle  
b

Layout, Array. Fig. 3 The effect of skewing

If the algorithm accesses a matrix by rows, as in:

```
for(j=0; j<N; j++)
... X[i][j] ...
```

performance will be maximal. However, when accessing columns, consecutive items will be separated by  $B$  rows, and be located all in the same bank. All parallelism will be lost.

A better solution is *skewing* (Fig. 3). The cell  $(i, j)$  is now allocated to bank  $(S \cdot i + j) \bmod B$ .  $S$  is the skewing factor. Here, two consecutive cells in a row are still at a distance of 1; hence, a row can still be accessed in one cycle. But two consecutive cells in a column,  $(i, j)$  and  $(i + 1, j)$  are at a distance of  $S$ . If  $S$  is selected to be relatively prime to  $B$  (for instance,  $S = 1$  if  $B$  is even Fig. 3 (b)) access to a column will also take one cycle.

This raises the question of whether other patterns can be accessed in parallel. Consider the problem of accessing the main diagonal of a matrix. In the above skewing scheme, the distance from cell  $(i, i)$  to  $(i+1, i+1)$  is  $S+1$ , and  $S$  and  $S+1$  both cannot be odd. Hence, accessing both columns and diagonals (or both rows and diagonals) in parallel with the same skewing scheme is impossible when  $B$  is even.

### Skewing Schemes: More Templates

It is clear that a more general theory is needed when the subject algorithm needs to use several templates at the same time. As seen above, a template has a valid layout if and only if it tiles the two-dimensional plane. This result seems natural if the template is required to cover once and only once each cell of the underlying array. If bank numbers are assigned in the same order in each tile [4] or are regularly permuted from tile to tile [3] then the layout will obviously be valid for each tile. The striking fact is that the layout will also be valid when the template is offset from a tile position. Observe that the previous

results on matrix layouts corresponds to the many ways of tiling the plane with  $B$ -sized linear templates.

A tiling is defined by a set of vectors  $v_1, \dots, v_n$  (translations). If a template instance has been anchored at position  $(i, j)$ , then there are other instances at positions  $(i, j) + v_1, \dots, (i, j) + v_n$ . The translations  $v_1, \dots, v_n$  must be selected in such a way that the translates do not overlap.

If an algorithm needs several templates, the first condition is that each of them tiles the plane. But each tiling defines a layout, and these layouts must be compatible. One can show that the compatibility condition is that the translation vectors are the same for all templates. Since a template may tile the plane in several different ways, finding the right tiling may prove a difficult combinatorial problem.

### Pipelined Processors and GPU

Consider the loop:

```
for(i=0; i<n; i=i+1)
 s = s + A[i],
```

to be run on a pipelined processor which executes one addition per cycle. If the memory latency is equal to  $B$  processor cycles, the memory banks can be activated in succession, in such a way that, after a prelude of  $B$  cycles, the processor receives an element of  $A$  at each cycle. As for parallel processors, if the loop has a step of  $d$ , the performance will be reduced by a factor of  $\gcd(d, B)$ .

While today vector processors are confined to niche applications, the same problem is reemerging for Graphical Processing Units (GPU), which can access  $B$  words in parallel under the name “Global Memory Access Coalescing.”

### Reordering

With nonstandard layouts, the results of a parallel access may not be returned in the natural order. Consider, for instance, the problem of having parallel access both for rows and for the main diagonal of a  $4 \times 4$  matrix on a  $4$  banks memory. The skewing factor  $S$  must be such that  $S + 1$  is relatively prime to 4:  $S = 2$  is a valid choice. The corresponding layout is shown on Fig. 4. The integer in row  $i$  and column  $j$  is the number of the bank which holds element  $(i, j)$  of the matrix. One can see that bank 0 holds element  $(0, 0)$ , bank 1 holds element  $(3, 3)$ , and so on. If the banks are connected to processors in

|   |          |          |          |          |
|---|----------|----------|----------|----------|
|   | 0        | 1        | 2        | 3        |
| 0 | <b>0</b> | 1        | 2        | 3        |
| 1 | 2        | <b>3</b> | 0        | 1        |
| 2 | 0        | 1        | <b>2</b> | 3        |
| 3 | 2        | 3        | 0        | <b>1</b> |

Layout, Array. Fig. 4 The need for reordering

the natural order, the elements of the main diagonal are returned in the order  $(0,0), (3,3), (2,2), (1,1)$ . This might be unimportant in some cases, for instance, if the elements of the main diagonal are to be summed (the *trace* computation), since addition is associative and commutative.

In other cases, returned values must be reordered. This can be done by inserting a  $B$  words fast memory between the main memory subsystem and the processors. One can also use a *permutation network* which may route a datum from any bank to any processor.

## The Number of Banks

Remember that in vector processing, when the step  $d$  is not equal to one, performance is degraded by a factor  $\gcd(d, B)$ . It is tempting to use a prime number for  $B$ , since then the gcd will always be one except when  $d$  is a multiple of  $B$ . However, having  $B$  a power of two considerably simplifies the addressing hardware, since computing  $x \bmod B$  and  $x \div B$  is done just by routing wires. This has lead to the search for prime numbers with easy division, which are of one of the forms  $2^p \pm 1$ . See [2] for a discussion of this point.

## Synonyms

FLAME

## Definition

libflame is a software library for dense matrix computations.

## Discussion

### Introduction

The libflame library is a modern, high-performance dense linear algebra library that is extensible, easy to use, and available under an open source license. It is both a framework for developing dense linear algebra solutions and a ready-made library that strives to be user-friendly while offering competitive (and in many cases superior) real-world performance when compared to the more traditional Basic Linear Algebra Subprograms (BLAS) and Linear Algebra PACKAGE (LAPACK) libraries. It was developed as part of the FLAME project.

### The FLAME Project

A solution based on fundamental computer science. The FLAME project advocates a more stylized notation for expressing loop-based linear algebra algorithms. This notation, illustrated in Fig. 1, closely resembles how matrix algorithms are illustrated with pictures. The notation facilitates formal derivation of algorithms so that the algorithms are developed hand-in-hand with their proof of correctness. For a given operation this yields a family of algorithms so that the best option for a given situation (e.g., problem size or architecture) can be chosen.

---

**Algorithm:**  $A \leftarrow \text{CHOL\_BLK}(A)$

---

$$\text{Partition } A \rightarrow \left( \begin{array}{c|c} A_{TL} & A_{TR} \\ \hline A_{BL} & A_{BR} \end{array} \right)$$

where  $A_{TL}$  is  $0 \times 0$

while  $m(A_{TL}) < m(A)$  do

Determine block size  $b$

Repartition

$$\left( \begin{array}{c|c} A_{TL} & A_{TR} \\ \hline A_{BL} & A_{BR} \end{array} \right) \rightarrow \left( \begin{array}{c|c|c} A_{00} & A_{01} & A_{02} \\ \hline A_{10} & A_{11} & A_{12} \\ \hline A_{20} & A_{21} & A_{22} \end{array} \right)$$

where  $A_{11}$  is  $b \times b$

---

$$\begin{aligned} A_{11} &:= A_{11} - A_{10}A_{11}^T && (\text{SYRK}) \\ A_{21} &:= A_{21} - A_{20}A_{10}^T && (\text{GEMM}) \\ A_{11} &:= \text{CHOL}(A_{11}) && (\text{CHOL}) \\ A_{21} &:= A_{21}A_{11}^{-T} && (\text{TRSM}) \end{aligned}$$

---

Continue with

$$\left( \begin{array}{c|c} A_{TL} & A_{TR} \\ \hline A_{BL} & A_{BR} \end{array} \right) \leftarrow \left( \begin{array}{c|c|c} A_{00} & A_{01} & A_{02} \\ \hline A_{10} & A_{11} & A_{12} \\ \hline A_{20} & A_{21} & A_{22} \end{array} \right)$$

endwhile

**libflame. Fig. 1** Blocked Cholesky factorization expressed with FLAME notation. Subproblems annotated as SYRK, GEMM, and TRSM correspond to level-3 BLAS operations while CHOL performs a Cholesky factorization of the submatrix  $A_{11}$

**Object-based abstractions and API.** The libflame library is built around opaque structures that hide implementation details of matrices, such as data layout, and exports object-based programming interfaces to operate upon these structures. FLAME algorithms are expressed (and coded) in terms of smaller operations on sub-partitions of the matrix operands. This abstraction facilitates programming without array or loop indices, which allows the user to avoid index-related programming errors altogether, as illustrated in Fig. 2.

**Educational value.** The clean abstractions afforded by the notation and API, coupled with the systematic methodology for deriving algorithms, make FLAME well suited for instruction of high-performance linear algebra courses at the undergraduate and graduate level.

## The libflame Library

The techniques developed as part of the FLAME project have been instantiated in the libflame library.

**A complete dense linear algebra framework.** The libflame library provides ready-made implementations of common linear algebra operations. However, libflame differs from traditional libraries in two important ways. First, it provides families of algorithms for each operation so that the best can be chosen for a given circumstance. Second, it provides a framework for building complete custom linear algebra codes. This makes it a flexible and useful environment for prototyping new linear algebra solutions.

**High performance.** The libflame library dispels the myth that user- and programmer-friendly linear algebra codes cannot yield high performance. Implementations of operations such as Cholesky factorization and triangular matrix inversion often outperform the corresponding implementations currently available in traditional libraries. For sequential codes, this is often simply the result of implementing the operations with algorithmic variants that cast the bulk of their computation in terms of higher-performing matrix operations such as general matrix rank-k updates.

**Support for nontraditional storage formats.** The libflame library supports both column-major and row-major order (“flat”) storage of matrices. Indeed, it allows for general row and column strides to be specified. In addition, the library supports storing matrices hierarchically, by blocks, which can yield performance gains through improved spatial locality. Previous efforts [2] at implementing storage-by-blocks focused on solutions that required intricate indexing. libflame simplifies the implementation by allowing the elements within matrix objects to be references to smaller submatrices. Furthermore, the library provides user-level APIs which allow application programmers to read and modify individual elements and submatrices while simultaneously abstracting away the details of the storage scheme.

**Supported operations.** As of this writing, the following operations have been implemented within libflame to operate on both “flat” and hierarchical matrix objects:

- **Factorizations.** Cholesky; LU with partial pivoting; QR and LQ.
- **Inversions.** Triangular; Symmetric/Hermitian Positive Definite.

```

void FLA_Chol_blk(FLA_Obj A, int nb_alg)
{
 FLA_Obj ATL, ATR, A00, A01, A02,
 ABL, ABR, A10, A11, A12,
 A20, A21, A22;
 int b;

 FLA_Part_2x2(A, &ATL, &ATR,
 &ABL, &ABR, 0, 0, FLA_TL);

 while (FLA_Obj_length(ATL) < FLA_Obj_length(A))
 {
 b = min(FLA_Obj_length(ABR), nb_alg);

 FLA_Repart_2x2_to_3x3(
 ATL, /**/ ATR, &A00, /**/ &A01, &A02,
 /* **** */ /* **** */ /* **** */
 &A10, /**/ &A11, &A12,
 ABL, /**/ ABR, &A20, /**/ &A21, &A22,
 b, b, FLA_BR);
 /* ----- */
 FLA_Syrk(FLA_LOWER_TRIANGULAR, FLA_NO_TRANSPOSE,

 FLA_ONE, A11, A21);
 /* ----- */
 FLA_Cont_with_3x3_to_2x2(
 &ATL, /**/ &ATR, A00, A01, /**/ A02,
 A10, A11, /**/ A12,
 /* **** */ /* **** */ /* **** */
 &ABL, /**/ &ABR, A20, A21, /**/ A22,
 FLA_TL);
 }
}

```

**libflame.** Fig. 2 The algorithm shown in Fig. 1 implemented with the FLAME/C API

- **Solvers.** Linear systems via any of the factorizations above; Solution of the Triangular Sylvester equation.
- **Level-3 BLAS.** General, Triangular, Symmetric, and Hermitian matrix-matrix multiplies; Symmetric and Hermitian rank-k and rank-2k updates; Triangular solve with multiple right-hand sides.
- **Miscellaneous.** Triangular-transpose matrix multiply; Matrix-matrix AXPY and COPY; and several other supporting operations.

**Cross-platform support.** The libflame distribution includes build systems for both GNU/Linux and

Microsoft Windows. The GNU/Linux build system provides a configuration script via GNU autoconf and employs GNU make for compilation and installation, and thus adheres to the well-established “configure; make; make install” sequence of build commands.

**Compatibility with LAPACK.** A set of compatibility routines is provided that maps conventional LAPACK invocations to their corresponding implementations within libflame. This compatibility layer is optional and may be disabled at configure-time in order to allow the application programmer to continue to

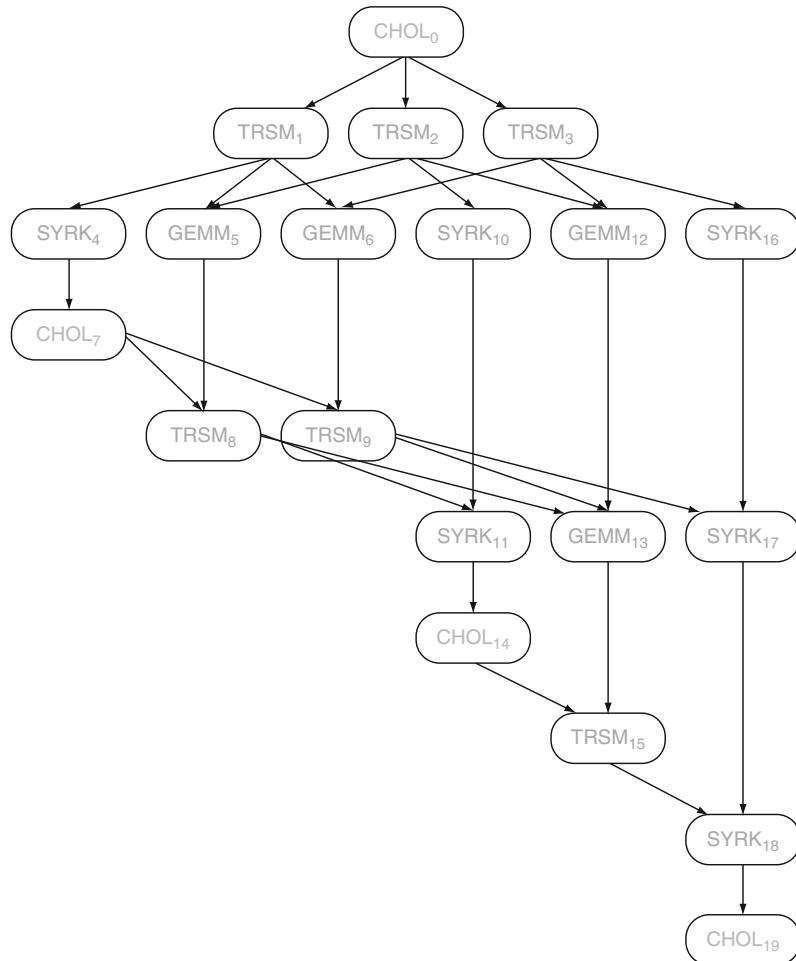

use legacy LAPACK implementations alongside native libflame functions.

## Support for Parallel Computation

**Multithreaded BLAS.** A simple technique for exploiting thread-level parallelism is to link the sequential algorithms for flat matrices in libflame to multithreaded BLAS libraries where each call to a BLAS routine is parallelized individually. Inherent synchronization points occur between successive calls to BLAS routines and thus restrict opportunities for parallelization between subproblems. Routines are available within libflame to adjust the block size of these sequential implementations in order to attain the best performance from the multithreaded BLAS libraries.

SuperMatrix. The fundamental bottleneck to exploiting parallelism directly within many linear algebra codes is the web of data dependencies that frequently exists between subproblems. As part of libflame, the SuperMatrix runtime system has been developed to detect and analyze dependencies found within algorithms-by-blocks (algorithms whose subproblems operate only on block operands). Once data dependencies are known, the system schedules sub-operations to independent threads of execution. This system is completely abstracted from the algorithm that is being parallelized and requires virtually no change to the algorithm code while exposing abundant high-level parallelism.

The directed acyclic graph for the Cholesky factorization, given a  $4 \times 4$  matrix of blocks (a hierarchical

libflame. Fig. 3 The directed acyclic graph for the Cholesky factorization on a  $4 \times 4$  matrix of blocks

matrix stored with one level of blocking), is shown in Fig. 3. The nodes of the graph represent tasks that operate over different submatrix blocks, and the edges represent data dependencies between tasks. The subscripts in the names of each task denote the order in which the tasks would typically be executed in a sequential algorithm-by-blocks. Many opportunities for parallelism exist within the directed acyclic graph such as  $\text{TRSM}_1$ ,  $\text{TRSM}_2$ , and  $\text{TRSM}_3$  being able to be executed in parallel.

**PLAPACK.** FLAME and `libflame` have their roots in the distributed-memory parallel PLAPACK library. Integrating PLAPACK into `libflame` is a current effort.

## Bibliographic Notes and Further Reading

The FLAME notation and APIs have their root in the Parallel Linear Algebra Package (PLAPACK). Eventually the insights gained for implementing distributed-memory libraries found their way back to the sequential library `libflame`.

The first papers that outlined the vision that became the FLAME project were published in 2001 [3, 4]. A book has been published that describes in detail the formal derivation of dense matrix algorithms using the FLAME methodology [6]. How scheduling of tasks is supported was first published in [1] and discussed in more detail in [5]. An overview of `libflame` can be found in [7] and an extensive reference guide has been published [8].

## Linda

ROBERT BJORNSEN  
Yale University, New Haven, CT, USA

### Definition

Linda [1] is a coordination language for parallel and distributed computing, invented by David Gelernter and first implemented by Nicholas Carriero. Work on Linda was initially done at SUNY Stony Brook and continued at Yale University. Linda uses tuple spaces as the mechanism for communication, coordination, and process control. The goal is to provide a tool that makes it simple to develop parallel programs that are easy to understand, portable and efficient.

### Discussion

#### Introduction

Linda is a coordination language concerned with issues related to parallelism and distributed computing, such as communication of data, coordination of activities, and creation and control of new threads/processes.

Linda is not concerned with other programming language issues such as control structures (testing, looping), file I/O, variable declaration, etc. Thus, it is orthogonal to issues of traditional programming languages, and is normally embedded in a sequential language such as C, Fortran, Java, etc., resulting in a Linda dialect of that language (C-Linda, Fortran-Linda, Java-Linda, etc). It is important to distinguish between Linda as a conceptual model for coordination and a concrete X-Linda implementation. The latter necessarily imposes restrictions and limitations on the former.

## Tuples and Tuple Spaces

Tuples (**too-pulls**) are the fundamental data objects in Linda. A tuple is an ordered, typed collection of any number of elements. These elements can be whatever values or objects are supported by the host language. Elements can also be typed place holders, or *formals*, which will act as wild cards. Here are some example tuples:

```
(“counter”, 3)
(“table”, 4, 6, 5.67)
(“table, i, j, ? a)
```

Tuples exist in tuple spaces. Processes communicate and synchronize with one another by creating and consuming tuples from a common tuple space. Tuple spaces exist, at least abstractly, apart from the processes using them. Tuple space is sometimes referred to as an associative memory. A tuple establishes associations between the values of its constituent elements. These associations are exploited by specifying some subset of the values to reference the tuple as a whole.

## Tuple Space Operations

There are two operations that create tuples: `out` and `eval`. `Out` simply evaluates the expressions that yield its elements in an unspecified order and then places the resulting tuple in tuple space:

```
out(“counter”, 5)
```

A tuple space is a multiset: if the above operation is repeated  $N$  times (and no other operations are done), then the tuple space will contain  $N$  identical (“counter”, 5) tuples.

`Eval` is identical to `out`, except that the tuple is placed into tuple space without completing the evaluation of

its elements. Instead, new execution entities are created to evaluate the elements of the tuple (depending on the implementation, these entities might be threads or processes). Once all elements have been evaluated, the tuple is indistinguishable from one created via `out`. `Eval` is typically used with tuples that contain function calls, and is an idiomatic and portable way to create parallelism in Linda.

For example, a process might create a new worker by doing:

```
eval(“new worker”, worker(i))
```

`Eval` will immediately return control to the calling program, but in the background a new execution entity will begin computing `worker(i)`. When that subroutine returns, its value will be the second element of a “new worker” tuple.

There are two operations that can extract tuples from tuple space: `in` and `rd` (Traditionally read was spelled `rd` to avoid collisions with `read` from the C library. The exact verbs used have varied somewhat, with `store` and `write` common variants of `out`, and `take` a common variant of `in`). These operations take a template and perform a match of its arguments against the tuples currently in tuple space. A template is similar to a tuple, consisting of some number of actual and formal fields.

If a match is found, the tuple is returned to the process performing the `in` or `rd`. In the case of `in`, the tuple is deleted from tuple space after matching, whereas `rd` leaves the tuple in tuple space. If multiple matches are available, one is chosen arbitrarily. If no matches are available, the requesting process blocks until a match is available. Tuples are always created and consumed atomically.

In order to match, the tuple and template must:

1. Agree on the number of fields
2. Agree on the types of corresponding fields
3. Agree in the values of corresponding actual fields
4. Have no corresponding formals (this is unusual)

‘?’ indicates that the argument is a place-holder, or formal argument. In this case, only the types must match, and as a side effect, the formal variable in the template will be assigned the value from the tuple. Formals normally appear only in templates, but in some limited circumstances can appear in tuples as well (it is

not uncommon for a particular implementation to omit support for formals in tuples). Some work was also proposed to allow a “ticking” type modifier to enable specification of elements still under evaluation. Absent this, the matching above implicitly enforces matches on tuples whose elements have all completed evaluation.

For example, the template:

`in("counter", 5)`

would match the above tuple, as would

`in("counter", ?i) also setting i to 5`

`in("counter", i) assuming i was bound to 5`

But these templates would not match:

`in("counter", 5, 5) rule 1`

`in("counter", 5.0) rule 2`

`in("counter", 6) rule 3`

In addition to `in` and `rd`, there are non-blocking variants `inp` and `rdp`, which return `FALSE` rather than blocking. These variants can be useful in certain circumstances, but their use has generally been discouraged since it introduces timing dependencies.

In the above examples, note that the first field is always a string that serves to name the tuple. This is not required, but is a common useful idiom. It also provides a useful hint to the Linda implementation that can improve performance, as discussed below.

## Linda Examples

Linda programmers are encouraged to think of coordination in terms of data structure manipulations rather than message passing, and a number of useful idioms have been developed along these lines. Indeed, Linda can be viewed as a means to generalize Wirth’s “Algorithms + Data Structures = Programs”: “Algorithms + Distributed Data Structures = Parallel Programs” [2]. That is, tuples can be used to create rich, complex *distributed* data structures in tuple space. Distributed data structures can be shared and manipulated by cooperating processes that transform them from an initial configuration to a final result. In this sense, the development of a parallel program using Linda remains conceptually close to the development of a sequential (ordinary) program. Two very simple, yet common, examples are a FIFO queue and a master/worker pattern.

## FIFO Queue

In the FIFO queue (Fig. 1), each queue is represented by a number of tuples: one for each element currently in the queue, plus two counter tuples that indicate the current position of the head and tail of the queue. Pushing a value onto the tail of the queue is accomplished by assigning it the current value of the tail counter, and then incrementing the tail, and similarly for popping. Important to note is that no additional synchronization is needed to allow multiple processes to push and pop from the queue “simultaneously.” The head and tail tuples act as semaphores, negotiating access to each position of the queue automatically.

## Master/Worker Pattern

In the master/worker example (Fig. 2), the master initially creates some number of worker processes via `eval`. It then creates task tuples, one per task, and waits for the results. Once all the results are received, a special “poison” task is created that will cause all the workers to shut down.

The workers simply sit in a loop, waiting to get a tuple that describes a task. When they do, if it is a normal task, they process it into a result tuple that will be consumed by the master. In the case of a poison task, they immediately use its elements to create a new task tuple to replace the one they consumed, poisoning another worker, and then finish.

```

init(qname) {
 out(qname, 'head', 0)
 out(qname, 'tail', 0)
}

push(qname, elem) {
 in(qname, 'tail', ?p)
 out(qname, 'elem', p, elem)
 out(qname, 'tail', p+1)
}

pop(qname) {
 in(qname, 'head', ?p)
 in(qname, 'elem', p, ?elem)
 out(qname, 'head', p+1)
 return elem
}

```

Linda. Fig. 1 A FIFO queue written in Linda

```

master() {
 for (i=0; i<NUMWORKERS; ++i) {
 eval(worker())
 }

 for (i=0; i<NUMTASKS; ++i) {
 out('task', i, task[i])
 }

 for (i=0; i<NUMTASKS; ++i) {
 in('result', ?taskid, ?result)
 /* process result */
 ...

 out('task', -1, POISON)
 }
}

worker() {
 while (1) {
 in('task', ?taskid, ?task)
 if (taskid===-1) {
 /* return poison and quit */
 out('task', taskid, task)
 break
 /* this is the actual work */
 result = process(task, taskid)
 out('result', taskid, result)
 }
}

```

**Linda. Fig. 2** The master/worker pattern written in Linda

This is the simplest sort of master/worker pattern one could imagine, yet it still presents a number of interesting features. Process startup and shutdown is represented. Load balancing occurs automatically, since slow workers or large tasks will simply take longer, and as long as there are significantly more tasks than workers the processing time will tend to balance.

The code as shown can be modified in a number of simple but interesting ways:

1. If there are a very large number of tasks, rather than having the master create all the task tuples at once (and thereby possibly filling memory) it can create an initial pool. Then, each time it receives a result it can create another task, thus maintaining a reasonable number of tasks at all times.
2. If the master needs to process the results in task order, rather than as arbitrarily received, the in statement that retrieves the result can be modified to make taskid an actual, i.e., in("result", i, ?result).
3. The program can be made fault-tolerant by wrapping the worker's inner loop in a transaction (for Linda implementations that support transactions) [3]. If a worker dies during the processing of a task,

the original task tuple will automatically be returned when the transaction fails, and another worker will pick up the task.

4. The program can be easily generalized to have new task tuples generated by the workers (in a sense, the propagation of the poison task is an example of this). This could, for example, be used to implement a dynamic divide-and-conquer decomposition.

## Implementations

Linda has been implemented on virtually every kind of parallel hardware ever created, including shared-memory-multiprocessors, distributed-memory-multi processors, non-uniform memory access (NUMA) multiprocessors, clusters, and custom hardware.

Linda is an extremely minimalist language design, and naive, inefficient implementations are deceptively simple to build. Most take the approach of building a runtime library that simply implements tuple space as a list of tuples and performs tuple matching by exhaustively searching the list. These sorts of implementations led to a suspicion that Linda is not suitable for serious computation. Many critics admired the language's elegance, but insisted that it could not be implemented efficiently enough to compete with other approaches, such as shared memory with locking, or native message passing. In response, considerable work was done at Yale and elsewhere during the 1980s and 1990s to create efficient implementations that could compete with lower-level approaches. The efforts focused on two main directions:

1. Compile-time optimizations. Carriero [4] recognized that tuple matching overhead could be greatly reduced by analyzing tuple usage at compile time and translating it to simpler operations. Tuple operations could be segregated into distinct, non-interacting partitions based on type information available at compile time. Each partition was then classified into one of a number of usage patterns and reduced to an efficient data structure such as a counter, hash table or queue, which could then be searched and updated very efficiently. This work demonstrated that Linda on shared-memory multiprocessors could be as efficient as handwritten codes using low level locks. An important part of the demonstration showed for a variety of

representative problems that on average fewer than two tuples would need to be searched before a match was found.

2. Run-time optimizations. For distributed memory implementations, optimization of tuple storage was key to reducing the overall number of messages required by tuple space operations. Each tuple had a designated node on which it would be stored, usually chosen via hashing. Naively, each out/in pair would require as many as three distinct messages, since out would require a single message sending the tuple to its storage location, and in would require two messages, a request to the storage location and a reply containing the matched tuple. Bjornson [5] built upon Carriero's compile-time optimizations by analyzing tuple traffic at runtime, recognizing common communication patterns such as broadcast (one-to-many), point-to-point, and many-to-one, and rearranging tuple space storage to minimize the number of messages required. This work demonstrated that most communication in Linda required only one or two sends, just as with message passing.

Overall, this work demonstrated that while in the abstract Linda programs could make unrestrained use of expensive operations such as content addressability and extensive search, in practice any given program was likely to confine itself to well-understood patterns that could be reduced through analysis to much simpler and more efficient low-level operations.

Implementations of Linda closely followed hardware developments in parallel computing. The first implementation was on a custom, bus-based architecture called the S/Net [4], followed by implementations on shared memory multiprocessors (Sequent Balance, Encore Multimax), distributed memory multiprocessors (Intel iPSC/1 and 2 hypercubes, Ncube, IBM SP1), collections of workstations, and true cluster architectures.

In terms of host languages, Linda has been embedded in many of the most commonly used computer languages. Initial imbedding was done in C, but important embeddings were built in Fortran, Lisp, and Prolog. In the 1990s, Java became an important host language for Linda, including the Jini, JavaSpaces [6], and Gigaspaces [7] implementations. More recently, Scientific Computing Associates (SCAI) created a variant of Linda

called NetWorkSpaces that is designed for interactive languages such as Perl, Python, R (see below).

## Open Linda

Initial compile-time Linda systems can be termed “closed,” in the sense that the Linda compiler needed to see all Linda operations that would ever occur in the program, in order to perform the analysis and optimization. In addition, only a single global tuple space was provided, which was created when the program started and destroyed when it completed. Linda programs tended to be collections of closely related processes that stemmed from the same code, and started, ran for a finite period, and stopped together.

During the 1990s, interest in distributed computing increased dramatically, particularly computing on collections of workstations. These applications consisted of heterogeneous collections of processes that derived from unrelated code, started and stopped independently, and might run indefinitely. The components could be written by different users and using different languages. In 1995, SCAI developed an Open Linda (Open referred to the fact that the universe of tuples remained flexible and open at runtime, rather than fixed and closed at compile time), which was later trademarked as “Paradise.” With Open Linda, tuple spaces became first-class objects. They could be created and destroyed as desired, or persist beyond the lifetime of their creator. Other Open Lindas that were created include JavaSpaces [6], TSpaces [8], and Gigaspaces [7].

In 2005 SCAI created a simplified Open Linda called NetWorkSpaces (NWS) [9], designed specifically for high productivity languages such as Perl, R, Python, Matlab, etc. In NetWorkSpaces, rather than communicating via tuples in tuple spaces, processes use shared variables stored in network spaces. Rather than use associative lookup via matching, in NetWorkSpaces shared data is represented as a name/value binding. Processes can create, consult, and remove bindings in shared network spaces.

[Figure 3](#) contains an excerpt from a NWS code for performing a maximization search, using the Python API. In NWS, store, find, and fetch correspond to Linda's out, rd, and in, respectively. In the code, a single shared variable “max” is used to hold the current best value found by any worker. The call NetWorkSpace (“my

```

def init():
 ws=NetWorkSpace('my space')
 ws.store('max', START)

def worker():
 ws=NetWorkSpace('my space')
 for x in MyCandidateList:
 currentMax = ws.find('max')
 y = f(x)
 if y > currentMax:
 currentMax = ws.fetch('max')
 if y > currentMax: currentMax = y
 ws.store('max', currentMax)

```

**Linda. Fig. 3** Excerpt of NetWorkSpaces code for performing a maximization search

space") connects to the space of that name, creating it if necessary, and returning a handle to it.

### Key Characteristics of Linda, and Comparison to Other Approaches

Linda presents a number of interesting characteristics that contrast with other approaches to parallel computing:

**Portability:** A Linda program can run on any parallel computer, regardless of the underlying parallel infrastructure and interconnection, whether it be distributed- or shared-memory or something in between. Most competing parallel approaches are strongly biased toward either shared- or distributed-memory.

**Generative Communication:** In Linda, when processes communicate, they create tuples, which exist apart from the process that created them. This means that the communication can exist long after the creating process has disappeared, and can be used by processes unaware of that process' existence. This aids debugging, since tuples are objects that can be inspected using tools like TupleScope [10].

**Distribution in space and time:** Processes collaborating via tuple spaces can be widely separated over both these dimensions. Because Linda forms a virtual shared memory, processes need not share any physical memory. Because tuples exist apart from processes, those processes can communicate with one another even if they don't exist simultaneously.

**Content Addressability:** Processes can select information based on its content, rather than just a tag or

the identity of the process that sent it. For example, one can build a distributed hash table using tuples.

**Anonymity:** Processes can communicate with one another without knowing one another's location or identity. This allows for a very flexible style of parallel program. For example, in a system called Piranha [11], idle compute cycles are harvested by creating and destroying workers on the fly during a single parallel run. The set of processes participating at any given time changes constantly. Linda allows these dynamic workers to communicate with the master, and even with one another, because processes need not know details about their communication partners, so long as they agree on the tuples they use to communicate.

**Simplicity:** Linda consists of only four operations, in, out, rd, eval, and two variants, inp and rdp. No additional synchronization functions are needed, nor any administrative functions.

When Linda was invented in the early 1980s, there were two main techniques used for parallel programming: shared memory with low-level locking, and message passing. Each parallel machine vendor chose one of these two styles and built their own, idiosyncratic API. For example, the first distributed-memory parallel computers (Intel iPSC, nCube, and IBM SP1) each had their own proprietary message passing library, which was incompatible with all others. Similarly, the early shared-memory parallel computers (Sequent Balance, Encore Multimax) each had their own way of allocating shared pages and creating synchronization locks.

Linda presented a higher level approach to parallelism that combined the strengths of both. Like shared memory, Linda permits direct access to shared data (no need to map such data onto an "owner" process, as is the case for message passing). Like message passing, Linda self-synchronizes (no need to worry about accessing uninitialized shared data, as is the case for hardware shared memory). Once the corresponding Linda implementation had been ported to a given parallel computer, any Linda program could be simply recompiled and run correctly on that computer.

At the time of this writing, it is fair to say that message passing, as embodied by Message Passing Interface (MPI), has become the dominant paradigm for writing parallel programs. MPI addressed the portability

problem in message passing by creating a uniform library interface for sending and receiving messages. Because of the importance of MPI to parallel programming, it is worth contrasting Linda and MPI.

*Compiler Support:* Linda's compiler support performs both type and syntax checking. Since the Linda compiler understands the types of the data being passed through tuple space, marshalling can be done automatically. The compiler can also detect outs that have no matching in, or vice versa, and issue a warning. In contrast, MPI is a runtime library, and the burdens of type checking and data marshalling fall largely to the programmer.

*Decoupled/anonymous communication:* In Linda, communicating processes are largely decoupled. In MPI, processes must know one another's location and exist simultaneously. In addition, receivers must anticipate sends. If, on the hand, the coordination needed by an application lends itself to a message passing style solution, this is still easy to express in Linda using associative matching. In this case, the compile and runtime optimization techniques discussed will often result in wire traffic similar, if not identical, to that obtained if message passing was used.

*Simplicity:* MPI is a large, complex API. Debugging usually requires the use of a sophisticated parallel debugger. Even simple commands such as `send()` exist in a number of subtly differently variants. In the spirit of Alan Perlis's observation "If you have a procedure with 10 parameters, you probably missed some," the MPI standard grew substantially from MPI 1 to MPI 2. Acknowledging the lack of a simple way to share data, MPI 2 introduced one-sided communication. This was not entirely successful [12]. In contrast, Linda consists of four simple commands.

## Future

In 2010, parallel computing stands at an interesting crossroads. The largest supercomputer in the world contains 224,000 cpus [13]. Meanwhile, multicore systems are ubiquitous; modern high performance computers typically contain 8–32 cpu cores, with hundreds envisioned in the near future. These two use cases represent two very different extrema on the spectrum of parallel programming. The largest supercomputers require

extremely efficient parallel codes in order to scale to tens of thousands of cpus, implying expert assistance by highly skilled programmers, careful coding, optimization and verification of programs, and are well suited to large-scale development efforts in languages such as C and tools such as MPI.

In contrast, nearly everyone with a compute-bound program will have access to a non-trivial parallel computer containing tens or hundreds of cpus, and will need a way to make effective use of those cpus.

An interesting characteristic of many of these users is that, rather than using traditional high performance languages such as C, Fortran, or even Java, they use scripting languages such as Perl, Python or Ruby, or high-productivity environments such as Matlab or R. These languages dramatically improve their productivity in terms of writing and debugging code, and therefore in terms of their overall goals of exploring data or testing theories. That is, they have explicitly opted for simplicity and expressivity in their tool of choice for sequential programming. However, these environments pose major challenges in terms of performance and memory usage. Parallelism on a relatively modest scale can permit these users to compute effectively while remaining comfortably within an environment they find highly productive. But, to be consistent with the choice made when selecting these sequential computing environments, the parallelism tool must also emphasize simplicity and expressivity. High level coordination languages like Linda can provide them with simple tools for accessing that parallelism.

## Influences

Some of the work influencing Linda includes: Sussman and Steele's language, Scheme, particularly continuations [14], Dijkstra's semaphores [15], Halstead's futures [16], C.A.R. Hoare's CSP [17], and Shapiro's Concurrent Prolog [18], particularly the concept of unification.

## History

Linda was initially conceived by David Gelernter while a graduate student at SUNY Stony Brook in the early 1980s. After taking a faculty position at Yale University in 1982, Gelernter, along with a number of graduate students, most notably Carriero, built a number of Linda implementations as well as high level applications that used Linda.

In the early 1990s Scientific Computing Associates (SCAI), founded by Yale professors Stan Eisenstat and Martin Schultz, began commercial development of Linda. Linda systems created by SCAI were sold in a variety of industries, most notably finance and energy. Large-scale systems, running on hundreds of computers, were built and used in production environments for years at a time, performing tasks such as portfolio pricing, risk analysis, and seismic image processing.

Around 2000, interest grew in more flexible languages and approaches. Java became the rage, particularly in financial organizations, and a number of commercial Java Linda systems were built. Although they varied in detail, all shared many common features: an object oriented design, open tuple spaces, and support for transactions.

## Linear Algebra Software

JACK DONGARRA, PIOTR LUSZCZEK  
University of Tennessee, Knoxville, TN, USA

### Definition

Linear algebra software is software that performs numerical calculations aimed at solving a system of linear equations or related problems such as eigenvalue,

singular value, or condition number computations. Linear algebra software operates within the confines of finite precision floating-point arithmetic and is characterized by its computational complexity with respect to the sizes of matrix and vectors involved. Equally important metric is that of numerical robustness: The linear algebra methods aim to deliver a solution that is as close as possible (in a numerical sense by taking into account the accuracy of the input data) to the true solution (obtained in sufficiently extended floating-point precision) if such a solution exists.

## Discussion

The increasing availability of high-performance computers has a significant effect on all spheres of scientific computation, including algorithm research and software development in numerical linear algebra. Linear algebra – in particular, the solution of linear systems of equations – lies at the heart of most calculations in scientific computing. There are two broad classes of algorithms: those for dense, and those for sparse matrices. A matrix is called sparse if it has a substantial number of zero elements, making specialized storage and algorithms necessary.

Much of the work in developing linear algebra software for high-performance computers is motivated by the need to solve large problems on the fastest computers available. For the past 15 years or so, there has been a great deal of activity in the area of algorithms and software for solving linear algebra problems. The goal of achieving high performance on codes that are portable across platforms has largely been realized by the identification of linear algebra kernels, the Basic Linear Algebra Subprograms (BLAS). See discussion of the EISPACK, LINPACK, LAPACK, and ScaLAPACK libraries, which are expressed in successive levels of the BLAS.

The key insight to designing linear algebra algorithms for high-performance computers is that the frequency with which data are moved between different levels of the memory hierarchy must be minimized in order to attain high performance. Thus, the main algorithmic approach for exploiting both vectorization and parallelism in various implementations is the use of block-partitioned algorithms, particularly in conjunction with highly tuned kernels for performing

matrix–vector and matrix–matrix operations (the Level 2 and 3 BLAS).

Algorithms for sparse matrices differ drastically because they have to take full advantage of sparsity and its particular structure. Optimization techniques differ accordingly due to changes in the memory access patterns and data structures. Commonly, then, the sparse methods are discussed separately.

## Dense Linear Algebra Algorithms

### Origins of Dense Linear Systems

A major source of large dense linear systems is problems involving the solution of boundary integral equations [1]. These are integral equations defined on the boundary of a region of interest. All examples of practical interest compute some intermediate quantity on a two-dimensional boundary and then use this information to compute the final desired quantity in three-dimensional space. The price one pays for replacing three dimensions with two is that what started as a sparse problem in  $O(n^3)$  variables is replaced by a dense problem in  $O(n^2)$ .

Dense systems of linear equations are found in numerous applications, including:

- Airplane wing design
- Radar cross-section studies
- Flow around ships and other off-shore constructions
- Diffusion of solid bodies in a liquid
- Noise reduction
- Diffusion of light through small particles

The electromagnetics community is a major user of dense linear systems solvers. Of particular interest to this community is the solution of the so-called radar cross-section problem. In this problem, a signal of fixed frequency bounces off an object; the goal is to determine the intensity of the reflected signal in all possible directions. The underlying differential equation may vary, depending on the specific problem. In the design of stealth aircraft, the principal equation is the Helmholtz equation. To solve this equation, researchers use the *method of moments* [2, 3]. In the case of fluid flow, the problem often involves solving the Laplace or Poisson equation. Here, the boundary integral solution is known as the *panel methods* [4, 5], so named from the quadrilaterals that discretize and approximate a

structure such as an airplane. Generally, these methods are called *boundary element methods*.

Use of these methods produces a dense linear system of size  $O(N)$  by  $O(N)$ , where  $N$  is the number of boundary points (or panels) being used. It is not unusual to see size  $3N$  by  $3N$ , because of three physical quantities of interest at every boundary element.

A typical approach to solving such systems is to use LU factorization. Each entry of the matrix is computed as an interaction of two boundary elements. Often, many integrals must be computed. In many instances, the time required to compute the matrix is considerably larger than the time for solution.

The builders of stealth technology who are interested in radar cross sections are using direct Gaussian elimination methods for solving dense linear systems. These systems are always symmetric and complex, but not Hermitian.

## Basic Elements in Dense Linear Algebra Methods

Common operations involving dense matrices are the solution of linear systems  $Ax = b$ , the least squares solution of over- or underdetermined systems  $\min_x \|Ax - b\|_2$ , and the computation of eigenvalues and vectors  $Ax = \lambda x$ . Although these problems are formulated as matrix–vector equations, their solution involves a definite matrix–matrix component. For instance, in order to solve a linear system, the coefficient matrix is first factored as  $A = LU$  (or  $A = U^T U$  in the case of symmetry) where  $L$  and  $U$  are lower and upper triangular matrices, respectively. It is a common feature of these matrix–matrix operations that they take, on a matrix of size  $n$  by  $n$ , a number of operations proportional to  $n^3$ , a factor  $n$  more than the number of data elements involved.

It is possible to identify three levels of linear algebra operations:

- Level 1: vector–vector operations such as the update  $y \leftarrow y + \alpha x \times y$  and the inner product  $\alpha = x^T y$ . These operations involve (for vectors of length  $n$ )  $O(n)$  data and  $O(n)$  operations.
- Level 2: matrix–vector operations such as the matrix–vector product. These involve  $O(n^2)$  operations on  $O(n^2)$  data.

- Level 3: matrix–matrix operations such as the matrix–matrix product  $C = AB$ . These involve  $O(n^3)$  operations on  $O(n^2)$  data.

These three levels of operations have been realized in a software standard known as the Basic Linear Algebra Subprograms (BLAS) [6–8]. Although BLAS routines are freely available on the net, many computer vendors supply a tuned, often assembly-coded, BLAS library optimized for their particular architecture. The relation between the number of operations and the amount of data is crucial for the performance of the algorithm.

## Optimized Implementations

Due to its established position, BLAS form the foundation for optimized dense linear algebra operation on homogeneous as well as heterogeneous multicore architectures. Similarly, LAPACK API serves as the defacto standard for accessing various decompositional techniques. Currently active optimized implementations include ACML from AMD, cuBLAS from NVIDIA, LibSci from Cray, MKL from Intel, and open source ATLAS. In the distributed memory regime, Basic Linear Algebra Communication Subroutines (BLACS), PBLAS, and ScaLAPACK serve the corresponding role of defining an API and are accompanied by vendor-optimized implementations.

## Sparse Linear Algebra Methods

### Origin of Sparse Linear Systems

The most common source of sparse linear systems is the numerical solution of partial differential equations. Many physical problems, such as fluid flow or elasticity, can be described by partial differential equations (PDE). These are implicit descriptions of a physical model, describing some internal relation such as stress forces. In order to arrive at an explicit description of the shape of the object or the temperature distribution, the PDE needs to be solved, and for this, numerical methods are required.

### Discretized Partial Differential Equations

Several methods for the numerical solution of PDEs exist, the most common ones being the methods of finite elements, finite differences, and finite volumes. A common feature of these is that they identify discrete

points in the physical object, and give a set of equations relating these points.

Typically, only points that are physically close together are related to each other in this way. This gives a matrix structure with very few nonzero elements per row, and the nonzeros are often confined to a “band” in the matrix.

### Sparse Matrix Structure

Matrices from discretized partial differential equations contain so many zero elements that it pays to find a storage structure that avoids storing these zeros. The resulting memory savings, however, are offset by an increase in programming complexity, and by decreased efficiency of even simple operations such as the matrix–vector product.

More complicated operations, such as solving a linear system, with such a sparse matrix present a next level of complication, as both the inverse and the *LU* factorization of a sparse matrix are not as sparse, thus needing considerably more storage. Specifically, the inverse of a band sparse matrix is a full matrix, and factoring such a sparse matrix fills in the band completely.

### Basic Elements in Sparse Linear Algebra

#### Methods

Methods for sparse systems use, like those for dense systems, vector–vector, matrix–vector, and matrix–matrix operations. However, there are some important differences.

For iterative methods, there are almost no matrix–matrix operations. Since most modern architectures prefer these Level 3 operations, the performance of iterative methods will be limited from the outset.

An even more serious objection is that the sparsity of the matrix implies that indirect addressing is used for retrieving elements. For example, in the popular row-compressed matrix storage format, the matrix–vector multiplication looks like

```
for i=1 ... n
 p←pointer to row i
 for j=1 ... ni
 yi ← yi + a(p+j)* (c(p+j))
```

where  $n_i$  is the number of nonzeros in row  $i$ , and  $p(.)$  is an array of column indices. A number of such algorithms for several sparse data formats are given in [9].

Direct methods can have a BLAS 3 component if they are a type of dissection method. However, in a given sparse problem, the denser the matrices are, the smaller they are on average. They are also not general full matrices, but only banded. Thus, very high performance should not be expected from such methods either.

### Direct Sparse Solution Methods

For the solution of a linear system, one needs to factor the coefficient matrix. Any direct method is a variant of Gaussian elimination. As remarked above, for a sparse matrix, this fills in the band in which the nonzero elements are contained. In order to minimize the storage needed for the factorization, research has focused on finding suitable orderings of the matrix. Re-ordering the equations by a symmetric permutation of the matrix does not change the numerical properties of the system in many cases, and it can potentially give large savings in storage. In general, direct methods do not make use of the numerical properties of the linear system, and thus, their execution time is affected in a major way by the structural properties of the input matrix.

### Iterative Solution Methods

Direct methods, as sketched above, have some pleasant properties. Foremost is the fact that their time to solution is predictable, either *a priori*, or after determining the matrix ordering. This is due to the fact that the method does not rely on numerical properties of the coefficient matrix, but only on its structure. On the other hand, the amount of fill can be substantial, and with it the execution time. For large-scale applications, the storage requirements for a realistic size problem can simply be prohibitive.

Iterative methods have far lower storage demands. Typically, the storage, and the cost per iteration with it, is of the order of the matrix storage. However, the number of iterations strongly depends on properties of the linear system, and is at best known up to an order estimate; for difficult problems, the methods may not even converge due to accumulated round-off errors.

### Basic Iteration Procedure

In its most informal sense, an iterative method in each iteration locates an approximation to the solution of the problem, measures the error between the approximation and the true solution, and based on the

error measurement improves on the approximation by constructing a next iterate. This process repeats until the error measurement is deemed small enough.

### Stationary Iterative Methods

The simplest iterative methods are the “stationary iterative methods.” They are based on finding a matrix  $M$  that is, in some sense, “close” to the coefficient matrix  $A$ . Instead of solving  $Ax = b$ , which is deemed computationally infeasible,  $Mx_1 = b$  is solved. The true measure of how well  $x_1$  approximates  $x$  is the error  $e_1 = x_1 - x$ , but, since the true solution  $x$  is not known, this quantity is not computable. Instead, the “residual”:  $r_1 = Ae_1 = Ax_1 - b$  is monitored since it is a computable quantity. It is easy to see that the true solution satisfies  $x = A^{-1}b = x_1 - A^{-1}r_1$ , so, replacing  $A^{-1}$  with  $M^{-1}$  in this relation,  $x_2 = x_1 - M^{-1}r_1$  can be defined.

Stationary methods are easily analyzed: It can be proven that  $r_i \rightarrow 0$  if all eigenvalues  $\lambda = \lambda(I - AM^{-1})$  satisfy  $|\lambda| < 1$ . For certain classes of  $A$  and  $M$ , this inequality is automatically satisfied [10, 11].

### Krylov Space Methods

The most popular class of iterative methods nowadays is that of “Krylov space methods.” The basic idea there is to construct the residuals such that the  $n$ -th residual  $r_n$  is obtained from the first by multiplication by some polynomial in the coefficient matrix  $A$ , that is,  $r_n = P^{n-1}(A)r_1$ . The properties of the method then follow from the properties of the actual polynomial [12–14].

Most often, these iteration polynomials are chosen such that the residuals are orthogonal under some inner product. From this, one usually obtains some minimization property, though not necessarily a minimization of the error.

Since the iteration polynomials are of increasing degree, it is easy to see that the main operation in each iteration is one matrix–vector multiplication. Additionally, some vector operations, including inner products in the orthogonalization step, are needed.

### Optimized Implementations

Sparse BLAS used to be available from some of the vendors. The more common approach is to have the dedicated sparse packages available publicly and have the vendors tune them for their software offerings. Examples of direct sparse solvers include MUMPS, SuperLU, UMFPACK, and Parafac. The iterative solvers in wide

use are PETSc and Trilinos. Also, autotuning efforts such as OSKI aim to provide basic building blocks for use with more complete iterative method frameworks.

### Available Software

You will find a comprehensive list of open source software that is freely available for solving problems in numerical linear algebra, specifically dense, sparse direct and iterative systems and sparse iterative eigenvalue problems at: <http://www.netlib.org/utk/people/JackDongarra/la-sw.html>

A sparse matrix is one that is populated mainly with zeros, and hence the need for storing only the nonzero elements especially for large problems. In the context of sparse matrix computations, one usually refers to sparse matrices with irregular sparsity structure. Designing algorithms that realize high performance for structured sparse matrix computations is much easier than the case of irregular sparsity. Irregular sparsity leads to lack of data locality and expensive memory references across the memory hierarchies of modern parallel architectures. While the creation of a standard set of *Sparse Basic Linear Algebra Subroutines* (SBLAS) was not as successful as the classical dense BLAS the most important kernels in sparse matrix computations are: (i) sparse matrix–vector multiplication and (ii) sparse matrix–tall dense matrix multiplication. Next to generating and applying preconditioners, these two kernels have a substantial impact on the realizable performance of Krylov subspace iterative schemes on these architectures.

One should also state that in *Finite Element Analysis* it has been the tradition to resort to *matrix-free* computations where the sparse matrices involved are not stored explicitly but algorithms are provided to compute their action, or the action of functions of such matrices, on a vector or a block of vectors. Such *matrix-free* approach makes it rather difficult to use effective preconditioners for solving large sparse linear systems with the needed iterative methods. Thus, matrix-free formulations may not be the optimal choice when using the emerging petascale parallel architectures with their abundant memories.

## Dense Matrix Computations

Unlike sparse matrix computations, dense matrix algorithms benefit from the regular storage of the dense matrices involved to achieve high data locality and hence high performance through the fine-tuned three-level dense BLAS on parallel architectures. The third level of this set BLAS-3 includes matrix–matrix multiplications, which are the procedures that reach the highest rate of computation on such architectures. Even when dealing with sparse matrix computations, the goal is often to transform algorithms that are originally vector-oriented into their block versions so as to involve dense matrix multiplications. Moreover, the very popular Krylov methods for solving sparse linear systems or eigenvalue problems consist of projecting the

Matrix computations

### Definition

Numerical linear algebra (or matrix computations) is the design and analysis of matrix operations and algorithms. Matrix computations plays a vital role in enabling the majority of computational science and engineering applications. Examples of such applications include: computational fluid dynamics, structural mechanics, fluid-structure interaction, computational electromagnetics, image processing, web search (PageRank), and information retrieval, just to list a few. Matrix computations can be divided into two classes: (a) dense matrix computations, and (b) sparse matrix computations, with the former being rich in data locality and hence can readily achieve high performance on modern architectures. The basic standard problems in numerical linear algebra are: (i) solving linear systems of equations, (ii) solving linear least squares problems with or without constraints, (iii) solving standard and generalized eigenvalue problems, and (iv) obtaining singular values or singular triplets of a matrix.

### Discussion

#### Sparse Matrix Computations

The overwhelming majority of science and engineering applications give rise to sparse matrix computations.

initial sparse problem onto some subspace of reduced dimension, leading to a similar dense matrix problem.

## Definition

A **linear least squares problem** is given by

obtain  $x \in \mathbb{R}^n$ , such that the two-norm  $\|b - Ax\|$  is minimized, (1)

where  $A \in \mathbb{R}^{m \times n}$  and  $b \in \mathbb{R}^m$ . The vector  $x$  is a solution if and only if the residual  $r = b - Ax$  is orthogonal to the range of  $A$ :  $A^T r = 0$ . When  $A$  is of full column rank  $n$ , there exists a unique solution. When  $\text{rank}(A) < n$ , the solution of choice is that one with the smallest two-norm.

## Discussion

**Note:** The number of the floating-point operations (additions, multiplications, divisions, square roots) of the algorithms are simply called operations in what follows.

## Full Rank Standard Problem

Consider first the case in which  $n \leq m$  and  $A$  is of full column rank  $n$ .

**General scheme.** Since the two-norm is invariant under orthogonal transformations, the most common approach for solving this least squares problem consists of computing the orthogonal factorization of  $A$ . The procedure amounts to premultiplying  $A$  and  $b$  by a finite number – say  $p$  – of orthogonal transformations  $Q_1, \dots, Q_p$ , such that

$$Q_p \cdots Q_2 Q_1 A = \begin{pmatrix} R \\ 0 \end{pmatrix}, \quad (2)$$

where  $R \in \mathbb{R}^{n \times n}$  is a nonsingular upper triangular or upper trapezoidal matrix. Therefore,

$$\|b - Ax\| = \|Q_p \cdots Q_1(b - Ax)\| = \left\| \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} - \begin{pmatrix} R \\ 0 \end{pmatrix} x \right\|$$

where  $c_1 \in \mathbb{R}^n$ , and the unique solution of (1) is given by solving  $Rx = c_1$ . In what follows, the orthogonal reduction to the triangular form will only be considered. For solving the resulting triangular system, please refer to [BLAS 12.c.ii.1.a, linear solvers 12.c.ii.2.a].

## Householder Reductions

**The sequential algorithm.** Given a vector  $a \in \mathbb{R}^s$ , a vector  $v \in \mathbb{R}^s$  can be determined such that the transformation  $H = H(v) = I_s - \beta vv^T$ , where  $\beta = (2/v^T v)$ , yields  $Ha = \pm \|a\|e_1$  where  $e_1$  is the first canonical vector of  $\mathbb{R}^s$  (there are two such transformations from which one is selected for numerical stability [16]).  $H$  is an elementary reflector, i.e.,  $H$  is orthogonal and  $H^2 = I_s$ . Application of  $H$  to a given vector  $x \in \mathbb{R}^s$  is given by  $H(v)x = x - \beta(v^T x)v$  and computed using two Level 1 BLAS routines [19], namely, DDOT and DAXPY, involving only  $4s$  operations and not  $2s^2$  as the case in matrix-vector multiplication.

The triangularization of  $A$  is obtained by successively applying such orthogonal transformations to  $A$ :  $A_0 = A$  and for  $k = 1 : \min(n, m-1)$ ,  $A_{k+1} = H_k A_k$  where

$$H_k = \begin{pmatrix} I_{k-1} & 0 \\ 0 & H(v_k) \end{pmatrix} \text{ with } v_k \text{ chosen such that all but}$$

the first entry of  $H(v_k)A_k(k : m, k)$  are zero. At step  $k$ , the multiplication  $H_k A_k$  is obtained from  $H(v_k)A_k(k : m, k : n)$  which involves  $4(n-k)(m-k) + O(m-k)$  operations. It can be implemented by two Level 2 BLAS routines [9], namely, the matrix-vector multiplication DGEMV and the rank-one update DGER. The procedure stores the matrix  $A_{k+1}$  in place of  $A_k$ .

The total procedure involves  $2n^2(m-n/3) + O(mn)$  operations for obtaining  $R$ . To apply simultaneously the transformations to the right-hand-side  $b$  of problem (1), one may append that vector as the  $n+1$ st column of  $A$ . When necessary for subsequent calculations, the sequence of the vectors  $(v_k)_{1,n}$  can be stored for instance in the lower part of the transformed matrix  $A_k$ . This is the case when  $n \ll m$  and an orthogonal basis  $\tilde{Q} = [q_1, \dots, q_n] \in \mathbb{R}^{m \times n}$  of the range of  $A$  is sought: the

basis is obtained by premultiplying the matrix  $\begin{pmatrix} I_n \\ 0 \end{pmatrix}$

successively by  $H_n, H_{n-1}, \dots, H_1$ . This process involves  $4(m^2n - mn^2 + n^3/3) + O(mn)$  operations.

Block versions of the procedure have been introduced by Bischof and Van Loan [4] (the  $WY$  form) and by Schreiber and Parlett [25] (the  $GG^T$  form). The generation and application of the  $WY$  form are implemented in the routines DLARFT and DLARFB of LAPACK [1]. The latter involves Level 3 BLAS primitives [9]. The  $WY$  form consists of considering a narrow window in which the single-vector algorithm is used

before applying the corresponding transformations to the remaining part of  $A$ : if  $s$  is the window width,  $s$  steps are accumulated in the form  $H_{k+s} \cdots H_{k+1} = I + WY^T$  where  $W, Y \in \mathbb{R}^{m \times s}$ . This expression allows the use of Level 3 BLAS in updating the remaining part of  $A$ . In LAPACK, the driver routine which implements the resolution of the least square problem (1) is DORGQR.

**The parallel algorithm.** Theoretically, by using  $O(mn)$  processors, the computation may be performed in  $O(n \log m)$  time steps. This is a direct extension to rectangular matrices of Sameh's result [22]: in each of the  $n$  update phases, each scalar product can be performed in  $O(\log m)$  time steps on  $m$  processors and there are at most  $n$  columns to be processed in parallel.

Since, except for very special computing architectures (e.g., systolic arrays), independent tasks cannot be reduced to one operation; a plausible approach is to wrap the columns of  $A$  across a ring of processors as shown in [14]. The block version of the algorithm above is the preferred parallel scheme which is implemented in ScaLAPACK [7] via the routines PDGEQRF and PDGELS where  $A$  and  $b$  are distributed on a two-dimensional grid of processes according to the block cyclic scheme [7] (see [4. Parallel programming / i. Data distribution]). The block size is chosen large enough to allow Level 3 BLAS routines to achieve maximum performances on each involved uniprocessor (at least 90% as recommended by the authors of ScaLAPACK [8]). While increasing the block size improves the granularity of the computation, it may negatively affect concurrency. An optimal tradeoff therefore must be found depending on the architecture of the computing platform.

## Givens Rotations

**The sequential algorithm.** In the standard Givens' process, the orthogonal matrices in (2) consist of  $p = mn - n(n+1)/2$  plane rotations extended to the entire space  $\mathbb{R}^m$ . The triangularization of  $A$  is obtained by successively applying plane rotations  $R_k$ , so that  $A_{k+1} = R_k A_k$  for  $k = 1 : mn - n(n+1)/2$  with  $A_0 = A$ . Each of these rotations will be chosen to introduce a single zero below the diagonal of  $A$ : at step  $k$ , eliminating the entry  $a_{i\ell}^{(k)}$  of  $A_k$  where  $1 \leq \ell \leq n$  and  $1 < i \leq m$  can be done by the rotation

$$R_{ij}^{(k)} = \begin{pmatrix} 1 & & & & & \\ & \ddots & & & & \\ & & 1 & & & \\ & & & \ddots & & \\ & & & & 1 & \\ & & -s & & & c \\ & & & & & 1 \\ & & & & & & 1 \end{pmatrix} \quad (3)$$

where  $1 \leq j \leq n$ , and  $c^2 + s^2 = 1$  are such that

$$\begin{pmatrix} c & s \\ -s & c \end{pmatrix} \begin{pmatrix} a_{j\ell}^{(k)} \\ a_{i\ell}^{(k)} \end{pmatrix} = \begin{pmatrix} a_{j\ell}^{(k+1)} \\ 0 \end{pmatrix}.$$

Two such rotations exist from which one is selected for numerical stability [16]. The construction of a rotation and its application to a couple of rows are implemented in the Level 1 BLAS [19] via the procedures DROTG and DROT, respectively.

The order of annihilation is quite flexible as long as applying a new rotation does not destroy a previously introduced zero. The simplest way is to organize columnwise eliminations. The total number of operations is  $3mn^2 - n^3 + O(mn)$  which is roughly 1.5 times that required by the Householder's reduction.

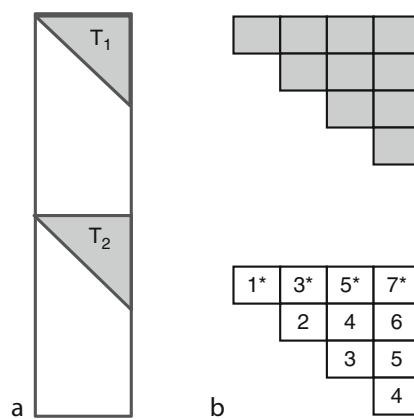

**Parallel algorithms.** One parallel algorithm consists of organizing the  $mn - n/(n + 1)/2$  rotations into sweeps which are sets of at most  $\lfloor m/2 \rfloor$  parallel rotations. For square matrices, Sameh and Kuck [24] and later, Cosnard and Robert [12], introduced such  $O(n)$  procedures using  $O(n^2)$  processors. In the general situation of rectangular matrices, Cosnard et al. in [11] proved the theoretical optimality of the greedy algorithm introduced by Modi and Clarke in [21] over any other algorithm. More details on the chronological appearance of the Givens algorithms and

their comparison with the Householder reductions are given in [14].

## Hybrid Algorithms ( $m \gg n$ )

**Dense matrix.** This is a situation that arises in some computations like in the adjustment of geodetic networks [15], or in the parallel construction of a Krylov basis where often  $m$  is larger than a million and  $n$  is smaller than 100 [26].

The algorithm was introduced by Sameh [23]. It is depicted in Fig. 1 in the case where two processors are used. It consists of partitioning  $A$  into contiguous blocks of  $r$  rows where  $r \geq n$ , with each block assigned to one processor. In the first step (Fig. 1a), each block is triangularized by Householder reduction. This step consumes the major part of the overall computation and is void of any communications. The second step is devoted to annihilating all the resulting triangular factors except the first one. There are several possibilities for achieving this goal. In [15], for annihilating the entries of the triangular matrix  $T_2$ , the rotations are chosen as depicted in Fig. 1b. The entry (1,1) of the first row of  $T_2$  is annihilated by rotating the first rows of  $T_1$  and  $T_2$ . Then all the other entries of the first diagonal of  $T_2$  can easily be annihilated by rotating rows of  $T_2$ . As soon as the entry (2,2) of  $T_2$  is annihilated, the entry (1,2) of  $T_2$  can be annihilated before the annihilation of the first diagonal of the matrix is completed. Rotations indicated with stars are the only ones which require synchronization.

## Linear Least Squares and Orthogonal Factorization. Fig. 1

By following that strategy, Sidje [26] developed the software RODDEC which performs the QR factorization on a ring of processors.

**Block angular matrix.** In some applications, a domain decomposition provides a matrix such that under some appropriate numbering of the domains and corresponding interfaces, the matrix  $A$  is of the form:

$$A = \begin{pmatrix} B_1 & C_1 \\ B_2 & C_2 \\ \ddots & \vdots \\ B_r & C_r \end{pmatrix} \quad (4)$$

where  $A$  as well as each block  $B_i$ , for  $i = 1, \dots, r$  is of full column rank. The special structure implies that the QR factorization of  $A$  yields an upper triangular matrix with the same block structure; this can be seen as shown by Golub et al. in [15] from the Cholesky factorization of  $A^T A$  which is a block arrowhead matrix. Therefore, similar to the first step of the algorithm previously described, for  $i = 1, \dots, r$ , processor  $i$  first performs the QR factorization of the block  $B_i$ . The corresponding blocks of  $[B_i, C_i]$  are now transformed into  $\begin{pmatrix} R_i \\ 0 \end{pmatrix}, \begin{pmatrix} D_{i1} \\ D_{i2} \end{pmatrix}$ . By virtually reordering the block

rows, the resulting matrix can be expressed by :

$$A_1 = \begin{pmatrix} R_1 & D_{11} \\ R_2 & D_{21} \\ \ddots & \vdots \\ R_r & D_{r1} \\ D_{12} & \\ D_{22} & \\ \vdots & \\ D_{r2} & \end{pmatrix}. \quad (5)$$

To complete the QR factorization of  $A$ , it is therefore necessary to obtain the QR factorization of the submatrix defined by the sub-blocks  $D_{i2}$  for  $i = 1, \dots, r$ . This is exactly the situation where the procedure RODDEC
