can be used. Other approaches can also be considered as mentioned in [6]. For instance Golub et al. in [15] introduce a version of the algorithm adapted to the hierarchical definition of the subdomains. The algorithm takes advantage of the locality of the frontiers to minimize communications.

**Gram-Schmidt procedures.** The goal of these procedures is to obtain the orthogonal factorization  $A = QR$  of a full rank matrix  $A = [a_1, \dots, a_n] \in \mathbb{R}^{m \times n}$  where  $Q = [q_1, \dots, q_n] \in \mathbb{R}^{m \times n}$  has orthonormal columns, and  $R \in \mathbb{R}^{n \times n}$  is a nonsingular upper-triangular matrix with positive diagonal elements thus insuring the uniqueness of the factorization. This factorization is often referred to as the *skinny* QR factorization. Since orthogonality of the vectors  $q_j$  deteriorates rather quickly, reorthogonalization is often necessary. The general structure of the scheme is given by

ALGORITHM : Gram-Schmidt

```
do k = 0 : n-1,
 w = P_k(a_{k+1});
 q_{k+1} = w / \|w\|;
end
```

where  $P_k$  is the orthogonal projector onto the orthogonal complement of the subspace spanned by  $\{a_1, \dots, a_k\}$  ( $P_0$  is the identity).  $R = Q^T A$  can be built step by step during the process.

Two different versions of the algorithm are obtained by expressing  $P_k$  in distinct ways:

**Classical\_GS:** for the Classical Gram-Schmidt  $P_k = I - Q_k Q_k^T$ , where  $Q_k = [q_1, \dots, q_k]$ . Unfortunately, this version has been proved by Bjorck [5] to be numerically unreliable except when it is applied two times which makes it numerically equivalent to **Modified\_GS**.

**Modified\_GS:** for the Modified Gram-Schmidt  $P_k = (I - q_k q_k^T) \cdots (I - q_1 q_1^T)$ . Numerically, the columns of  $Q$  are orthogonal up to a tolerance determined by the machine precision multiplied by the condition number of  $A$  [5]. By applying the algorithm a second time (i.e., with complete reorthogonalization), the columns of  $Q$  become orthogonal up to the tolerance determined by the machine precision parameter similar to the Householder or Givens reductions.

The basic procedures involve  $mn^2 + O(mn)$  operations. `Classical_GS` is based on Level 2 BLAS procedures but it must be applied two times while `Modified_GS` is based on Level 1 BLAS routines. By inverting the two loops of `Modified_GS`, the procedure can proceed with a Level 2 BLAS routine. This is only possible when  $A$  is available explicitly (for instance, this is not possible with the Arnoldi procedure [Krylov methods 12.c.ii.3.f]).

In order to proceed with Level 3 BLAS routines, a block version `Block_GS` is obtained by considering blocks of vectors instead of single vectors in `Modified_GS` and by replacing the normalizing step by an application of `Modified_GS` on the individual blocks. Jalby and Philippe [17] proved that it is necessary to apply the normalizing step twice to reach the numerical accuracy of `Modified_GS`. However, with  $q$  blocks of  $r$  vectors ( $n = qr$ ), the `Block2_GS` procedure only involves  $(1/q)(mn^2) + O(mn)$  additional operations which makes `Block2_GS` faster than `Modified_GS` as soon as  $q$  is not too small.

Parallel implementations of the different forms of Gram-Schmidt orthogonalization are similar to those of Gauss elimination schemes in which there are two nested loops of vector operations. To orthogonalize the columns of  $A$  on a cluster, the procedure `Modified_GS` can be expressed by:

```
ALGORITHM : Parallel Modified_GS
do j=1 : n,
 aj = aj / ||aj|| ;
 doall k = j+1 : n,
 ak = ak - (aj^T ak)aj ;
 end
end
```

By inserting a synchronizing mechanism to insure that normalizing a vector happens only after it is completely updated, it is even possible to transform the sequential outer loop into a `doacross` loop.

On distributed memory platforms, this algorithm may also be used, but it might be more efficient to use a block partitioning similar to that of ScaLAPACK for either `Modified_GS` or `Block2_GS`.

## Other Least Squares Problems

**Rank-deficient problems.** When  $A$  is rank  $q < n$ , there is an infinite set of solutions for (1): for any solution  $x$ , the

set of all solutions is expressed by  $\mathcal{S} = x + \mathcal{N}(A)$  where  $\mathcal{N}(A)$  is the  $(n - q)$ -dimensional null space of  $A$ . The Singular Value Decomposition (SVD) of  $A$  is given by

$$A = U \begin{pmatrix} \Sigma & 0_{q,n-q} \\ 0_{m-q,q} & 0_{m-q,n-q} \end{pmatrix} V^T, \quad (6)$$

where the diagonal entries of the matrix  $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_q)$  are positive,  $U \in \mathbb{R}^{m \times m}$ ,  $V \in \mathbb{R}^{n \times n}$  are

orthogonal matrices. Let  $c = U^T b = \begin{pmatrix} c_1 \\ c_2 \end{pmatrix}$  where  $c_1 \in \mathbb{R}^q$ . Therefore,  $x \in \mathcal{S}$  if and only if there exists  $y \in \mathbb{R}^{n-q}$  such that  $x = V \begin{pmatrix} \Sigma^{-1} c_1 \\ y \end{pmatrix}$  and the corresponding minimum residual norm is equal to  $\|c_2\|$  which is null when  $m = q$ . In  $\mathcal{S}$ , the classically selected solution is the one with the smallest norm, i.e., when  $y = 0$ .

**Householder QR with column pivoting.** In order to avoid computing the singular-value decomposition which is quite expensive, the factorization (6) is often replaced by a similar factorization where  $\Sigma$  is not assumed to be diagonal. Such factorizations are called *complete orthogonal factorizations*. One way to compute such factorization relies on the procedure introduced by Businger and Golub [10]. It computes the QR factorization by Householder reductions with column pivoting. Factorization (2) is now replaced by

$$Q_q \cdots Q_2 Q_1 A P_1 P_2 \cdots P_q = \begin{pmatrix} T \\ 0 \end{pmatrix}, \quad (7)$$

where matrices  $P_1, \dots, P_q$  are permutations and  $T \in \mathbb{R}^{q \times n}$  is upper-trapezoidal. The permutations are determined so as to insure that the absolute values of the diagonal entries of  $T$  are nonincreasing. To obtain a complete orthogonal factorization of  $A$  the process performs first the factorization (7) and then computes an LQ factorization of  $T$  (equivalent to a QR factorization of  $T^T$ ). The process ends up with a factorization similar to (6) with  $\Sigma$  being a nonsingular lower-triangular matrix.

In LAPACK, Householder QR with column pivoting is implemented in the routine DGEQPF which only involves Level 1 and Level 2 BLAS routines. The new

routine DGEQP3 is proposed with Level 3 BLAS calculations. The rank-deficient linear least squares problems are solved by the routines DGELSX which uses DGEQPF or DGELSY which, in turn, uses DGEQP3.

**Parallel implementation.** In ScaLAPACK, Householder QR with column pivoting and complete orthogonal factorization are both implemented via the routines PDGEQPF and PDTZRZF, respectively.

Bischof introduced a method that avoids global pivoting to achieve a better parallel efficiency [2]. It consists of a local pivoting strategy limited to each block allocated to a single processor. This strategy is numerically acceptable as long as the condition number of a block remains below some threshold. In order to control it, the author uses an Incremental Condition Estimator (ICE) studied in [3]. Achieving adequate local pivoting strategies is a topic that is yet to be completely settled.

**Generalized least squares and total least squares problems.** In many applications, the right-hand-side  $b$  of problem (1) is known only with some uncertainty: its error is known to follow a statistical law given by its covariance matrix  $\Omega$ . In general,  $\Omega$  is positive definite and its Cholesky factorization  $\Omega = LL^T$  does exist. The Generalized Least Squares problem consists of computing  $x \in \mathbb{R}^n$  such that  $\|b - Ax\|_{\Omega^{-1}}$  is minimized. It can therefore be recast into the regular least squares problem: compute  $x \in \mathbb{R}^n$  such that  $\|L^{-1}(b - Ax)\|$  is minimized. This approach is acceptable when (1)  $\Omega$  is not ill-conditioned and (2) the factor  $L$  can be computed.

When the matrix  $A$  suffers from uncertainty as well, the problem becomes one of Total Least Squares. The basic problem is then given by

$$\text{minimize } \| [A; b] - [\hat{A}; \hat{b}] \|_F, \quad \text{subject to } \hat{b} \in R(\hat{A}),$$

where  $\|\cdot\|_F$  denotes the Frobenius norm and where  $R(\hat{A})$  is the range of  $\hat{A}$ . Any  $x \in \mathbb{R}^n$  for which  $\hat{A}x = \hat{b}$  is a Total Least Squares solution (TLS). By denoting, respectively,  $\sigma_n$  and  $\tilde{\sigma}_{n+1}$  the smallest singular values of  $A$  and  $[A; b]$ , assuming that  $\sigma_n > \tilde{\sigma}_{n+1}$ , the only TLS solution is  $\hat{x} = (A^T A - \tilde{\sigma}_{n+1}^2 I)^{-1} A^T b$ . Total Least Squares theory, problems, as well as solution schemes are given by Van Huffel and Vandewalle in [27].

Parallel algorithms for the Generalized or Total Least Squares problems are based on Linear Least

Squares, Cholesky factorization, and Singular Value Decomposition.

Kontoghiorghes considers the Seemingly Unrelated Regression Equations Models (SURE) models as Generalized Least Squares problems [18]. In subsequent work with his co-authors, he considers updating (adding equations to the model), down-dating (deleting equations) as well as parallel resolution of the models. Gang Lou and Shih-Ping Han introduced in [20] a general class of parallel methods for solving other Least Squares problems with constraints.

## Linear Regression

### ► Linear Least Squares and Orthogonal Factorization

## LINPACK Benchmark

JACK DONGARRA, PIOTR LUSZCZEK  
University of Tennessee, Knoxville, TN, USA

### Definition

The LINPACK benchmark is a computer benchmark that reports the performance for solving a system of linear equations with a general dense matrix of size 100, 1,000, and also of arbitrary size. The matrices, the calculations, and the solution must use 64-bit floating point arithmetic, and partial pivoting needs to be used for numerical stability. The allowed parallelism modes include automatic parallelization done by the compiler as well as manual parallelization that uses hardware-assisted shared memory or explicit message passing on a distributed memory machine.

### Discussion

The original LINPACK Benchmark is, in some sense, an accident. It was originally designed to assist users of the LINPACK package [1] by providing information on execution times required to solve a system of linear equations. The first “LINPACK Benchmark” report appeared as an appendix in the LINPACK Users’ Guide in 1979. The appendix comprised data for one commonly used path in the LINPACK software package. Results were provided for a matrix problem of size 100, on a collection of widely used computers (23 computers in all). This was done so users could estimate the time required to solve their matrix problem by extrapolation.

Over the years, additional performance data was added, more as a hobby than anything else, and today the collection includes over 1,300 different computer systems. In addition to the increasing number of computers, the scope of the benchmark has also expanded. The benchmark report describes the performance for solving a general dense matrix problem  $Ax = b$  at three levels of problem size and optimization opportunity: 100 by 100 problem (inner loop optimization), 1,000 by 1,000 problem (three loop optimization – the whole program), and a scalable parallel problem.

The LINPACK benchmark features two routines: DGEFA and DGESL (these are the double precision versions, usually 64-bit floating point arithmetic, SGEFA and SGESL are the single-precision counter parts, usually 32 bit floating point arithmetic); DGEFA performs the decomposition with partial pivoting and DGESL uses that decomposition to solve the given system of linear equations. Most of the execution time –  $O(n^3)$  floating-point operations – is spent in DGEFA. Once the matrix has been decomposed, DGESL is used to find the solution; this requires  $O(n^2)$  floating-point operations.

DGEFA and DGESL in turn call three BLAS routines: DAXPY, IDAMAX, and DSCAL. By far the major portion of time – over 90% at order 100 – is spent in DAXPY. DAXPY is used to multiply a scalar,  $ff$ , times a vector,  $x$ , and add the results to another vector,  $y$ . It is called approximately  $n^2/2$  times by DGEFA and  $2n$  times by DGESL with vectors of varying length. The statement  $y_i \leftarrow y_i + ff x_i$ , which forms an element of the DAXPY operation, is executed approximately  $n^3/3 + n^2$  times, which gives rise to roughly  $2/3n^3$  floating-point operations in the solution. Thus, the  $n = 100$  benchmark requires roughly 2/3 million floating-point operations.

The statement  $y_i \leftarrow y_i + ff x_i$ , besides the floating-point addition and floating-point multiplication, involves a few one-dimensional index operations and storage references. While the LINPACK routines DGEFA and DGESL involve two-dimensional array references, the BLAS refer to one-dimensional arrays. The LINPACK routines in general have been organized to access two-dimensional arrays by column. In DGEFA, the call to DAXPY passes an address into the two-dimensional array  $A$ , which is then treated as a one-dimensional reference within DAXPY. Since the indexing is down

a column of the two-dimensional array, the references to the one-dimensional array are sequential with unit stride. This is a performance enhancement over, say, addressing across the column of a two-dimensional array. Since Fortran dictates that two-dimensional arrays be stored by column in memory, accesses to consecutive elements of a column lead to simple index calculations. References to consecutive elements differ by one word instead of by the leading dimension of the two-dimensional array.

### Detailed Operation Counts

The results reflect only one problem area: solving dense systems of equations using the LINPACK programs in a Fortran environment. Since most of the time is spent in DAXPY, the benchmark is really measuring the performance of DAXPY. The average vector length for the algorithm used to compute LU decomposition with partial pivoting is  $2/3n$ . Thus in the benchmark with  $n = 100$ , the average vector length is 66.

In order to solve this matrix problem, it is necessary to perform almost 700,000 floating point operations. The time required to solve the problem is divided into this number to determine the megaflops rate.

The routines DGEFA calls IDAMAX, DSCAL and DAXPY. Routine IDAMAX, which computes the index of a vector with largest modulus, is called 99 times, with vector lengths running from 2 to 100. Each call to IDAMAX gives rise to  $n$  double precision absolute value computation and  $n - 1$  double precision comparisons. The total number of operations is 5,364 double precision absolute values and 4,950 double precision comparisons.

DSCAL is called 99 times, with vector lengths running from 1 to 99. Each call to DSCAL performs  $n$  double precision multiplies, for a total of 4,950 multiplications.

DAXPY does the bulk of the work. It is called  $n$  times, where  $n$  varies from 1 to 99. Each call to DAXPY gives rise to one double precision comparison with zero,  $n$  double precision additions, and  $n$  double precision multiplications. This leads to 4,950 comparisons against 0, 328,350 additions and 328,350 multiplications. In addition, DGEFA itself does 99 double precision comparisons against 0, and 99 double precision reciprocals. The total operation count for DGEFA is given in [Table 1](#).

**LINPACK Benchmark. Table 1** Double precision operations counts for LINPACK 100's DGEFA routine

| Operation type | Operation count |
|----------------|-----------------|
| Add            | 328,350         |
| Multiply       | 333,300         |
| Reciprocal     | 99              |
| Absolute value | 5,364           |
| $\leq$         | 4,950           |
| $\neq 0$       | 5,247           |

**LINPACK Benchmark. Table 2** Double precision operations counts for LINPACK 100's DGESL routine

| Operation type | Operation count |
|----------------|-----------------|
| Add            | 9,900           |
| Multiply       | 9,900           |
| Divide         | 100             |
| Negate         | 100             |
| $\neq 0$       | 199             |

Routine DGESL, which is used to solve a system of equations based on the factorization from DGEFA, does much more modest amount of floating point operations. In DGESL, DAXPY is called in two places, once with vector lengths running from 1 to 99 and once with vector lengths running from 0 to 99. This leads to a total of 9,900 double precision additions, the same number of double precision multiplications, and 199 compares against 0. DGESL does 100 divisions and 100 negations as well. The total operation count for DGESL is given in [Table 2](#).

This leads to a total operation count for the LINPACK benchmark given in [Table 3](#) or a grand total of 697,509 floating point operations. (The LINPACK uses approximately  $2/3n^3 + 2n^2$  operations, which for  $n = 100$  has the value of 686,667.)

It is instructive to look just at the contribution due to DAXPY. Of these floating point operations, the calls to DAXPY from DGEFA and DGESL account for a total of 338,160 additions, 338,160 multiplications, and 5,147 comparisons with zero. This gives a total of 681,467 operations, or over 97% of all the floating point operations that are executed. The total time is taken up with more than arithmetic operations. In particular, there is quite a lot of time spent loading and storing the

**LINPACK Benchmark. Table 3** Double precision operations counts for LINPACK 100 benchmark

| Operation type | Operation count |
|----------------|-----------------|
| Add            | 338,250         |
| Multiply       | 343,200         |
| Reciprocal     | 99              |
| Divide         | 100             |
| Negate         | 100             |
| Absolute value | 5,364           |
| $\leq$         | 4,950           |
| $\neq 0$       | 5,446           |
| Total          | 697,509         |

operands of the floating point operations. We can estimate the number of loads and stores by assuming that all operands must be loaded into registers, but also assuming that the compiler will do a reasonable job of promoting loop-invariant quantities out of loops, so that they need not be loaded each time within the loop. Then DAXPY accounts for 681,468 double precision loads and 338,160 double precision stores. IDAMAX accounts for 4,950 loads, DSCAL for 5,049 loads and 4,950 stores, DGEFA outside of the loads and stores in the BLAS does 9,990 loads and 9,694 stores, and DGESL for 492 loads and 193 stores. Thus, the total number of loads is 701,949 and stores is 352,997. Here again DAXPY dominates the statistics. The other overhead that must be accounted for is the load indexing, address arithmetic, and the overhead of argument passing and calls.

## Precision

In discussions of scientific computing, one normally assumes that floating-point computations will be carried out to full precision or 64-bit floating point arithmetic. Note that this is not an issue of single or double precision as some systems have 64-bit floating point arithmetic as single precision. It is a function of the arithmetic used.

## \*Lisp

GUY L. STEELE JR.  
Oracle Labs, Burlington, MA, USA

### Definition

\*Lisp (pronounced “star-lisp”) is a data-parallel dialect of Lisp developed around 1984 for Connection Machine supercomputers manufactured by Thinking Machines Corporation. It consists of Common Lisp (or, in its earliest implementations, Symbolics Zetalisp) augmented with a package of relatively low-level data-parallel operations. The language design draws a sharp distinction between data residing in the front-end Common Lisp processor and data residing in the massively parallel Connection Machine coprocessor. While pointers to any Lisp data could reside in the Connection Machine processors, parallel processing was most effective on arrays of numeric and character data.

### Discussion

Of the four programming languages (\*Lisp, C\*, CM Fortran, and CM-Lisp) provided by Thinking Machines Corporation for Connection Machine Systems, \*Lisp was the first to be implemented and the one most closely aligned to details of the Connection Machine architecture; essentially anything that could be done with the Connection Machine hardware could be expressed in \*Lisp, but the programmer was freed from much drudgery because expression evaluation made automatic use of a stack for parallel data structures and provided automatic conversions among data types and sizes as necessary.

To quote from the *Connection Machine Model CM-2 Technical Summary*, 1987:

- The parallel primitives of \*Lisp support a model of the Connection Machine in which each processor executes a subset of Common Lisp, with a single thread of control residing on the front-end computer. For most Common Lisp functions, \*Lisp provides a corresponding parallel function that can operate on all processors, or some selected subsets, simultaneously. In addition, the language provides Lisp-level operators for communicating between processors, both through pointers and in regular patterns. Sequential Common Lisp code, running on the front end, can be freely intermixed with the parallel code executed on the Connection Machine.

Most \*Lisp functionality corresponds directly to underlying Paris [Connection Machine PARallel Instruction Set] instructions.... As a result ... direct calls to Paris instructions and special purpose microcode blend in naturally with \*Lisp code [1, p. 46], [2, p. 223].

By 1989 the phrase “most Common Lisp functions” had been amended to “many Common Lisp functions” [3, p. 27].

A \*Lisp *pvar* (parallel variable) was, in effect, an array indexed by processor number, so that each (virtual) Connection Machine processor contained one array element. A unary parallel operation would perform the same scalar operation on each element simultaneously; a binary parallel operation would operate on corresponding elements of two *pvars*. While, in general, a *pvar* could hold pointers to any Common Lisp objects, not all operations on Common Lisp objects were supported in parallel form. In particular, classic list operations such as CAR and CDR and ASSOC had no parallel versions (“\*Lisp does not implement list *pvars*” [4, p. 155]). On the other hand, most atomic Common Lisp types were eventually supported, including integers and floating-point numbers of various fixed sizes, complex numbers, and characters; and many of the Common Lisp sequence functions were provided in parallel form for operating on many arrays simultaneously. “The eight basic *pvar* types are boolean, integer, floating-point, complex, character, structure, and front-end value” [5, p. 80]. The operation of indexing into a *pvar* to fetch or store a specified element was supported in both scalar and parallel forms; in this way either the front-end computer or the entire set of Connection Machine processors could freely fetch or store any element of a *pvar*.

\*Lisp was useful because it provided all the program-building tools of Common Lisp [6, 7],

including user-defined macros, and because it provided convenient access to *all* the facilities of the Connection Machine hardware, including (on the model CM-2) the multidimensional NEWS network, “backwards routing” in the hypercube network, the thousands of red LEDs that were a distinctive feature of the Connection Machine cabinetry, and operations on integers and floating-point numbers that could be of any specified length, such as 23-bit integers or floating-point numbers with 9-bit exponents and 43-bit significands (a flexibility of the model CM-1 that few users exploited in practice once the hardware floating-point accelerators came into use on the model CM-2).

By 1990, \*Lisp had grown to include over 400 functions and macros, listed in a *\*Lisp Dictionary* of over 1,100 pages [8]. Compared with other dialects and extensions of Lisp, \*Lisp had a distinct visual style because of its consistent use of either a leading “\*” or a trailing “!!” in names:

- ▶ The names of functions and macros that return pvars as their values end in !!. This suffix, pronounced *bang-bang*, is meant to look like two parallel lines.... All \*Lisp functions that perform parallel computation and do not end in !! begin with \* (pronounced *star*); hence, the name \*Lisp [9, p. 5].

A later document further explains:

- ▶ The characters “!!” are meant to resemble the mathematical symbol ||, which means *parallel*. [5, p. 82]

(It should be noted that the lexical syntax of Common Lisp [6, 7] would have made it awkward to use two vertical-bar symbols “||” rather than two exclamation points.)

**Figure 1** shows an early (1987) example of a \*Lisp program that identifies prime numbers less than 100,000 by the method of the Sieve of Eratosthenes, taken (with minor corrections) from [1]. A set of virtual processors of size 100,000 is assumed to have been established before the function `find-primes` is called. The special form `*all` enables all virtual processors for activity. The special form `*let` is analogous to Common Lisp `let` in that it binds local variables, but `*let` binds local *parallel* variables, allocating them on a stack within the Connection Machine (actually, one stack per virtual processor). In this case, the local parallel variable `prime` is initially `nil` (false) within each processor, and the local parallel variable `candidate` is initially `t` (true) within each processor. The conditional form `*when` is analogous to Common Lisp `when`, but operates by (a) evaluating a parallel test form; (b) temporarily disabling for execution any processors that computed `nil` for the test form in step (a); (c) executing the form(s) in the body of the `*when` construct; and finally (d) re-enabling any processors disabled in step (b). The function `self-address!!` returns the virtual processor address, which is a different integer in each virtual processor (starting from zero); the function `!!` broadcasts a scalar value from the front-end processor to all Connection Machine processors, so that `(!! 2)` is a parallel quantity with value 2 in every virtual processor; and function `<!!` compares two parallel quantities, producing a parallel Boolean (`t` or `nil`) result. The functions `*or` and `*min` are reduction operations, producing the logical OR or the arithmetic minimum of one value taken from every *active* virtual processor; thus `(*or candidate)` will be `nil` only if every virtual

```

 (*set candidate (!! nil))))))
 prime)))
 prime)))
```

\*Lisp. Fig. 1 Example \*Lisp program for identifying prime numbers

processor has the value nil for candidate, and (\*min (self-address!!)), because it occurs within (\*when candidate ...), will return the smallest integer for which candidate is true. The function pref is analogous to Common Lisp aref; it may be used by the front end to access a single element of a parallel value by supplying an integer index. (The parallel equivalent, not used in this example, is pref !!, which allows every Connection Machine processor to fetch a value by indexing into a parallel value; this is one way of performing interprocessor communication in \*Lisp.) The functions zerop !! and mod are parallel arithmetic operations that are analogous to Common Lisp zerop and mod.

## Little's Law

JOHN L. GUSTAFSON

Intel Labs, Intel Corporation, Santa Clara, CA, USA

## Synonyms

Little's lemma; Little's principle; Little's result; Little's theorem

## Definition

Little's Law says that in the long-term, steady state of a production system, the average number of items  $L$  in the system is the product of the average arrival rate  $\lambda$  and the average time  $W$  that an item spends in the system, that is,

$$L = \lambda W.$$

## Discussion

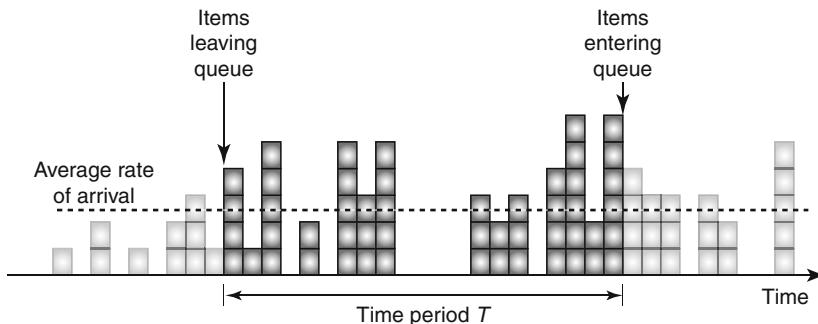

At first glance, Little's Law looks like common sense. If items arrive faster than the system can process them, the system will overflow. Perhaps the earliest mention of the relation is by A. Cobham in 1954, and he states it as a fact without proof [2]. However, the law is insightful in two ways. First, it does not depend on the probability distributions of any of the variables. Second, since arrival rates are generally less than maximum processing rates, it says what the capacity of the system must be to handle the queue in a system design.

Figure 1 shows a visualization of a queue in steady state that explains Little's Law:

Proofs of Little's Law use the Law of Large Numbers, which is implicit in the phrase “steady state” of the system. The number of items in any time period  $T$  is the integral of the arrival rate over the period, so if there is a steady state average rate  $\lambda$ , then  $L = \lambda W$  is the area of the rectangle under the dotted line for time period  $W$ . A more formal proof appears in [3] or [4].

Notice that the units in the expression are like that of a speed equation: work equals rate times time. Here, “work” is items that complete processing, “rate” is the arrival rate, and “time” is the time spent in the system.

The result is from queuing theory, and the meaning of  $L$ ,  $\lambda$ , and  $W$  varies by application. In manufacturing,  $L$  might mean inventory,  $\lambda$  the rate of arrival of materials, and  $W$  the amount of time the materials spend

**Little's Law. Fig. 1** Visualization of Little's law

in inventory. In retail applications,  $L$  might mean the average number of customers in a store,  $\lambda$  the rate they arrive at the store, and  $W$  the average time a customer spends in the store.

### Example

Suppose a fast food restaurant has an average business of one customer every two minutes, and the average customer takes 40 minutes to eat. For purposes of planning seating to accommodate the customers, Little's Law says how many seats in the restaurant will be in use, on average. Here,  $\lambda = 0.5$  customers per minute, and  $W = 40$  minutes; hence,  $L = 0.5 \times 40 = 20$  occupied seats.

If the business doubles to  $\lambda = 1.0$  customers per minute and the restaurant does not have enough seating area, then Little's Law says there are two solutions: double the seating area, or halve the average amount of time customers spend eating to 20 minutes, say, by making the seats less comfortable.

### Compound Queues

It is often useful to apply Little's Law in compound ways. For example, a store has a rate at which customers arrive and are in the process of browsing, and after selecting an item, they enter the checkout queue within the store to pay for the item. Thus, the law predicts the length of the checkout line and how crowded the store will be. Alternatively, it can predict how many checkout tellers suffice to prevent the checkout lines from averaging more than a certain goal in length.

### Example

Suppose the same fast food business assesses the trade-off between the cost of personnel and the effect waiting in line has on customer satisfaction. It then sets a goal

that the average amount of time a customer wishing to order food should have to wait in line is 6 minutes. Suppose also that there are two queues for ordering. How long will the line be to order food, on the average?

Since the two queues must accommodate the total arriving customer rate of  $\lambda = 1.0$  customers per minute, the rate for each food-ordering line is 0.5 customers per minute. Each line will then have an average length of

$$L = \lambda W = 0.5 \times 6 = 3 \text{ customers.}$$

### Implications for Computer Design

Little's Law is of obvious value for computer design, especially for *decoupled architectures*. Computer architect Burton Smith first noted the following form of Little's Law in 1995:

$$\text{Concurrency} = \text{Latency} \times \text{Bandwidth}.$$

Bandwidth is a rate of arrival of data into a processing queue. Latency is the time spent in the queue, and concurrency (or degree of parallelism) is the number of simultaneous data items to process. Some refer to this as *Little's Law of High Performance Computing* [1].

Processing elements require holding areas for data (buffers), and Little's Law provides guidance for how to match the processing rate, storage size of a buffer, and time a datum spends in the buffer. Just as more checkout tellers can reduce the average size of the checkout queue, parallel computing elements can reduce the amount of buffer space and the time spent in the buffer.

### Example

Suppose the processing units in a parallel computer can collectively process 1 trillion ( $10^{12}$ ) items of data in main memory per second, and the latency between the

main memory and the processors is 50 ns. Then Little's Law says that the number of parallel elements for processing memory must be

$$\text{Concurrency} = 10^{12} \times (50 \times 10^{-9}) = 50,000 \text{ processors.}$$

The parallel elements could be in the form of pipeline stages, data parallel units, or any other way that permits concurrent activity at the level of 50,000 items of data processed at once. Thus, if the system consists of 10,000 servers organized as a networked cluster, then each server must have an internal parallelism of a factor of five to accommodate the demands of the queue.

Even within a single processor, Little's Law is quite useful for answering architectural questions. For example, if the latency to the main memory is 60 ns for one core of a multicore processor, and the core operates at 3.0 GHz, then the memory system must be able to accommodate

$$(3.0 \times 10^9) \times (60 \times 10^{-9}) = 180 \text{ outstanding memory references,}$$

if each core is to make full use of its capability (that is, if the average arrival rate is the same as the maximum possible arrival rate).

Another important computer application of Little's Law is in assuring the fairness of benchmarks, especially those related to transaction processing. When measuring a system, if the benchmarking engineer asks it to process so many transactions (arrival rate  $\lambda$ ) that the storage (number of items  $L$  in the system) is larger than the main memory and thus spills into mass storage, the performance will drop catastrophically.

## Perspective

Operations Research (OR) originated in the 1950s, and courses on the subject rely heavily on queuing theory. Little was teaching formal queuing theory at Case Western Reserve University and noticed that the  $L = \lambda W$  behavior was independent of the probability distribution of the arrival times. At the urging of one of his students (Sid Hess), Little published the proof of the generality of the law. Little's 1961 theorem was one of the simplest yet most useful results from that early era. While formal queuing theory requires an understanding of concepts like Poisson distributions and a somewhat advanced level of statistics and mathematics, the simple formula  $L = \lambda W$  is one that requires no advanced

training to understand and apply. There was no thought in those early years of OR about answering questions of computer design. The traditional textbook examples are for inventory, manufacturing, order entry, and so on. Computer designs of that era tended to be tightly coupled, and so deterministic that the only statistical queuing behavior that would enter into their use would be that of users submitting jobs to the batch queue and waiting for computed results.

Burton Smith (Tera Computer) and David Bailey (NASA Ames Research) deserve credit for showing, in the late 1990s, the applicability of Little's Law to many issues of computing design. It seems obvious in retrospect that a law originally intended for use in the arena of business operations with human time scales could apply to computing design. Here the use is a subtle variation on the "average" behavior, in that the law assesses the *optimum* behavior. If the processing speed is to be some idealized maximum, and the latency is as small as possible, then the law predicts a lower bound on the capacity or parallelism required for near-peak performance.

Little's Law for High Performance Computing provides perhaps the simplest way to explain the necessity for the parallel computing approach. Latency tends to be difficult to reduce because of the laws of physics; concurrency is the product of latency and bandwidth (processing rate), so increasing bandwidth forces the need for more concurrency.

## Bibliographic Notes and Further Reading

Little's original 1961 paper is of historic interest, as is a less general precedent text (1958) by OR pioneer Philip Morse: *Queues, Inventories and Maintenance* [6]. A very readable account with many examples drawn from everyday situations is in [5]. The latter work also gives perspective on the impact of the law over four

decades, and provides examples from managing email, traffic created by toll booths, and the housing market.

Bailey's brief 1997 paper [1] promulgated the use of Little's Law in High Performance Computing, and credits Burton Smith for the first restatement of the law in computer architecture terms.

## Livermore Loops

JACK DONGARRA, PIOTR LUSZCZEK  
University of Tennessee, Knoxville, TN, USA

## Definition

Livermore Loops are a set of 24 Fortran DO-loops (The Livermore Fortran Kernels, LFK) extracted from operational codes used at the Lawrence Livermore National Laboratory [1, 2]. They have been used since the early 1970s to assess the arithmetic performance of computers and their compilers. They are a mixture of vectorizable and nonvectorizable loops and test rather fully the computational capabilities of the hardware as well as the skill of the software in compiling and vectorization of efficient code. The main value of the benchmark is the range of performance that it demonstrates, and in this respect it complements the limited range of loops tested in the LINPACK benchmark.

## Discussion

As a benchmark, the Livermore Loops provide the individual performance of each loop, together with various averages (arithmetic, geometric, harmonic) and the quartiles of the distribution. However, it is difficult to give a clear meaning to these averages, and the value of the benchmark is more in the distribution itself. In particular, the maximum and minimum give the range of likely performance in full applications. The ratio of maximum to minimum performance has been called the instability or the specialty [3], and is a measure of how difficult it is to obtain good performance from the computer, and therefore how specialized it is. The minimum or worst performance obtained on these loops is of special value, because there is much truth in the saying that “the best computer to choose is that with the best worst-performance.”

The LFK set began in the early 1970s with only 12 kernels and was timed on the mainframes of the era with CPU-times of microsecond accuracy. By the early 1980s the number of kernels in the set grew to 24 and, during the decade, statistical features of the results reporting code were enhanced and adaptations were made to accommodate crude UNIX timers of only millisecond resolution. A port of LFK to C happened in the middle

of 1980s. By the beginning of the 1990s, the compilers were able to perform code-hoisting which necessitated changes to the code like introducing functions to embed the critical kernels inside it and hide it from the optimization. The 1990s brought new hardware from HP, SGI, and SUN which exhibited vast performance improvements but still suffered with low timer resolution which required increase in the repetition count to assure 1% accuracy of the reported timings.

The origins or functions of each of the LFK kernels are the following:

1. Fragment of hydrodynamics code
2. ICCG (Incomplete Cholesky Conjugate Gradient) excerpt
3. Inner product calculation
4. Banded linear equations
5. Tri-diagonal elimination below the diagonal
6. General linear recurrence equations
7. Fragment of equation of state code
8. ADI (Alternating Direction Implicit) integration scheme for differential equations
9. Integrate predictor kernel
10. Difference predictor kernel
11. Summation with storage of partial sums
12. First difference scheme
13. 2D PIC (Particle In Cell) code
14. 1D PIC
15. A challenging (for the compiler) ordering of scalar operations in FORTRAN
16. Monte Carlo search loop
17. Implicit conditional computation
18. 2D explicit hydrodynamics fragment
19. General linear recurrence equations
20. Discrete ordinates transport: recurrence
21. Matrix-matrix multiplication
22. Planckian probability distribution
23. 2D implicit hydrodynamics fragment
24. A loop that finds location of first minimum in an array

In the LFK collection, scalar tests are numbered 5, 11, 17, 19, and 20 [1], page 14]. In the late 1980s, the scalar features of the contemporary machines were important for supercomputing at Los Alamos (LANL) – as much as 30% of the code executed at the laboratory might have been scalar [4]. The LFK scalar codes are small, so their indicated performance is generally higher than

that measured with larger benchmarks. Nonetheless, a good correlation exists among the LFK scalar tests and others [5].

Vectorization at the compiler level was turned on and off in the LFK kernels through special comments that were recognized as compiler directives. Similarly, code directives were used to render selected kernels scalar and force their execution onto the scalar units of the processor. The scalar execution was used as the definition of necessary computation and the appropriated number of the performed floating point operations. The actual number of floating point operations for vectorized execution could have been larger. For the purposes of the calculation of the performance results, each type of floating operation was weighted. The weight represented the execution time relative to floating point addition. For example, the weight of floating point division was 4 which meant that it takes four times as many cycles to complete a division than an addition of two floating point numbers.

The authors of LFK suggested to use the results by weighing their performance in proportion to the actual usage of that category of computation in the total workload. For example, for a hydrodynamics code, kernels 1, 18, and 23 would be the most relevant and consequently they should be given the greatest weight.

Another important aspect of performance benchmarking stressed by the LFK report was the treatment of the results' data as statistical quantity. A single number quoted as the performance rate was considered insufficient. Statistical sampling was encouraged and each reported number was to be accompanied by minimum and maximum values obtained as well as the equi-weighted harmonic, geometric, and arithmetic means. In addition, the first, second, third, and fourth quartiles were used to perform sensitivity analysis of harmonic mean rate with respect to various weight distributions.

At the time of release of the LFK set, the available hardware included machines from Cray, DEC, IBM, and NEC. The clock frequencies were of order 100 MHz and the achieved performance varied between single digit Mflop/s to man hundreds of Mflop/s depending on the kernel and the type of processor (vector or RISC).

- [METIS and ParMETIS](#)

## Load Balancing, Distributed Memory

AARON BECKER, GENGBIN ZHENG, LAXMIKANT V. KALÉ  
University of Illinois at Urbana-Champaign, Urbana, IL, USA

### Definition

Load balancing in distributed memory systems is the process of redistributing work between hardware resources to improve performance, typically by moving work from overloaded resources to underloaded resources.

### Discussion

In a parallel application, when work is distributed unevenly so that underloaded processors are forced to wait for overloaded processors, the application is suffering from *load imbalance*. Load imbalance is one of

the key impediments in achieving high performance on large parallel machines, especially when solving highly dynamic and irregular problems. *Load balancing* is a technique that performs the task of distributing computation and communication load across the hardware resources of a parallel machine so that no single processor is overloaded. It can reduce processor idle time across the machine while also reducing communication costs by colocating related work on the same processor.

Balancing an application’s load involves making decisions about where to place newly created computational tasks on processors, or where to migrate existing work among processors. Orthogonally, some applications only require static load balancing: They have consistent behaviors over their lifetimes, and once they are balanced they remain balanced. Other applications exhibit dynamic changes in behavior and require periodic rebalancing. Typically it is far too expensive to compute an optimal distribution of work in any realistic application, but a wide variety of heuristic algorithms have been developed that are very effective in practice across a wide variety of application domains.

The load associated with an application can be conceptualized as a graph, where the nodes are discrete units of work and an edge exists between two nodes if there is a communication between them. To solve the load balancing problem one must split this graph into parts, with each part representing the work to be associated with a particular hardware resource. This partitioning process is at the heart of load balancing.

Given the heuristic nature of load balancing, which makes perfect load balance an unrealistic goal, it is important to remember that the goal of load balancing is not so much to equalize the amount of work on each processor as it is to minimize the load of the most heavily loaded processor in the system. The most overloaded processor is the bottleneck that determines time to completion. A heuristic that leaves some processors idle is preferable to one that reduces the variance in load, as long it reduces the load on the most loaded processor. Load balancing heuristics can also take factors beyond time to completion into account, for example by trying to minimize power usage over an application’s lifetime.

Modern HPC systems include clusters of multi-core nodes. The general load balancing strategies described

in this entry are still applicable at the level of nodes (i.e., work is assigned to nodes). Finer grained load balancing within a node (work assigned to cores) can be performed independently. In the simplest case, it can be done by applying the same load balancing strategies that are used for node-level load balancing, except that the cost of communication among cores within a node is much smaller than the internode communication, and the number of cores involved within a node is relatively small.

### Periodic Load Balancing

In a periodic load balancing scheme, computational tasks are persistent; load is balanced only as needed, and the balancing consists of migrating existing tasks and their associated data. With periodic load balancing, expensive load balancing decision making and data migration are not continuous processes. They occur only distinct point in the application when a decision to do balancing has been made. Periodic load balancing schemes are suitable for iterative scientific applications such as molecular dynamics, adaptive finite element simulation, and climate simulation, where the computation typically consists of a large number of time steps, iterations (as in iterative linear system solvers), or a combination of both. A computational task in these applications is executed for a long period of time, and tends to be persistent. During execution, at periodic intervals, partially executed tasks may be moved to different processors to achieve global load balance.

### The Load Balancing Process

In an application which rebalances its load periodically, there are four distinct steps in the load balancing process. The first step is load estimation, which tries to gauge what the load on each processor will be in the near future if no rebalancing is done. This may involve the use of a model that predicts future performance based on current conditions, or it may be based directly on past measured load, with the assumption that the near future will closely resemble the near past. The second step is making a decision of *when* to execute load balancing. This is a trade-off between the cost of load balancing itself (i.e., the cost of determining a new mapping of application tasks to hardware and the cost of migration) and the savings one can expect from a

better load distribution. The nature of the application being balanced and the cost of the load balancing method to be used factor heavily into this decision. The third step is determining how the load will be rebalanced. There are many algorithms devoted to computing a good mapping of work onto processors, each with its own strengths and weaknesses. This section describes some of the most widely used methods. The general problem of creating a mapping of work onto processors which minimizes time to completion is NP-hard, so all strategies we discuss are heuristic. The final step in the load balancing process is migration, the process by which work is actually moved. This may simply be a matter of relocating application data, but it can also encompass thread and process migration.

### Initial Balancing

For some classes of application, there is very little change in load balance over time once the application reaches a steady state. Thus, once good load balance is achieved, no further balancing need be done. However, load balancing is often still an important part of such applications. For example, consider the case of molecular dynamics, where one must distribute simulated particles onto processors. These applications do not experience significant dynamic load imbalance, but determining a good initial mapping may be difficult because of the difficulty of estimating the load of multiple computational tasks accurately *a priori*.

In cases like this, one can simply start the application with an unoptimized distribution of work, run the application long enough to accurately measure the load, rebalance based on those measurements, and then continue without the need for any further balancing.

### Classifying Load Balancers

There are many families of load balancing approaches that can be classified according to how they answer the fundamental questions of load balancing: How do we estimate the load, at what granularity should one balance the load, and where should the load balancing decisions be made.

Load estimation underlies all load balancing algorithms. Load balancing is fundamentally a forward-looking task which aims to improve the future performance of the application. To do this effectively, the load balancer must have some model of what the

future performance of the application will be in different scenarios. There are two common approaches to estimating future load. The first is to measure the current load associated with each piece of work in the application and to assume that this load will remain the same after load balancing. This assumption is based on the *principle of persistence*, which posits that, for certain classes of scientific and engineering applications, computational loads and communication patterns tend to persist over time, even in dynamically evolving computations. This approach has several advantages: It can be applied to any application, it accurately and automatically accounts for the particular characteristics of the machine on which the application is running, and it removes some of the burden of load estimation from the application developer.

The alternative is to build some model of application performance which will provide a performance estimate for any given distribution of work. These models can be sophisticated enough to take into account dynamic changes in application performance that a measurement-based scheme will not account for, but they must be created specifically to match the actual characteristics of the application they are used for. If the model does not match reality then poor load balancing may result.

Load balancing may take place at any of several levels of *granularity*. The greatest flexibility in mapping work onto hardware resources can be achieved by exposing the smallest possible meaningful units of data to the load balancer. For example, these may be nodes in a finite element application or individual particles in a molecular simulation. Alternatively, one may group this data into larger chunks and only expose those chunks to the load balancing algorithm. This makes the load balancing problem smaller while guaranteeing respect for locality within the chunks. For example, in a molecular simulation the load balancer might only try to balance contiguous regions which may contain a large number of particles without being directly aware of the particles. It is also possible to balance load by migrating entire processes, avoiding the need for application developers to write code dedicated to migrating their data during the load balancing process.

Load balancers may be further categorized according to *where* decisions are made: locally, globally, or

according to some hierarchical scheme. Global load balancers collect global information about load across the entire machine and can use this information to make decisions that take the entire state of the application into account. The advantage of these schemes is that load balancing decisions can take a global view of the application, and all decisions about which objects should migrate to which processors can be made without further coordination during the load balancing process. However, these schemes inherently lack scalability. As problem sizes increase, the object communication graph may not even fit in memory on a single node, making global algorithms infeasible. Even if the load balancing process is not constrained by memory, the time required to compute an assignment for very large problems may preclude the use of a global strategy. However, with coarse granularity, it is possible to use global strategies up to several thousand processors, especially if load balancing is relatively infrequent.

Parallelized versions of global load balancing schemes are also possible. These use the same principles for partitioning as a serial global scheme, but to improve scalability the task graph is spread across many processors. This introduces some overhead in the partitioning process, but allows much larger problems to be solved than a purely serial scheme. One example of a parallel global solver is ParMETIS, the parallel version of the METIS graph partitioner.

Distributed load balancing schemes lie at the opposite end of the scale from global schemes. Distributed schemes use purely local information in their decision-making process, typically looking to offload work from overloaded processors to their less-loaded immediate neighbors in some virtualized topology. This leads to a sort of diffusion of work through the system as objects gradually move away from overloaded regions into underloaded regions. These schemes are very cheap computationally, and do not require global synchronization. However, they have the disadvantage of redistributing work slowly compared to global schemes, often requiring many load balancing phases before achieving system-wide load balance, and they typically perform more migrations before load balance is achieved.

Hybrid load balancing schemes represent a compromise between global and distributed schemes. In a hybrid load balancer, the problem domain is split

into a hierarchy of sub-domains. At the bottom of the hierarchy, global load balancing algorithms are applied to the small sub-domains, redistributing load within each sub-domain. At higher levels of the hierarchy, the load balancing strategies operate on the sub-domains as indivisible units, redistributing these larger units of work across the machine. This keeps the size of the partitioning problem to be solved low without giving up some global decision-making capabilities.

## Algorithms

An application's load balancing needs can vary widely depending on its computational characteristics. Accordingly, a wide variety of load balancing algorithms have been developed. Some do careful analysis of an application's communication patterns in an effort to reduce internode communication; others only try to minimize the maximum load on a node. Some try to do a reasonably good job as quickly as possible; others take longer to provide a higher quality solution. Some are even tailored to meet the needs of particular application domains. Despite the wide variety of algorithms available, there are a few in wide use that demonstrate the range of available techniques.

## Parallel Prefix

In some cases, the pattern of communication between objects is unimportant, and we care only about keeping an equal amount of work on each processor. In this scenario, load may be effectively distributed using a simple parallel prefix strategy (also known as scan or prefix sum).

The input to the parallel prefix algorithm is simply a local array of work unit weights on each processor reflecting the amount of work that each unit represents. The classic parallel prefix algorithm computes the sum of the first  $i$  units for each of the  $n$  unit in the list. Once the prefix sum is computed, all work can be equally distributed across processors by sending each unit to the processor number given by its prefix sum value divided by the total work divided by the number of processors.

The primary advantage of the parallel prefix scheme is its fast, inexpensive nature. The computation can be shared across  $p$  processors using only  $\log p$  communications, and efficient prefix algorithms are widely available in the form of library functions like MPI\_Scan. An assignment of work units to processors based on parallel

prefix can be computed virtually instantaneously even for extremely large processor counts, regardless of variations in work unit weights.

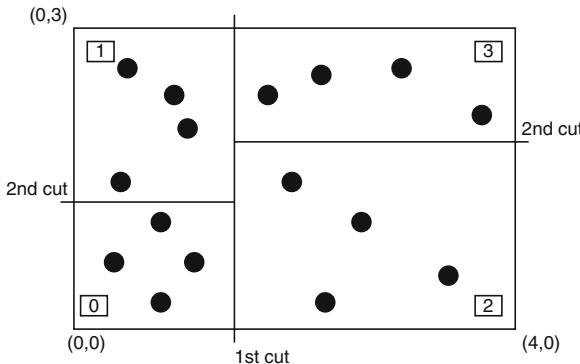

The corresponding disadvantage of using the parallel prefix algorithm for load balancing is its simplicity. It does not account for the structure of communication between processors and will not attempt to minimize the communication volume of the resulting partition. It also does not attempt to minimize the amount of migration needed.

## Recursive Bisection

Recursive bisection is a divide-and-conquer technique that reduces the partitioning problem to a series of bisection operations. The strategy of recursive bisection is to split the object graph in two approximately equal parts while minimizing communication between the parts, then proceeding to subdivide each half recursively until the required number of partitions is achieved. This recursive process introduces parallelism into the partitioning process itself. After the top-level split is completed, the two child splits are independent and can be computed in parallel, and after  $n$  levels of bisection there are  $2^n$  independent splitting operations to perform. In addition, geometric bisection operations can themselves be parallelized by constructing a histogram of the nodes to be split.

There are many variations of the recursive bisection algorithm based on the algorithm used to split the graph. Orthogonal recursive bisection (ORB), shown in Fig. 1, is a geometric approach in which each object is associated with coordinates in some spatial domain. The bisection process splits the domain in two using an axis-aligned cutting plane. This can be a fast way of creating a good bisection if most communication between objects is local. However, this method does not guarantee that it will produce geometrically connected sub-domains, and it may also produce sub-domains with high aspect ratios. Further variations exist which allow cutting planes that are not axis-aligned.

An alternate approach is to use spectral methods to do the bisection. This involves constructing a sparse matrix from the communication graph, finding an eigenvector of that matrix, and using it as a separator field to do the bisection. This method can produce superior results compared with ORB, but at a substantially higher computational cost.

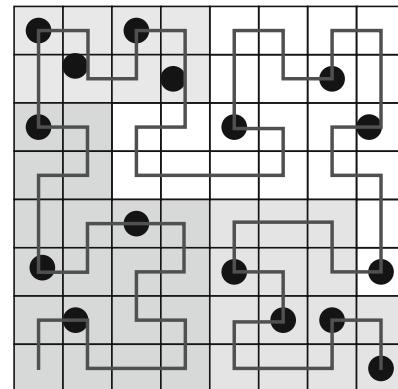

**Load Balancing, Distributed Memory.** Fig. 1 Orthogonal recursive bisection (ORB) partitions by finding a cutting plane that splits the work into two approximately equal pieces and recursing until the resulting pieces are small enough [8]

For many problems, recursive bisection is a fast way of computing good partitions, with the added benefit that the recursive procedure naturally exposes parallelism in the partitioning process itself. The advantages and disadvantages of recursive bisection depend greatly on the nature of the bisection algorithm used, which can greatly affect partition quality and computational cost.

### Space-Filling Curve

A space-filling curve is a mathematical function that maps a line onto the entire unit square (in two dimensions, or the entire unit  $N$ -cube in  $N$  dimensions). There are many such curves, and they are typically defined as the limit of sequence of simple curves, so that closer and closer approximations to the space-filling curve can be constructed using an iterative process. The value of space-filling curves for load balancing is that they can be used to convert  $n$ -dimensional spatial data into one-dimensional data. Once the higher-dimensional data has been linearized, it can be easily partitioned by splitting the line into pieces with equal numbers of elements.

Consider the case where each object in the application has a two-dimensional coordinate associated with it. Starting with a coarse approximation to the space-filling curve, a recursive refinement process can be used to create closer and closer approximations until each object is associated with its own segment of the approximated curve. This creates a linear ordering of the objects, as depicted in Fig. 2, which can then be split into even partitions.

**Load Balancing, Distributed Memory.** Fig. 2 To partition data using a space-filling curve, a very coarse approximation of the curve is replaced with finer and finer approximations until each unit of work is in its own segment. The curve is then split into pieces, with each piece containing an equal number of work units. This figure shows a Hilbert curve [8]

A good choice of space-filling curve will tend to keep objects which are close together in the higher-dimensional space. This property is necessary so that the partitions that result respect the locality of the data. Many different curves have been used for load balancing purposes, including the Peano curve, the Morton curve, and the Hilbert curve. The Hilbert curve is a common choice of space-filling curve for partitioning applications because it provides good locality.

### Graph Partitioning

The pattern of communication in any parallel program can be represented as a graph, with nodes representing discrete units of work, and weighted edges representing communication. Graph partitioning is a general-purpose technique for splitting such a graph into pieces, typically with the goal of creating one piece for each processor. There are two conflicting goals in graph partitioning: achieving equal-size partitions, and minimizing the total amount of communication across partition boundaries, known as the edge cut. Finding an optimal solution to the graph partitioning problem is NP-Hard, so heuristic algorithms are required.

Because it is computationally infeasible to attempt to partition the whole input graph at once, the graph partitioning algorithm proceeds by constructing a series of

coarser representations of the input graph by combining distinct nodes in the input graph into a single node in the coarser graph. By retaining information about which nodes in the original graph have been combined into each node of the coarse graph, the algorithm maintains basic information about the graph's structure while reducing its size enough that computing a partitioning is very simple.

Once the coarsest graph has been partitioned, the coarsening process is reversed, breaking combined nodes apart. At each step of this uncoarsening process, a refinement algorithm such as the Kernighan–Lin algorithm can be used to improve the quality of the partition by finding advantageous swaps of nodes across partition boundaries. Once the uncoarsening process is complete, the user is left with a partitioning for the original input mesh.

This technique can be further generalized to operate on hypergraphs. Whereas in a graph an edge connects two nodes, in a hypergraph a hyperedge can connect any number of nodes. This allows for the explicit representation of relationships that link several nodes together as one edge rather than the standard graph representation of pairwise edges between each of the nodes. For example, in VLSI simulations hypergraphs can be used to more accurately reflect circuit structure, leading to higher quality partitions. Hypergraphs can be partitioned using a variation of the basic graph partitioning algorithm which coarsens the initial hypergraph until it can be easily partitioned, then refining the partitioned coarse hypergraph to obtain a partitioning for the full hypergraph.

The primary advantages of load balancing schemes based on graph partitioning are their flexibility and generality. An object communication graph can be constructed for any problem without depending on any particular features of the problem domain. The resulting partition can be made to account for varying amounts of work per object by weighting the nodes of the graph and to account for varying amounts of communication between objects by weighting the edges. This flexibility makes graph partitioners a powerful tool for load balancing.

The primary disadvantage of these schemes is their cost. Compared to the other methods discussed here, graph partitioning may be computationally intensive, particularly when a very large number of partitions

is needed. The construction of an explicit communication graph may also be unnecessary for problems where communication may be inferred from domain-specific information such as geometric data associated with each object.

## Rebalancing with Refinement Versus Total Reassignment

There are two ways to approach the problem of rebalancing the computational load of an application. The first approach is to take an existing data distribution as a baseline and attempt to incrementally improve load balance by migrating small amounts of data between partitions while leaving the majority of data in place. The second approach is to perform a total repartitioning, without taking the existing data distribution into account. Incremental load balancing approaches are desirable when the application is already nearly balanced, because they impose smaller costs in terms of data motion and communication. Incremental approaches are more amenable to asynchronous implementations that operate using information from only a small set of processors.

## Software Frameworks

Many parallel dynamic load balancing libraries and frameworks have been developed before for specialized domains. These libraries are often particularly useful because they allow application developers to specify the structure of their application once and then easily try a number of different load balancing strategies to see which is most effective in practice without needing to reformulate the load measurement and task graph construction process for each new algorithm.

The Zoltan toolkit [1] provides a suite of dynamic load balancing and parallel repartitioning algorithms, including geometric, hypergraph, and graph methods. It provides a simple interface to switch between algorithms, allowing straightforward comparisons of algorithms in applications. The application developers provide an explicit cost function and communication graph for the Zoltan algorithms to use.

Charm++ [2] adopts a migratable object-based load balancing model. As such, Charm programs have a natural grain size determined by their objects, and can be load balanced by redistributing their objects among processors. Charm provides facilities for automatically

measuring load, and provides a variety of associated measurement-based load balancing strategies that use the recent past as a guideline for the near future. This avoids the need for developers to explicitly specify any cost functions or information about the application's communication structure. Charm++ includes a suite of global, distributed, and hierarchical load balancing schemes.

DRAMA [3] is a library for parallel dynamic load balancing of finite element applications. The application must provide the current distributed mesh, including information about its computation and communication requirements. DRAMA then provides it with all necessary information to reallocate the application data. The library computes a new partitioning, either via direct mesh migration or via parallel graph re-partitioning, by interfacing to the ParMetis or Jostle graph partitioning libraries. This project is no longer under active development.

The Chombo [4] package was developed by Lawrence Berkeley National Lab. It provides a set of tools including load balancing for implementing finite difference methods for the solution of partial differential equations on block-structured adaptively refined rectangular grids. It requires users to provide input indicating the computational workload for each box, or mesh partition.

## Task Scheduling Methods

Some applications are characterized by the continuous production of tasks rather than by iterative computations on a collection of work units. These tasks, which are continually being created and completed as the application runs, form the basic unit of work for load balancing. For these applications, load balancing is essentially a task scheduling or task allocation problem. This task pool abstraction captures the execution style of many applications such as master/worker and state-space search computations. Such applications are typically non-iterative.

Load balancing strategies in this category can be classified as centralized, fully distributed, or hierarchical. Hierarchical strategies are hybrids that aim to combine the benefits of centralized and distributed methods. In centralized strategies, a dedicated "central" processor gathers global information about the state of the entire machine and uses it to make global

load balancing decisions. On the other hand, in a fully distributed strategy, each processor exchanges state information only with other processors in its neighborhood.

Fully distributed load balancing received significant attention from the early days in parallel computing. One way to categorize them is based on which processor initiates movement of tasks.

Sender-initiated schemes assign newly created tasks to some processor, chosen randomly or from one of the neighbors in a physical or virtual topology. The decision to assign it to another processor, instead of retaining the task locally may also be taken randomly, or based on a load metric such as a queue size. Random assignment has some good statistical properties but suffers from high communication costs, by requiring that most tasks be sent to remote processors. With neighborhood strategies, global balancing is achieved as tasks are moved from heavily loaded neighborhood diffuse onto lightly loaded processors. In the adaptive contraction within neighborhood (ACWN) scheme, tasks always travel to topologically adjacent neighbors with the least load, but only if the difference in loads is more than a predefined threshold. In addition, ACWN does saturation control by classifying the system as being either lightly, moderately, or heavily loaded.

In receiver-initiated schemes, the underloaded processors request load from heavily loaded processors. You may chose the victim to request work from randomly, or via a round-robin policy, or from among "neighboring" processors. Randomized work stealing is yet another distributed dynamic load balancing technique, which is used in some runtime systems such as Cilk.

The distinction between sender or receiver initiation is blurred when processors exchange load information, typically with neighbors in a virtual topology. Although the decision to send work is taken by the sender, it is taken in response to load information from the receiver. For example, in neighborhood averaging schemes, after periodically exchanging load information with neighbors in a virtual (and typically, low-diameter) topology, each processor that is overloaded compared with its neighbors, sends equalizing work to its lower-loaded neighbors. Such policies tend to be proactive compared with work stealing, trading better load balance for extra communication.

Another strategy in this category, and one of the oldest ones, is the gradient model. Here each processor participates in a continuous fixed-point computation with its neighbors to identify the neighbor that is closest to an idle processor. Overloaded processors then send work toward the idle processors via that neighbor.

The gradient model is a demand-driven approach. In gradient schemes, underloaded processors inform other processors of their state, and overloaded processors respond by sending a portion of their load to the nearest lightly loaded processor. The resulting effect is a form of a gradient map that guides the migration of tasks from overloaded to underloaded processors.

The dimensional exchange method is a distributed strategy in which balancing is performed in an iterative fashion by “folding” an  $P$  processor system into  $\log P$  dimensions and balancing one dimension at a time. that is, in phase  $i$ , each processor exchanges load with its neighbor in the  $i$ th dimension so as to equalize load among the two. After  $\log P$  phases, the load is balanced across all the processors. This scheme is conceptually designed for a hypercube system but may be applied to other topologies with some modification.

Several hierarchical schemes have been proposed that avoid the bottleneck of a centralized strategies, while retaining some of their ability to achieve global balance quickly. Typically, processors are organized in a two-level hierarchy. Managers at the lower level behave like masters in centralized strategies for their domain of processors, and interact with other managers as processors in a distributed strategies. Alternatively, load balancing is initiated at the lowest levels in the hierarchy, and global balancing is achieved by ascending the tree and balancing the load between adjacent domains at each level in the hierarchy.

Often, priorities are associated with tasks, especially for applications such as branch-and-bound or searching for one solution in a state-space search. Task balancing for these scenarios is complicated because of the need to balance load while ensuring that high priority work does not get delayed by low priority work. Sender-initiated random assignment as well as some hierarchical strategies have shown good performance in this context.

## Bibliographic Notes and Further Reading

There is a rich history of load balancing literature that spans decades. This entry is only able to cite a very small amount of this literature, and attempts to include modern papers with broad scope and great impact. Kumar et al. [5] describe the scalability and performance characteristics of several task scheduling schemes, and Devine et al. [6] gives a good overview of the range of techniques used for periodic balancing in modern scientific applications and the load balancing challenges faced by these applications. Xu and Lau [7] give an in-depth treatment of distributed load balancing articles, covering both mathematical theory and actual implementations.

For practical information on integrating load balancing frameworks into real applications, literature describing principles and practical use of such systems as DRAMA [3], Charm++ [2, 9], Chombo [4], and Zoltan [1] is a crucial resource.

More information is available on the implementation of task scheduling methods, whether they are centralized [10, 11], distributed [12–14], or hierarchical [14]. Work stealing is described in detail by Kumar et al. [5], while associated work on Cilk is described in Frigo et al. [15]. Dinan et al. [16] extended work stealing to run on thousands of processors using ARMCI.

## Locality of Reference and Parallel Processing

KESHAV PINGALI

The University of Texas at Austin, Austin, TX, USA

### Definition

The term *locality of reference* refers to the fact that there is usually some predictability in the sequence of memory addresses accessed by a program during its execution. Programs are said to exhibit *temporal locality* if they access the same memory location several times within a small window of time. Programs that access nearby memory locations within a small window of time are said to exhibit *spatial locality*. Many parallel processors are nonuniform memory access (NUMA) machines in which the time required by a given processor to access a memory location may depend on the address of that location. Parallel programs that exploit this nonuniformity are said to exhibit *network locality*. Exploiting all types of locality is critical in parallel processing because the performance of most programs is limited by the latency of memory accesses. Hardware mechanisms for exploiting locality include caches and pre-fetching. Software mechanisms include program and data transformations, software pre-fetching, and topology-aware mappings of computations and data. Multithreading can reduce the impact of memory latency on programs that have a lot of parallelism but little locality of reference.

### Discussion

#### Introduction

The sequence of memory addresses accessed by a program or a thread during its execution is called its memory trace. Memory traces are not random number sequences since there is some predictability to the addresses in most traces, which arises from fundamental features of the von Neumann model of computation. For example, instructions between branches are executed sequentially, so if an instruction at address  $i$  is executed and it is not a branch

instruction, the instruction at address  $i + 1$  must be executed next. This kind of predictability in address traces is called locality of reference, and exploiting it is key to obtaining good performance on sequential and parallel machines.

There are three kinds of locality of reference: *temporal*, *spatial*, and *network*.

### Temporal Locality

A *program execution* exhibits temporal locality if the occurrences of a given memory address in its memory trace occur close to each other. A *program* is said to exhibit temporal locality if its executions for most inputs of interest exhibit temporal locality.

Temporal locality in instruction addresses arises mainly from the execution of loops (in particular, innermost loops in loop nests). For example, when multiplying two  $N \times N$  matrices using the standard algorithm shown below, the body of the innermost loop is executed  $N^3$  times back to back, resulting in temporal locality in instruction addresses. Temporal locality in instruction addresses may also arise from the execution of “hot” methods that are called repeatedly during program execution.

```
for (i = 0; i < N; i++)
 for (j = 0; j < N; j++)
 for (k = 0; k < N; k++)
 C[i][j] = C[i][j] + A[i][k] * B[k][j];
```

Temporal locality in data addresses may arise from accesses to constants and memory locations accessed repeatedly within loops. For example, in the matrix multiplication code shown above, every iteration of the innermost loop for given outer loop indices  $(i, j)$  accesses the same array location  $C[i][j]$ , giving rise to temporal locality. Some compilers can exploit this temporal locality by loading  $C[i][j]$  into a register just before the innermost loop begins execution, and performing the additions to this register rather than to the memory location  $C[i][j]$  (the value in the register is written back to memory when loop finishes execution). In contrast, there is little temporal locality in the references to the  $B$  array since successive accesses to a given element of  $B$  are separated by  $O(N^2)$  other addresses in the trace.

### Spatial Locality

A program execution exhibits spatial locality if the occurrences in its trace of nearby memory addresses

occur close together in that trace. A program is said to exhibit spatial locality if its executions for most inputs of interest exhibit spatial locality.

Spatial locality in instruction accesses arises because instructions between branches are executed sequentially, so if an instruction at address  $i$  is executed and it is not a branch, the instruction at address  $i + 1$  must be executed next. Instruction accesses within innermost loops therefore exhibit both temporal and spatial locality. Programs that perform operations on vectors exhibit spatial locality if successive vector elements are accessed during the computation, such as the following program which adds the elements of two vectors:

```
for (i = 0; i < N; i++)
 C[i] = A[i]+B[i];
```

Notice that in this program, there are no fewer than four sources of spatial locality: the accesses to the three vectors, and the instructions in the loop body. Programs that access vector elements with some small stride also exhibit spatial locality.

Programs that access arrays of two or more dimensions will exhibit spatial locality if array elements are accessed successively (or with some small non-unit stride) in the order in which they are stored in memory. For example, in the C programming language, arrays are stored in row-major order, so the elements of the matrix are stored row by row in memory. If a program accesses such arrays row by row, these accesses will exhibit spatial locality. In the matrix multiplication code shown above, the accesses to arrays  $A$  and  $C$  have spatial locality of reference, since these arrays are accessed row by row, but the accesses to array  $B$  do not since this array is accessed by columns.

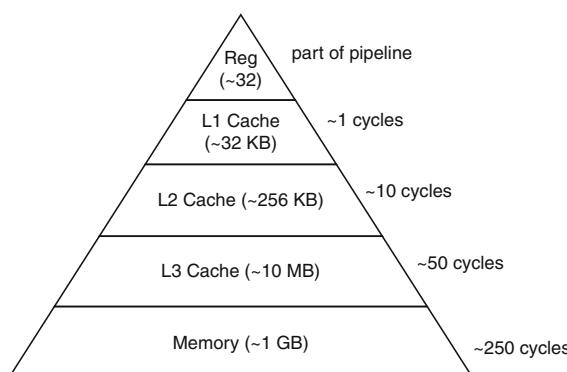

### Network Locality

In a parallel computer in which memory addresses are distributed across the processors, a processor may have faster access to memory locations mapped locally than to memory locations mapped to other processors. There may also be differences in the access times to memory locations mapped to different processors because most communication networks for parallel computers are multi-stage networks in which communication packets from a given processor may go through different numbers of stages to get to different processors, and each

stage adds some latency to the communication. Parallel computers that exhibit these kinds of nonuniform memory access times are called Non-Uniform Memory Access (NUMA) parallel computers. A parallel program that attempts to exploit features of NUMA parallel computers is said to exhibit *network locality*.

### Exploiting Locality: Caches

Cache memories exploit temporal and spatial locality of reference to provide programmers with the performance characteristics of a large and fast memory system but at reasonable cost. The key is a hierarchical organization of the storage, known usually as the memory hierarchy and shown pictorially below. On modern processors, there may be many memory hierarchy levels such as the registers, Level 1 (L1) cache, Level 2 (L2) cache, Level 3 (L3) cache, and main memory. The virtual memory system can be considered to be another level in the memory hierarchy. L1 cache memory is small, fast, and usually implemented in SRAM, while main memory is large, relatively slow, and implemented in DRAM; the other levels of cache fall somewhere in between these two extremes. For example, on the Intel Nehalem multicore processor, each core has 32 KB L1 instruction and data caches, and a 256 KB L2 cache; all the cores share a 8 MB L3 cache. The size of the main memory may be many GB. On most processors, accesses to the L1 cache typically take around 1–3 cycles, and the latency of memory accesses increases by roughly an order of magnitude in going from one level to the next (Fig. 1).

**Locality of Reference and Parallel Processing. Fig. 1**

Memory hierarchy of a typical processor

Given such a memory hierarchy, the effective latency of memory accesses as observed by the processor will be considerably less than DRAM access time provided most of the memory accesses are satisfied by the faster cache levels. One way to accomplish this is to store the addresses and contents of the most recently accessed memory locations in the cache memories. When a processor issues a memory request, the fastest cache level in which that address is cached responds to the request, so the long-latency trip to memory is required only if the address is not cached anywhere. Programs that have good temporal locality obviously benefit from this caching strategy. When a memory request goes all the way to main memory, most memory systems will fetch not just the contents of the desired address but the contents of a block of addresses, one of which is the desired address (this block of addresses is called the *cache block* or *cache line* containing that address). Because the latency of fetching a cache block from memory is almost the same as the latency of fetching the contents of a single address, programs with spatial locality benefit from this caching policy.

The design of caches becomes more complex in parallel machines because of the *cache-coherence* problem. A major advantage of caches is that they are transparent to the programmer in the sense that although caches may confer performance benefits, they do not change the output of the program. Ensuring this transparency in a shared-memory multiprocessor is complicated by the fact that a memory location may be cached in the local caches of several cores/processors, so it is necessary to ensure that updates to that address made by different processors are coordinated in some way to preserve the transparency of caching to the programmer. This is referred to as the cache-coherence problem, and many solutions to this problem have been explored in the literature.

### Program Transformations for Exploiting Caches

While caches are transparent to the programmer, obtaining the performance benefits of caching may require the programmer to be aware of the cache hierarchy and to transform programs to become more “cache-friendly” by enhancing temporal and spatial locality. For the most part, these transformations can be divided

into two classes: (1) rescheduling of operations and (2) reordering of data structures.

The goal of rescheduling operations is to ensure that operations that access the same memory address (or more generally, the same cache line) are executed more or less contemporaneously, thereby improving locality. In dense matrix computations, loop permutation and loop tiling are the most important transformations for enhancing locality. For example, consider the matrix multiplication program discussed above. As is well known, all six permutations of the three loops produce the same output; however, their locality characteristics are very different. If the *j* loop is permuted into the innermost position in the loop nest, the references to arrays C and B enjoy good spatial locality since the inner loop accesses these arrays row by row, and the reference to array A enjoys good temporal locality since all iterations of the inner loop for given outer loop indices access the same element of A. Conversely, permuting the *i* loop into the innermost position is bad for exploiting spatial locality since none of the matrices will be accessed by row in the innermost loop.

While loop permutation is useful, the most important transformation for enhancing locality is loop tiling. A tiled version of matrix multiplication is shown below. The effect of this transformation is to produce block matrix programs, in which the inner loops can be viewed as operating on blocks of the original matrices. In the tiled code shown below, BLOCK\_SIZE is a parameter that determines the size of the blocks multiplied in the inner three loops. The value of this parameter must be chosen carefully so that the working set of the three innermost loops fits in cache. If there are multiple cache levels, it may be necessary to tile for some or all these levels.

Choosing an optimal tile size is a difficult problem in general, and it may be necessary to execute the program for different tile sizes and determine the best one by measurement. This approach is called empirical optimization and it is used by the ATLAS system, which generates high-performance Basic Linear Algebra Subroutines (BLAS). It is often possible to use simple machine models to reduce the search space.

```
for (ii = 0; ii < N; ii += BLOCK_SIZE)
 for (kk = 0; kk < N; kk += BLOCK_SIZE)
 for (jj = 0; jj < N; jj += BLOCK_SIZE)
 for (i = ii; i < ii +
```

```
BLOCK_SIZE && i < N; i++)
 for (k = kk; k < kk +
 BLOCK_SIZE && k < N; k++)
 for (j = jj; j < jj +
 BLOCK_SIZE && j < N; j++)
 C[i][j] = C[i][j] + A[i][k] * B[k][j];
```

Spatial locality can also be improved by changing the layout of data structures in memory. For example, in the *(i, j, k)* order of the three nested loop version of matrix multiplication, changing the layout of B to column-major order will improve spatial locality for the references to array B. For data transformations to be useful, the overhead of transforming the data layout must be amortized by the benefits of improved spatial locality in computing with that data. For example, when performing the tiled matrix multiplication shown above, high performance implementations will usually copy blocks of the matrices into contiguous memory locations because the overhead of copying the data is amortized by the benefits of improved spatial locality when performing the block matrix multiplication.

Many techniques for changing the layouts of other kinds of data structures have been explored in the literature. For example, records and structures that span multiple cache lines can be allocated so that fields that are often accessed contemporaneously are packed together into the same cache line, if possible, rather than being allocated in different cache lines. In managed languages like Java and C#, the garbage collector can improve locality by moving data items that are accessed contemporaneously into the same page of virtual memory.

## Cache-Oblivious Programs

Divide-and-conquer algorithms for many problems are naturally cache-friendly because they repeatedly generate sub-problems of smaller size until they reach a base case, and then assemble the solution to the problem from the solutions to these sub-problems. If the base case of the divide-and-conquer algorithm is chosen so that the working set of that sub-problem fits in the cache, and the data movement required for assembling the solution from the solutions to the sub-problems is small, the program may have excellent locality. Divide-and-conquer algorithms for problems like matrix multiplication, FFT, and Cholesky factorization enjoy this

property and they are known as cache-oblivious programs because they have good temporal locality even though they are not explicitly optimized for any particular cache size or structure; this is in contrast to iterative algorithms for these problems, which require tiling to be made cache-friendly. Spatial locality in cache-oblivious matrix multiplication programs can be enhanced by using space-filling curves to order the storage of matrix elements.

## Prefetching

Caches can be classified as latency-avoidance mechanisms since the goal is to avoid long latency memory operations by exploiting locality of reference. The performance impact of long latency memory operations can also be reduced by latency-tolerance techniques such as prefetching. If the memory accesses of a program can be predicted well in advance of when the values are actually required in the computation, the processor might be able to prefetch these values from memory into the cache so that they are available immediately when they are needed for the computation. This is an instance of a more general optimization technique in parallel programming called *overlapping communication with computation*: the key idea is to perform data movement in parallel with computation to reduce the effective overhead of the data movement. Prefetching is particularly useful for streaming programs since these programs touch large volumes of data and have predictable data accesses but have little temporal locality, so caches are not effective for reducing the effective memory latency.

In some processors, prefetching is under the control of the programmer. For example, the iA32 SSE instruction set has prefetch instructions for prefetching data into some or all cache levels. The programmer or compiler is responsible for inserting prefetch instructions into the appropriate places in the program. In other processors, prefetching is implemented in hardware. Usually, the prefetch unit monitors the stream of memory addresses from the processor and attempts to detect sequences of fixed stride memory accesses. If it finds such a sequence, it uses that sequence to determine memory addresses for prefetching. To avoid unnecessary page faults, prefetching usually does not cross page boundaries.

## Exploiting Network Locality

For techniques to exploit network locality, see the Encyclopedia entry on ► [Topology Aware Task Mapping](#).

## Using Parallelism to Tolerate Memory Latency

When programs have little locality of reference and also make unpredictable memory accesses, neither caching nor prefetching is effective in reducing the performance impact of long latency memory accesses. Many irregular programs such as graph computations fall in this category. For such programs, it is possible to tolerate latency by exploiting parallelism, provided the processor can switch rapidly between parallel threads of execution. There are many implementations of this scheme, but a simple approach is the following. The processor issues instructions from a thread until that thread becomes idle waiting for a memory load to complete. At that point, the processor switches to a different thread that is ready to execute and begins issuing instructions from that thread, and so on. As long as there is enough parallelism in the program and the processor can switch quickly between threads, the performance impact of long latency loads from memory is minimized. In other designs, the processor switches between ready threads at every cycle.

This approach requires specially designed processors since the processor needs to be able to switch between threads very rapidly. Tera's MTA processor is an example. Each processor can support 128 simultaneous threads. *Simultaneous multi-threading* (SMT) is an implementation of this idea in general-purpose processors. The same principle also underlies the design of dataflow computers, although threads in that case are very fine-grain, comprising of a single instruction.

## Bibliographic Notes and Further Reading

Although the importance of exploiting locality of reference in programs was recognized from the very start of computing by pioneers like von Neumann, the first machine to incorporate cache memory was the IBM 360 Model 85 [8]. Work on transforming programs to optimize them for parallelism and locality of reference began at the University of Illinois, Urbana-Champaign in the 1960s [2, 12]. The automation of loop and data transformations was enabled by the development of powerful integer linear programming tools in the 1990s [5, 6, 13]. For the most part, these techniques are restricted to dense matrix programs. Data-shackling is a more general data-centric approach to reasoning about locality [11]. Data transformations for non-array data structures are described in [4].

Determining optimal values for parameters such as tile sizes is an active topic of research. The empirical optimization approach is incorporated in the popular ATLAS system, which produces automatically tuned Basic Linear Algebra Subroutines (BLAS) [1]. An approach using simple performance models and a detailed comparison with the empirical optimization approach can be found in [14]. Cache-oblivious algorithms [7] are based on the notion of I/O complexity [9].

Latency tolerance through multithreading was implemented in the Tera computer [3]. Network locality and network-oblivious algorithms are explored in [4].

## Definition

The common name of *Parallel Logic Languages* groups those languages which are based on logic programming and which, while respecting as much as possible the declarative semantics, have an operational semantics which exploits parallelism or concurrency, either explicitly or implicitly, to gain in efficiency or expressiveness.

## Discussion

### Logic Programming

The application of logic and mechanized proofs to express problems and their solutions is at the origins of computer science [6]. The basis of this approach is to express the knowledge on some problem (e.g., how a sorted tree is organized) as a consistent theory in some logic and to model the desired goal (e.g., storing an item on the tree) as a formula. If the formula is true in the theory capturing the problem conditions, then the objective expressed by such formula is achievable (i.e., the item can be stored). The set of formulas which are true in the theory are those which state the set of objectives achievable (computable) by the program. This constitutes the *declarative semantics* of logic programs.

A usual proof strategy is to add to the initial theory a formula stating the *negation* of the desired goal and to prove the inconsistency of the resulting theory by generating a counterexample. The valuation(s) of the free variable(s) in the counterexample constitute a solution to the initial problem.

As an example, Fig. 1 presents a set  $\mathcal{T}$  of formulas describing insertion in a sorted tree, where constants, predicate names, and term names are written

in lowercase, and variables start with uppercase letters, in conformance with logic programming languages. Arithmetic predicates are assumed to be available. *void* represents the empty tree. An argument of the form  $tree(L, I, R)$  represents a tree node with item  $I$  and left and right children  $L$  and  $R$ , respectively. A fact  $insert(T_1, I, T_2)$  can be inferred from this theory if  $T_2$  is the resulting tree after inserting item  $I$  in tree  $T_1$ . Given the term  $T_1$  representing a sorted tree and an item  $I$  to be stored, the inconsistency of  $\mathcal{T} \wedge \neg \exists T_2 . insert(T_1, I, T_2)$  can be proved with a counterexample for  $T_2$  which will be, precisely, the tree which results from inserting  $I$  into  $T_1$ .

From the *procedural point of view*, the method used to generate a counterexample is basically a search, where at each step one of the inference rules in the logic is applied, maybe leaving other rules pending to be applied. Making this search as efficient as possible is paramount in order to make logic a practical programming tool. This can be achieved by reducing the set of inference rules to be applied and the number of places where they can be applied.

Concrete logic programming languages specify the deduction method (*operational semantics*) further as well as the syntax and (possibly) subsets of the logic. The most successful combination is *resolution* (only one inference rule) on *Horn clauses* (conjunctions of non-negated literals implying a non-negated literal, as in Fig. 1). In particular, the usual operational semantics (SLD resolution) for the logic programming language Prolog uses the resolution principle with two rules to decide which literals the inference rule is applied to. SLD resolution in Prolog:

- Explores conjunctions in every implication from left to right, as written in the program text (computation rule).
- Tries to match and evaluate clauses from top to bottom (search rule).

From a goal like  $insert(tree(void, 3, void), 4, T_2)$ , SLD resolution selects one of the implications with a matching head, renames apart its parameters (i.e., variables with new names which do not clash with previous ones are created), and expands the right-hand side. The

$$\begin{array}{lll}
 (\forall I.insert(void, I, tree(void, I, void))) & & \wedge (1) \\
 (\forall L, I, R, It, II.insert(tree(L, I, R), It, tree(II, I, R))) \leftarrow It < I \wedge insert(L, It, II) & \wedge (2) \\
 (\forall L, I, R, It, Ir.insert(tree(L, I, R), It, tree(L, I, Ir))) \leftarrow It > I \wedge insert(R, It, Ir) & \wedge (3) \\
 (\forall L, I, R, It.insert(tree(L, I, R), It, tree(L, I, R))) \leftarrow It = I & \wedge (4)
 \end{array}$$

**Logic Languages. Fig. 1** Insertion in a sorted tree

first matching clause is (2), and expanding its body results in:

$$T_2 = tree(II, 3, void) \wedge 4 < 3 \wedge insert(void, 4, II)$$

This conjunction of goals is called a *resolvent*. The left-most one is a unification [12] (i.e., an equation which expresses syntactical equality between terms) which, when successful, generates bindings for the variables in it. In this case, as  $T_2$  is a variable, it just succeeds by assigning the term  $tree(II, 3, void)$  to it. That leaves the resolvent:

$$4 < 3 \wedge insert(void, 4, II)$$

The next goal to be solved is  $4 < 3$ , which is false, and therefore the whole conjunction is false and another alternative for the last selection is to be taken. Bindings made since the last selection are undone, and clause (3) is selected:

$$T_2 = tree(void, 3, Ir) \wedge 3 < 4 \wedge insert(void, 4, Ir)$$

In this case, the arithmetic predicate succeeds and the resolvent is reduced to  $insert(void, 4, Ir)$ . This matches the head of the first clause and succeeds with the binding  $Ir = tree(void, 4, void)$ . The initial goal is then proved with the output binding:

$$T_2 = tree(void, 3, tree(void, 4, void))$$

which represents a tree with a 3 at its root and a 4 in its (unique) right subtree.

Logic programming languages include additional nonlogical constructs to perform I/O, guide the execution, and provide other facilities. They also offer a compact, programming-oriented syntax (e.g., avoiding as much as possible quantifiers; compare the rest of the

programs in this text with the mathematical representation of Fig. 1).

### Operational View and Comparison with Other Programming Paradigms

Due to the fixed computation and search rules, SLD resolution can be viewed as a relatively simple operational semantics that has significant similarities to that of other programming paradigms. This provides a highly operational view of resolution-based theorem proving.

In fact, in the procedural view, SLD is akin to a traditional execution that traverses clauses sequentially from left to right, in the same way execution traverses procedure bodies in traditional languages. Predicates take the role of procedures, clause head arguments are procedure arguments, clauses are similar to case statements, etc. Predicate invocation takes the role of procedure calling and unification amounts to parameter passing (both for input and output). Logical variables are similar to (declarative) pointers that can be used to pass data or pointers inside data structures. Thus, pure deterministic logic programs can be seen as traditional programs with pointers and dynamic memory allocation but without destructive update. In addition, in nondeterministic programs clause selection offers a built-in backtracking-based search mechanism not present in other paradigms, which allows exploring the possible ways to accomplish a goal. Finally, unification provides a rich, bidirectional pattern matching-style parameter passing and data access mechanism. Similarly, logic programming (specially variants that support higher order) can be seen as a generalization of functional programming where pattern matching is bidirectional, logic variables are allowed, and more than one definition is possible for each function. See, for example, [8] for a more detailed discussion of the correspondence between logic programming and other programming paradigms.

## Toward Parallelism and Concurrency

*Parallel logic programming languages* aim at retaining the observable semantics while speeding up the execution w.r.t. a sequential implementation. *Concurrent logic languages* (►Sect. Concurrency in Logic Programming) focus more on expressiveness and often adopt an alternative semantics. Opportunities for parallel and concurrent execution come from relaxing the left-to-right, top-to-bottom order of the computation and search rules: it is, in principle, possible to select *several different literals* in a logical conjunction to resolve against simultaneously (*and-parallelism*), or explore *several different clauses* at the same time (*or-parallelism*) [4, 7].

The distinction between parallel and concurrent logic languages is not as clear-cut as implied so far. In fact, parallel execution models have been proposed for concurrent logic languages in which independent parts of the execution of concurrent processes are executed in different processors simultaneously. Conversely, the language constructs developed for parallelism have also been used for concurrency and distributed execution. The current trend is toward designing languages that combine in useful ways parallelism, concurrency, and search capabilities.

Most parallel logic programming languages have been implemented for shared-memory multicollectors. There is no *a priori* reason not to execute a logic program in a distributed fashion, as demonstrated by distributed implementations [11]. However, the need to maintain a consistent binding store seen by all the agents involved in an execution imposes an overhead which does not appear in the shared memory case. The focus will, therefore, be on linguistic constructions which, although not necessarily requiring shared-memory computers, have been mainly exploited in this kind of architectures.

## Exploiting Parallelism in Logic Programming

Independently from whether parallelism is exploited among conjunctions of literals or among different clauses, it can be detected in several ways:

**Implicit parallelism:** The compiler and run-time system decide what can be executed in parallel with no programmer intervention, analyzing, for example, data dependencies. One disadvantage of this

approach is that it may impose considerable run-time overhead, and the programmer cannot give clues as to what can (or should) be executed in parallel.

**Explicit parallelism:** The compiler and run-time system know beforehand which clauses/goals are to be executed in parallel typically via programmer annotations. This has the disadvantage that it puts the responsibility of parallelization (a hard task) solely in the hands of the programmer.

**Combinations:** This is realized in practice as a combination of handwritten annotations, static analysis, and run-time checks.

The last option is arguably the one with the most potential, as it aims at both reducing run-time effort and simplifying the task of the programmer, while still allowing annotating programs for parallel execution. In the following sections, variants of these sources of parallelism will be revised briefly, assuming that annotations to express such parallelism at the source language level are available and the programs have been annotated with them. Methods for introducing these annotations automatically (briefly mentioned in ►Sect. Automatic Detection of Parallelism) are the subject of another entry (►Parallelization, Automatic).

## And-Parallelism

And-parallelism stems from simultaneously selecting several literals in a resolvent (i.e., several steps in a procedure body). While the semantics of logic programming makes it possible to safely select *any* goal from the resolvent, practical issues make it necessary to carefully choose which goals can be executed in parallel. For example, the evaluation of arithmetic expressions in classical Prolog needs variables to be adequately instantiated, and therefore the sequential execution order should be kept in some fragments; input/output also needs to follow a fixed execution order; and tasks which are too small may not benefit from parallel execution [8].

Whether a sequential execution order has to be respected (either for efficiency or correctness) can be decided based on *goal independence*, a general notion which captures whether two goals can proceed without mutual interference. Deciding whether the amount of

work inside a goal is enough to benefit from parallel execution can be done with the use of (statically inferred) cost (complexity) functions. With them, the expected sequential and parallel execution time can be compared at compile time or at run time (but before executing the parallel goals).

### An Illustrating Example

The code in Fig. 2 implements a parallel matrix by matrix multiplication. Commas denote sequential conjunctions (i.e., A, B means “execute goal A first, and when successfully finished, execute goal B”), while goals separated by an ampersand (A & B) can be safely executed in parallel.

Matrices are represented using nested lists, and matrix multiplication is decomposed into loops performing vector by matrix and vector by vector multiplication, which are in turn expressed by means of recursion. Every iteration step can be performed independently of the others in the same loop and therefore parallelism can be expressed by stating that predicate calls in the body of the recursive clauses (e.g., mat\_vec\_multiply in mat\_mat\_multiply) can be executed in parallel with the corresponding recursive call (mat\_mat\_multiply). Note that the arithmetic operation R is Prod + NewRes is performed after executing the other goals in the clause, because it needs NewRes to be computed.

```
mat_mat_multiply([], _, []).
mat_mat_multiply([V0|Rest], V1, [R|Os]) :-
 mat_vec_multiply(V1, V0, R) &
 mat_mat_multiply(Rest, V1, Os).

mat_vec_multiply([], _, []).
mat_vec_multiply([V0|Rest], V1, [R|Os]) :-
 vec_vec_multiply(V0, V1, R) &
 mat_vec_multiply(Rest, V1, Os).

vec_vec_multiply([], [], 0).
vec_vec_multiply([H1|T1], [H2|T2], R) :-
 Prod is H1*H2 &
 vec_vec_multiply(T1, T2, NewRes),
 R is Prod + NewRes.
```

Logic Languages. Fig. 2 Matrix multiplication

The & construct is similar to a FORK-JOIN, where the existence of A & B implicitly marks a FORK for the goals A and B and a JOIN after these two goals have finished their execution. Such parallel execution can be nested to arbitrary depths. The strict fork-join structure is also not compulsory and other, more flexible parallelism primitives are also available.

A relevant difference with procedural languages is the possible presence of search, that is, a goal can yield several solutions on backtracking, corresponding to the selection of different clauses, or even fail without any solution. Parallel execution should cope with this: when A & B can yield several solutions, an adequate operational semantics (and underlying execution mechanism) has to be adopted. Several approaches exist depending on the relationship between A and B. Perhaps, the simplest one is to execute in parallel and in separate environments A and B, gather all the solutions, and then build the cross product of the solutions. However, even if A and B can be safely executed in parallel, this approach is often not satisfactory for performance reasons.

### Independent And-Parallelism

Independent and-parallelism (IAP) only allows the parallel execution of goals which do not interfere through, for example, bindings to variables, input/output, assertions onto the shared database, etc. In absence of side effects, independence is customarily expressed in terms of allowing only compatible accesses to shared variables.

Independent and-parallelism can be *strict* or *non-strict*. The strict variant (SIAP) only allows parallel execution between goals which do not share variables at run time. The non-strict variant (NSIAP) relaxes this requirement to allow parallel execution of goals sharing variables as long as at most one of the parallel goals attempts to bind/check them or they are bound to compatible values. The matrix multiplication (Fig. 2) features SIAP if it is assumed that the input data (the first two matrices) does not contain any variable at all (i.e., these matrices are *ground*) and therefore independence is ensured as no variables can be shared.

As a further example, Fig. 3, left, is an implementation of the QuickSort algorithm, where it is assumed that a ground list of elements is given in order to be sorted. In this case, partition splits the input list into two lists which are recursively sorted and joined

```
qsort([], []).
qsort([X|Xs], Sorted) :-
 partition(Xs, X, Large, Small),
 qsort(Small, SmallSorted),
 qsort(Large, LargeSorted),
 append(Small, [X|Large], Sorted).
```

```
% Partition is common to all
% QuickSort versions
partition([], _, [], []).
partition([X|Xs], P, [X|Ls], Ss) :-
 X > P, partition(Xs, P, Ls, Ss).
partition([X|Xs], P, Ls, [X|Ss]) :-
 X <= P, partition(Xs, P, Ls, Ss).
```

**Logic Languages.** Fig. 3 QuickSort: sequential version (*left*) and SIAP version (*right*)

```
qsort(Unsrt, Sorted) :-
 qs(Unsrt, Sorted, []).
qsort([], S, S).
qsort([X|Xs], SortedSoFar, Tail) :-
 partition(Xs, X, Large, Small),
 qsort(Small, SortedSoFar, Rest),
 qsort(Large, Rest, Tail).
```

```
qsort(Unsrt, Sorted) :-
 qs(Unsrt, Sorted, []).
qsort([], S, S).
qsort([X|Xs], SortedSoFar, Tail) :-
 partition(Xs, X, Large, Small),
 qsort(Small, SortedSoFar, Rest) &
 qsort(Large, Rest, Tail).
```

**Logic Languages.** Fig. 4 QuickSort, using difference lists and annotated for non-strict and-parallelism

afterward. The code on the right is the SIAP parallelization, correct under these assumptions, where the two calls to QuickSort are scheduled for parallel execution.

A perhaps more interesting example is the implementation of QuickSort in Fig. 4. The sequential version on the left uses a technique called *difference lists*. The sorted list is, in this case, not ended with a `nil`, but with a free variable (a “logical pointer”) which is carried around. When this variable is instantiated, the tail of the difference list is instantiated. This makes it possible to append two lists in constant time. A procedural counterpart would carry around a pointer to the last element of a list, so that it can be modified directly. The two calls to `Qsort` share a variable and cannot be executed in parallel following the SIAP scheme. However, since only the second call will attempt to bind it they can be scheduled for NSIAP execution.

A last example of IAP (this time including some search) appears in Fig. 5. It is a solution to the problem

of placing  $N$  queens on an  $N \times N$  chessboard so that no two queens attack each other. It places the queens column by column picking (with `select/3`) a position from a list of candidates. `not_attack/3` checks that this candidate does not attack already placed queens. Search is triggered by the multiple solutions of `select/3`, and the program can return all the solutions to the queens problem via backtracking.

Checking that queens are attacked is independent from trying to place the rest of the queens, and so the two goals can be run in parallel, performing some speculative work. Unlike the previous examples, the `not_attack/3` check can fail and force the failure of a series of parallel goals which should be immediately stopped.

Applying the execution scheme sketched in ▶Sect. An Illustrating Example (collecting solutions and making a cross product) is not appropriate: if a candidate queen cannot be placed on the chessboard, the work invested in trying to build the rest of the solutions is

```

queens(N, Qs) :-

 range(1, N, Ns),

 queens(Ns, [], Qs).

queens([], Qs, Qs).

queens(UnplacedQs, SafeQs, Qs) :-

 select(UnplacedQs, UnplacedQs1, Q),

 not_attack(SafeQs, Q, 1) &

 queens(UnplacedQs1, [Q|SafeQs], Qs).

not_attack([], _, _).

not_attack([Y|Ys], X, N) :-

 X =\= Y+N, X =\= Y-N,

 N1 is N+1,

 not_attack(Ys, X, N1).

select([X|Xs], Xs, X).

select([Y|Ys], [Y|Zs], X) :-

 select(Ys, Zs, X).

```

**Logic Languages. Fig. 5** N-Queens annotated for and-parallelism

wasted. If only one solution is needed and the candidate queen is correctly placed, the work spent in finding all the solutions is wasted.

One workaround is to adapt the sequential operational semantics to the parallel case and perform recomputation. Assuming the conjunction A & B & C, forward execution is done as in a FORK-JOIN scheme, and backtracking is performed from right to left. New solutions are first sought for C and combined with the existing ones for A and B. When the solutions for C are exhausted, B is restarted to look for another solution while C is relaunched from the beginning. When the goal A finitely fails, the whole parallel conjunction fails. This generates the solutions in the same order as the sequential execution, which may be interesting for some applications.

Additionally, in the case of IAP, if one of the goals (say, B) fails without producing any solution, the parallel conjunction can immediately fail. This is correct because B does not see bindings from A, and therefore no solution for A can cause B not to fail. This semi-intelligent backtracking (combined with some constraints on scheduling) guarantees the no-slowdown property: an IAP execution will never take longer than a sequential one (modulo overheads due to scheduling and goal launching).

### Dependent And-Parallelism

IAP's independence restriction has its roots in technical difficulties: a correct, efficient implementation of a language with logical variables and backtracking and in which multiple processing units are concurrently trying to bind these variables is challenging – that is the scenario in Dependent And-Parallelism (DAP). On one

hand, every access to (potentially) shared variables and their associated internal data structures has to be protected. Additionally, when two processes disagree on the value given to a shared variable, one of them has to backtrack to generate another binding. Parallel goals sharing the variable whose binding is to be undone may have to backtrack if the binding was used to select which clause to take.

However, since DAP subsumes IAP, it offers *a priori* more opportunities for parallelism: in any of the Quick-Sort examples, the lists generated by `partition` can be directly fed to the `qsort` goals, which could run in parallel between them and with the `partition` predicate. When a new item is generated, the corresponding `qsort` call will wake up and advance the sorting process.

If the goals to be executed in parallel do not bind shared variables differently (i.e., they *collaborate* rather than *compete*), the problem of ensuring binding coherence disappears (it is, in fact, NSIAP). Moreover, if they are deterministic, there is no need to handle backtracking, and the parallel goals act as if they were producers and consumers. This is called (deterministic) *stream and-parallelism*, and can be (efficiently) exploited. The QuickSort program is an example when it is called with a free variable as second argument, because this ensures that sorting will not fail and will produce a single solution. On the other hand, an initial goal such as `?- qsort([1,2], [2,1])` will fail, and cannot be executed using stream parallelism.

Despite its complexity, proposals which fully deal with DAP exist. One approach to avoid considering all variables as potentially shared is to mark possibly shared variables at compile time, so that only these are tested at

run time [16] (note that in the example above X and Y are *aliased* after the execution of q):

```
p(X, Y) :-
q(X, Y),
dep([X, Y]) => r(X) & s(Y) & t(Y).

q(A, A).
```

Shared variables are given a special representation to, for example, make it possible to lock them. In order to control conflicts in the assignment to variables, goals are dynamically classified as producers or consumers of variables as follows: for a given variable X, the leftmost goal which has access to X is its producer, and can bind it. The rest of the goals are consumers of the variable, and they suspend should they try to bind the variable. In the previous code, r would initially be the producer of X (which is aliased to Y by q/2) and s and t its consumers. When r finishes, s becomes the producer of Y. The overhead of handling this special variable representation is large and impacts sequential execution: experiments show a reduction of 50% in sequential speed.

### Goal-Level and Binding-Level Independence

While IAP and DAP differ in the kind of problems they attack and the techniques needed to implement them, there are unifying concepts behind them: both IAP and DAP need, at some level, operations which are executed atomically and without interference. In the case of DAP, binding a shared variable and testing that this binding is consistent with those made by other processes is an atomic operation. Stream and-parallelism avoids testing

```
:- parallel select/3.

queens(N, Qs) :-
range(1, N, Ns),
queens(Ns, [], Qs).

queens([], Qs, Qs).
queens(UnplacedQs, SafeQs, Qs) :-
select(UnplacedQs, UnplacedQs1, Q),
not_attack(SafeQs, Q, 1),
queens(UnplacedQs1, [Q|SafeQs], Qs).
```

for consistency by requiring that bindings by different processes do not interfere; thereby it exhibits independence at the level of individual bindings, while in IAP noninterference appears at the level of complete goals. The requirement that variables are not concurrently written to makes variable locking unneeded for IAP. Other proposals (►Sect. Eventual and Atomic Tells) have a notion of independence at the level of groups of unifications explicitly marked in the program source.

### Or-Parallelism

*Or-Parallelism* originates from executing in parallel the different clauses which can be used to solve a goal in the resolvent. Multiple clauses, as well as the continuation of the calling goal, can thus be simultaneously tried. Or-parallelism allows searching for solutions to a query faster, by exploring in parallel the search space generated by the program. For example, in the queens program of Fig. 6 the two clauses of the `select/3` predicate can proceed in parallel *as well as* the calls to `not_attack/3` and `queens/3` which correspond to every solution of `select/3`: branches *continue in parallel* after the predicate which forked the execution has finished and into the continuations of the clauses calling such predicate. This means that each possible selection of a queen will be explored in parallel.

In principle, all the branches of the search tree of a program are independent and thus or-parallelism can apparently always be exploited. In practice, dependencies appear due to side effects and solution order-dependent control structures (such as the “cut”), and must be taken into account. Control constructs that are more appropriate for an or-parallel context have also

```
not_attack([], _, _).
not_attack([Y|Ys], X, N) :-
X =\= Y+N, X =\= Y-N,
N1 is N+1,
not_attack(Ys, X, N1).

select([X|Xs], Xs, X).
select([Y|Ys], [Y|Zs], X) :-
select(Ys, Zs, X).
```

Logic Languages. Fig. 6 N-Queens annotated for or-parallelism

been proposed. Much work has also been devoted to developing efficient task scheduling algorithms and, in general, or-parallel Prolog systems [1, 7, 13].

Or-parallelism frequently arises in applications that explore a large search space via backtracking such as in expert systems, optimization and relaxation problems, certain types of parsing, natural language processing, scheduling, or in deductive database systems.

### Data Parallelism and Unification Parallelism

Most work in parallel logic languages assumed an underlying MIMD execution model of parallel programs which were initially written for sequential execution. However, several approaches to exploiting SIMD parallelism exist.

And-data-parallelism, as in [2], tries to detect loops which apply a given operation to all the elements of a data structure in order to unroll them and apply the operation in parallel to every data item in the structure. In order to access quickly the different elements in the data structure, parallel unification algorithms were developed. This kind of data parallelism can be seen as a highly specialized version of independent and parallelism [9]. Or-data-parallelism, as in [17], changes the standard head unification to keep several environments simultaneously. Unifications of several heads can then be executed in parallel.

### Combinations of Or- and And-Parallelism

Combining or- and and-parallelism is possible, and in principle it should be able to exploit more opportunities for parallel execution. As an example, Fig. 7 shows the *Queens* program annotated to exploit

```

:- parallel select/3.

queens(N, Qs) :-
 range(1, N, Ns),
 queens(Ns, [], Qs).

queens([], Qs, Qs).
queens(UnplacedQs, SafeQs, Qs) :-
 select(UnplacedQs, UnplacedQs1, Q),
 not_attack(SafeQs, Q, 1) &
 queens(UnplacedQs1, [Q|SafeQs], Qs).

not_attack([], _, _).
not_attack([Y|Ys], X, N) :-
 X =\= Y+N, X =\= Y-N,
 N1 is N+1,
 not_attack(Ys, X, N1).

select([X|Xs], Xs, X).
select([Y|Ys], [Y|Zs], X) :-
 select(Ys, Zs, X).

```

Logic Languages. Fig. 7 N-Queens annotated for and- and or-parallelism

and+or-parallelism, by combining the annotations in Figs. 5 and 6. The efficient implementation of and+or-parallelism is difficult due to the antagonistic requirements of both cases: while and-parallelism needs variables shared between parallel goals to be accessible by independent threads, or-parallelism needs shared variables to have distinct instantiations in different threads. Restricted versions of and+or-parallelism have been implemented: for example, in [5], teams of processors execute deterministic dependent and-parallel goals. When a nondeterministic goal is to be executed, the team moves to a phase which executes the goal using or-parallelism. Every branch of the goal is deterministic, from the point of view of the agent executing it, so deterministic dependent and-parallelism can be used again.

### Automatic Detection of Parallelism

A number of parallelizing compilers have been developed for (constraint) logic programming systems [3, 10, 14]. They exemplify a *combined* approach to exploiting parallelism (►Sect. Exploiting Parallelism in Logic Programming): the compiler aims at automatically uncovering parallelism in the program by producing a version annotated with parallel operators, which is then passed to another stage of the compiler to produce lower-level parallel code. At the same time, programmers can introduce parallel annotations in the source program that the parallelizer will respect (and check for correctness, possibly introducing run-time checks for independence). The final parallelized version could always have been directly written by hand, but of course the possibility of being able to automatically parallelize (parts of)

programs initially written for sequential execution is very appealing. The parallelization can leave some independence checks for run time, also combining static and dynamic techniques. Experimental results have shown that this approach can uncover significant amounts of parallelism and achieve good speedups in practice [3, 14] with minimal human intervention. See the entry ▶Parallelization, Automatic for more details on this topic.

### Extensions to Constraint Logic Programming

Constraint logic programming extends logic programming with constraint solving capabilities by generalizing unification while preserving the basic syntax and resolution-based semantics of traditional logic programming. These extensions open a large class of new applications and also bring improved semantics for certain aspects of traditional logic programming, such as fully relational support for arithmetic operations. Constraint logic programs also explore a search space and Or-parallelism is directly applicable in this context. Parallelism can also be exploited within the constraint solving process itself in a similar way to unification parallelism. Finally, and-parallelism can also be exploited, and the constraints point of view brings new, interesting generalizations of the concepts of independence.

### Concurrency in Logic Programming

Concurrent logic programming languages [15, 18] do not aim primarily at improving execution speed but rather at increasing language expressiveness. As a consequence, their concurrency capabilities remain untouched in single-processor implementations. A strong point of these languages is the capability to express reactive systems. This affects their view of non-determinism: sequential logic programs adopt *don't know* non-determinism, where predicate clauses express different ways to achieve a goal, but it is not known which one of these clauses leads to a solution for a given problem instance before their execution successfully finishes. Unsuccessful branches can be discarded (i.e., backtracked over) at any moment and their intermediate results are undone, except for side effects such as input/output or changes to the internal database. These computations are not reactive, as their only “real” result is the substitutions produced after success.

*Don't care* non-determinism reflects the fact that, among the clauses that are eligible to generate a solution, any of them will do the job, and it does not matter which one is selected. Once a clause is committed to, the computation it performs is visible by the rest of the processes collaborating in the computation – hence the reactivity of the language – and backtracking cannot make this effect disappear.

### Syntax and (Intuitive) Semantics

A general, simplified syntax which is adopted in several proposals for concurrent logic languages will be used here. A concurrent logic program is a collection of clauses of the form

$$\text{Head} :- \text{Ask} : \text{Tell} \mid \text{Body}.$$

where variables have been abstracted. Their meaning is:

- *Head* is a literal whose formal arguments are distinct variables.
- *Ask*, the clause guard, is a conjunction of *constraints* (equality, disequality, simple tests on variables, and arithmetic predicates in the simplest case). These constraints are used to check the state of the head variables and do not introduce new bindings. If the *Ask* constraints succeed, the clause can be selected. Otherwise, the clause suspends until it becomes selectable or until another clause of the same predicate is selected to be executed (only one clause of a predicate can be selected to execute a given goal). If all clauses for all pending goals are suspended, the computation is said to *deadlock*.
- *Tell* is a conjunction of constraints which, upon clause selection, are to be executed to create new bindings, which are seen inside and outside the clause.
- *Body* is a conjunction of goals which can be *true* (in which case it can be omitted) to express the end of a computation, a single literal to express the transformation of a process into another process, or a conjunction of literals to denote spawning of a series of processes interconnected by means of shared variables.

**Fig. 8** (taken from [15]), left, shows an example. A nondeterministic merger accepts inputs from two lists of elements and generates an output list taking elements from both lists while respecting the relative order in them. Clauses are selected first depending on the

```

merge(In1, In2, Out) :-
 In1 = [X|Ins] : Out = [X|Rest] |
 merge(Ins, In2, Rest).
merge(In1, In2, Out) :-
 In2 = [X|Ins] : Out = [X|Rest] |
 merge(In1, Ins, Rest).
merge(In1, In2, Out) :-
 In1 = [] : Out = In2 | true.
merge(In1, In2, Out) :-
 In2 = [] : Out = In1 | true.

use_merge(L) :-
 skip_starting(0, 2, Evens),
 skip_starting(1, 2, Odds),
 merge(Evens, Odds, L).

skip_starting(Base, Skip, List) :-
 List = [Base|Rest] |
 NextBase is Base + Skip,
 skip_starting(NextBase, Skip, Rest).

```

**Logic Languages.** Fig. 8 Stream merger (*left*) and how to use it (*right*)

availability of elements in the input lists: when there is an element available in some input list (e.g.,  $In1 = [X|Ins]$ ), it is used to construct stepwise the output list ( $Out = [X|Rest]$ ), and the process is recursively called with new arguments.

The use of such a merger is shown in Fig. 8, right. Predicate `use_merge` is expected to return in `L` the list of natural numbers. Three processes are spawned: two of them generate a list of even numbers starting at 0 (resp. odd and starting at 1) and the third one merges these lists. The shared variables `Evens` and `Odds` act as communicating channels which are read by `merge` as they are instantiated.

**A note on syntax:** Other concurrent languages have adopted a different syntax to distinguish *Tell* from *Ask* constraints and, in some cases, to specify input and output modes. For example, the original syntax by Ueda [19] uses head unification for *Ask* constraints, and the first clause of `merge` would therefore be:

```

merge([X|Ins], In2, Out) :-
 Out = [X|Rest] |
 merge(Ins, In2, Rest).

```

Other languages (e.g., Parlog) include mode declarations to specify which formal arguments are going to be read from or written to, and require the programmer to provide them to the compiler.

Another example of the expressiveness of concurrent logic languages (which is in some sense related to that of lazy functional languages) appears in Fig. 9, which shows a solution [15] to the generation of the Hamming sequence: the ordered stream of numbers of the form  $2^i3^j5^k$ , where  $i,j,k$  are natural numbers, without repetition. The standard procedural solution keeps

a pool of candidates to be the next number and outputs the smallest one when it is sure that no smallest candidate can be produced.

Fig. 9 assumes that head unifications are *Ask* guards. The concurrent logic solution starts with a *seed* for  $i = j = k = 0$  and spawns three `multiply` processes which generate, from an existing partial stream, streams `X2`, `X3`, and `X5` with a last element depending on the previous last. These streams are merged, filtering duplicates, by two `ord_merge` predicates. The result of the last `ord_merge` predicate is fed back to the three `multiply` processes which can take then a step to generate the next candidate item in the answer stream every time `Xs` is further instantiated.

### Variations on Semantics

There are some variability points on the semantics of concurrent logic languages which, in addition to slightly different syntax, cause large differences among the languages. These semantic differences also have an important impact on the associated implementation techniques. It is remarkable that the history of concurrent logic languages was marked by a “simplification” of the semantics, which brought about less expressiveness of the language (such as, for example, eliminating the possibility of generating multiple solutions) and, accordingly, less involved implementations [18]. This has been partly attributed to such very expressive mechanisms not being needed for the tasks these languages were mainly used for, and in part to the complication involved in their implementation. Other research aimed at including concurrency without giving up multiple solutions includes some concurrent constraint languages such as Oz and AKL, as well as more traditional

```

hamming(Xs) :-

 multiply([1|Xs], 2, X2),

 multiply([1|Xs], 3, X3),

 multiply([1|Xs], 5, X5),

 ord_merge(X2, X3, X23),

 ord_merge(X23, X5, Xs).

multiply(In, N, Out) :-

 In = [] : Out = [].

multiply(In, N, Out) :-

 In = [X|Xs] :

 Out = [Y|Ys], Y is X * N |

 multiply(Xs, N, Ys).

ord_merge([X|Xs], [Y|Ys], Out) :-

 Out = [X|Os] |

 ord_merge(Xs, Ys, Os).

ord_merge([X|Xs], [Y|Ys], Out) :-

 X < Y : Out = [X|Os] |

 ord_merge(Xs, [Y|Ys], Os).

ord_merge([X|Xs], [Y|Ys], Out) :-

 X > Y : Out = [Y|Os] |

 ord_merge([X|Xs], Ys, Os).

ord_merge([], Ys, Out) :- Out = Ys.

ord_merge(Xs, [], Out) :- Out = Xs.

```

Logic Languages. Fig. 9 Generation of the Hamming sequence

logic programming systems which include extensions for distributed and concurrent execution (e.g., Ciao, SWI, or Yap).

### Deep and Flat Guards

*Flat guard* languages restrict the *Ask* guards to simple primitive operations (i.e., unifications, arithmetic predicates, etc.). Deep guards, on the other hand, can invoke arbitrary user predicates. Any bindings generated by deep guards have to be isolated from the rest of the environment (e.g., the caller) in order not to influence other guards which may be suspended or under evaluation.

Deep guards are more expressive than flat guards but the implementation techniques are much more complex. The technology necessary is related to that of the implementation of or-parallel systems, as bindings to variables in deep guards need to be kept in separate environments, just as in the or-parallel execution of logic programs.

### Fairness

The question of whether processes which can progress will effectively do so is decomposed into two different concepts, *or-fairness* and *and-fairness*, respectively, related to which clause (among those satisfying their guards) and process (among the runnable ones) is selected to execute.

*Or-fairness* can be exemplified with the merger in Fig. 8. For infinite stream producers, it does not

guarantee that items from any of the input streams will eventually be written onto its output stream. Whether this happens will depend on the concrete semantics under which it is being executed. If this is guaranteed to eventually happen, then the language has *or-fairness*.

*And-fairness* concerns the selection of which process can progress among the runnable ones. In Fig. 8, right, the two instances of *skip\_starting* do not need to suspend waiting for any condition. Therefore, it would be possible that one of them runs without interruption, generating a stream of numbers which are consumed by *merge*, which would forward them to its output list. Had *ord\_merge* been used instead of *merge*, the stream producers would alternatively suspend and resume.

### Eventual and Atomic Tells

*Tell* guards can be executed at once before the goals in the body, or be separately scheduled. In the former case, *Tells* are said to be *atomic* because all the bindings in the *Tell* are generated at once. In the latter case, they are said to be *eventual*, as they are handled according to the *and-fairness* rules of the language. *Atomic Tell* makes it possible to write some algorithms more elegantly than *eventual Tell*. However, *eventual Tell* make it possible to treat unifications and constraints more homogeneously, and are more adequate to reason on the actual properties of distributed implementations of concurrent logic languages.

## Definition

*Loop Nest Parallelization* refers to the problem of finding parallelism in a perfect nest of sequential loops. It typically deals with transformations that change the execution order of iterations of such a nest  $L$  by creating a different nest  $L'$ , such that  $L'$  is equivalent to  $L$  and some of its loops can run in parallel.

## Discussion

### Introduction

For a better understanding of the current essay, the reader should first go through the essay ► [Unimodular Transformations](#) in this encyclopedia.

The program model is a perfect nest  $\mathbf{L}$  of  $m$  sequential loops. An *iteration* of  $\mathbf{L}$  is an instance of the body of  $\mathbf{L}$ . The program consists of a certain set of iterations that are to be executed in a certain sequential order. This execution order imposes a *dependence structure* on the set of iterations, based on how they access different memory locations. A loop in  $\mathbf{L}$  *carries a dependence* if the dependence between two iterations is due to the unfolding of that loop. A loop can *run in parallel* if it carries no dependence.

In this essay, one considers transformations that change  $\mathbf{L}$  into a perfect nest  $\mathbf{L}'$  with the same set of iterations executing in a different sequential order. (The number of loops may differ from  $\mathbf{L}$  to  $\mathbf{L}'$ .) The new nest  $\mathbf{L}'$  is *equivalent* to the old nest  $\mathbf{L}$  (i.e., they give the same results), if whenever an iteration depends on another iteration in  $\mathbf{L}$ , the first iteration is executed after the second in  $\mathbf{L}'$ . If a loop in  $\mathbf{L}'$  carries no dependence, then that loop can run in parallel. The goal is to transform  $\mathbf{L}$  into an equivalent nest  $\mathbf{L}'$ , such that some inner and/or outer loops of  $\mathbf{L}'$  can run in parallel.

Two major loop nest transformations are discussed here: unimodular and echelon. Unimodular transformations have already been introduced in this encyclopedia in the essay under that name. There it is shown by examples how to achieve inner and outer loop parallelization via unimodular transformations. Detailed algorithms for achieving those goals are given in this essay. Echelon transformations are explained after that, and it is pointed out how a combination of both transformations can maximize loop parallelization.

### Mathematical Preliminaries

Lexicographic order and Fourier's method of elimination, as explained in the essay ► [Unimodular Transformations](#), will be used in the following. In this section, some of the elementary definitions and algorithms of matrix theory are stated, customized for integer matrices. From now on, a matrix is an integer matrix, unless explicitly designated to be otherwise.

The transpose of a matrix  $\mathbf{A}$  is denoted by  $\mathbf{A}'$ . The  $m \times m$  unit matrix is denoted by  $\mathcal{I}_m$ . A *submatrix* of a given matrix  $\mathbf{A}$  is the matrix obtained by deleting some rows and columns of  $\mathbf{A}$ . If  $\mathbf{A}$  is an  $m \times p$  matrix and  $\mathbf{B}$  an  $m \times q$  matrix, then the *column-augmented matrix*  $(\mathbf{A}; \mathbf{B})$  is the  $m \times (p + q)$  matrix whose first  $p$  columns are the columns of  $\mathbf{A}$  and the last  $q$  columns are the columns of  $\mathbf{B}$ . Thus,

$$\mathbf{A} = \begin{pmatrix} 1 & 2 \\ 0 & 0 \\ 0 & 5 \end{pmatrix} \text{ and } \mathbf{B} = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}$$

$$\text{yield } (\mathbf{A}; \mathbf{B}) = \begin{pmatrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ 0 & 5 & 0 \end{pmatrix}.$$

A *row-augmented matrix* is defined similarly.

The (*main*) *diagonal* of an  $m \times n$  matrix  $(a_{ij})$  is the vector  $(a_{11}, a_{22}, \dots, a_{pp})$  where  $p = \min(m, n)$ . The *rank* of a matrix  $\mathbf{A}$ , denoted by  $\text{rank}(\mathbf{A})$ , is the maximum number of linearly independent rows (or columns) of  $\mathbf{A}$ .

For a given  $m \times n$  matrix  $\mathbf{A}$ , let  $\ell_i$  denote the column number of the leading (first nonzero) element of row  $i$ . (For a zero row,  $\ell_i$  is undefined.) Then  $\mathbf{A}$  is an *echelon matrix*, if for some integer  $\rho$  in  $0 \leq \rho \leq m$ , the following holds:

1. The rows 1 through  $\rho$  are nonzero rows.
2. The rows  $\rho + 1$  through  $m$  are zero rows.
3. For  $1 \leq i \leq \rho$ , each element in column  $\ell_i$  below row  $i$  is zero.
4.  $\ell_1 < \ell_2 < \dots < \ell_\rho$ .

If there is such a  $\rho$ , then  $\rho = \text{rank}(\mathbf{A})$ . A zero matrix is an echelon matrix for which  $\rho = 0$ . Three nonzero echelon matrices with the values  $\rho = 4, 3, 2$ , respectively, are given below:

$$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 \\ 0 & 0 & 6 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \begin{pmatrix} 5 & 2 & 3 \\ 0 & -1 & 0 \\ 0 & 0 & 3 \\ 0 & 0 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 5 & 2 & 3 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

For any given matrix, there are three types of *elementary row operations*:

1. *Reversal*: multiply a row by  $-1$ .
2. *Interchange*: interchange two rows.
3. *Skewing*: add an integer multiple of one row to another row.

The *elementary column operations* are defined similarly.

An *elementary matrix* is any matrix obtained from a unit matrix by one elementary row operation. Thus, there are three types of elementary matrices. The elementary matrices can also be derived by column operations. For example, the same matrix is obtained from the  $3 \times 3$  unit matrix if we interchange rows 1 and 3, or interchange columns 1 and 3.

A *unimodular matrix* is a square integer matrix with determinant 1 or  $-1$ . Each elementary matrix is unimodular, and each unimodular matrix can be expressed as the product of a finite number of elementary matrices (Lemma 2.3 in [2]). For a given matrix  $\mathbf{A}$ , performing an elementary row operation is equivalent to forming a product of the form  $\mathbf{EA}$ , where  $\mathbf{E}$  is the corresponding elementary matrix. Applying a finite sequence of row operations to  $\mathbf{A}$  is the same as forming a product of the form  $\mathbf{UA}$ , where  $\mathbf{U}$  is a unimodular matrix.

*Reducing* an  $m \times n$  matrix  $\mathbf{A}$  to *echelon form* means finding an  $m \times m$  unimodular matrix  $\mathbf{U}$  and an  $m \times n$  echelon matrix  $\mathbf{S}$ , such that  $\mathbf{UA} = \mathbf{S}$ . Figure 1 gives an algorithm that reduces any given matrix  $\mathbf{A}$  to echelon form. Note that applying the same row operation to the two matrices  $\mathbf{U}$  and  $\mathbf{S}$  separately is equivalent

to applying that operation to the column-augmented matrix  $(\mathbf{U}; \mathbf{S})$ .

For a given matrix  $\mathbf{A}$ , one may need to find a unimodular matrix  $\mathbf{V}$  and an echelon matrix  $\mathbf{S}$  such that  $\mathbf{A} = \mathbf{VS}$ . This  $\mathbf{V}$  could be the inverse of the unimodular matrix  $\mathbf{U}$  of Algorithm 1. However, if  $\mathbf{U}$  is not needed, Algorithm 1 can be modified to yield directly a unimodular  $\mathbf{V}$  and an echelon  $\mathbf{S}$  such that  $\mathbf{A} = \mathbf{VS}$ . This is the algorithm of Fig. 2. In Algorithm 2, whenever a row operation is applied to  $\mathbf{S}$ , it is followed by a column operation applied to  $\mathbf{V}$ . The row operation is equivalent to forming a product of the form  $\mathbf{ES}$ , where  $\mathbf{E}$  is an elementary matrix. The column operation that follows is equivalent to forming the product  $\mathbf{VE}^{-1}$ . Hence, the relation  $\mathbf{A} = \mathbf{VS}$  remains unchanged since  $\mathbf{VS} = (\mathbf{VE}^{-1})(\mathbf{ES})$ .

Each algorithm can be modified by using extra reversal operations, as needed, so that any given rows of the computed echelon matrix are nonnegative.

The program model for all transformations is a perfect nest of loops  $\mathbf{L} = (L_1, L_2, \dots, L_m)$  shown in Fig. 3. The limits  $p_r$  and  $q_r$  are integer-valued linear functions of  $I_1, I_2, \dots, I_{r-1}$ . All distance vectors are assumed to be uniform. If there is no distance vector  $\mathbf{d}$  with  $\mathbf{d} >_r \mathbf{0}$ , then the loop  $L_r$  carries no dependence and is able to run in parallel.

## Unimodular Transformations

Let  $\mathbf{U}$  denote an  $m \times m$  unimodular matrix. The unimodular transformation of the loop nest  $\mathbf{L}$  induced by  $\mathbf{U}$  is

**Algorithm 1** Given an  $m \times n$  integer matrix  $\mathbf{A}$ , this algorithm finds an  $m \times m$  unimodular matrix  $\mathbf{U}$  and an  $m \times n$  echelon matrix  $\mathbf{S} = (s_{ij})$ , such that  $\mathbf{UA} = \mathbf{S}$ . It starts with  $\mathbf{U} = \mathcal{I}_m$  and  $\mathbf{S} = \mathbf{A}$ , and works on the matrix  $(\mathbf{U}; \mathbf{S})$ . Let  $i_0$  denote the row number in which the last processed column of  $\mathbf{S}$  had a nonzero element.

```

set $\mathbf{U} \leftarrow \mathcal{I}_m$, $\mathbf{S} \leftarrow \mathbf{A}$, $i_0 \leftarrow 0$
do $j = 1, n, 1$
 if there is at least one nonzero s_{ij} with $i_0 < i \leq m$
 then
 set $i_0 \leftarrow i_0 + 1$
 do $i = m, i_0 + 1, -1$
 do while $s_{ij} \neq 0$
 set $\sigma \leftarrow \text{sgn}(s_{i-1,j} * s_{ij})$
 $z \leftarrow \lfloor |s_{i-1,j}| / |s_{ij}| \rfloor$
 subtract σz times row i from row $(i-1)$ in $(\mathbf{U}; \mathbf{S})$
 interchange rows i and $(i-1)$ in $(\mathbf{U}; \mathbf{S})$
```

**Algorithm 2** Given an  $m \times n$  integer matrix  $\mathbf{A}$ , this algorithm finds an  $m \times m$  unimodular matrix  $\mathbf{V}$  and an  $m \times n$  echelon matrix  $\mathbf{S} = (s_{ij})$ , such that  $\mathbf{A} = \mathbf{VS}$ . It starts with  $\mathbf{V} = \mathcal{I}_m$  and  $\mathbf{S} = \mathbf{A}$ , and works on the matrices  $\mathbf{V}$  and  $\mathbf{S}$ . Let  $i_0$  denote the row number in which the last processed column of  $\mathbf{S}$  had a nonzero element.

```

set $\mathbf{V} \leftarrow \mathcal{I}_m$, $\mathbf{S} \leftarrow \mathbf{A}$, $i_0 \leftarrow 0$
do $j = 1, n, 1$
 if there is at least one nonzero s_{ij} with $i_0 < i \leq m$
 then
 set $i_0 \leftarrow i_0 + 1$
 do $i = m, i_0 + 1, -1$
 do while $s_{ij} \neq 0$
 set $\sigma \leftarrow \text{sgn}(s_{i-1,j} * s_{ij})$
 $z \leftarrow \lfloor |s_{i-1,j}| / |s_{ij}| \rfloor$
 subtract σz times row i from row $(i - 1)$ in \mathbf{S}
 add σz times column $(i - 1)$ to column i in \mathbf{V}
 interchange rows i and $(i - 1)$ in \mathbf{S}
 interchange columns i and $(i - 1)$ in \mathbf{V}

Loop Nest Parallelization. Fig. 4 Loop Nest  $\mathbf{L}'$

a loop nest  $\mathbf{L}'$  of the form shown in Fig. 4, where  $\mathbf{K} = \mathbf{IU}$  and  $H'(\mathbf{K}) = H(\mathbf{KU}^{-1})$ . The transformed program has the same set of iterations as the original program, executing in a different sequential order. The transformation  $\mathbf{L} \Rightarrow \mathbf{L}'$  is valid if and only if  $\mathbf{dU} > \mathbf{0}$  for each distance vector  $\mathbf{d}$  of  $\mathbf{L}$ . In that case, the vectors  $\mathbf{dU}$  are precisely the distance vectors of the new nest  $\mathbf{L}'$ .

### Inner Loop Parallelization

Let  $D$  denote the set of distance vectors of  $\mathbf{L}$ . For the transformation  $\mathbf{L} \Rightarrow \mathbf{L}'$  to be valid, the matrix  $\mathbf{U}$  must be so chosen that  $\mathbf{dU} > \mathbf{0}$  for each  $\mathbf{d} \in D$ . After a valid transformation by  $\mathbf{U}$ , the set of distance vectors of  $\mathbf{L}'$  is

$\{\mathbf{dU} : \mathbf{d} \in D\}$ . A loop  $L'_r$  of  $\mathbf{L}'$  can run in parallel if there is no  $\mathbf{d} \in D$  satisfying  $\mathbf{dU} >_r \mathbf{0}$ . Thus, a unimodular matrix  $\mathbf{U}$  will transform the loop nest  $\mathbf{L}$  into an equivalent loop nest  $\mathbf{L}'$  where the loops  $L'_2, L'_3, \dots, L'_m$  can all run in parallel, if and only if  $\mathbf{U}$  satisfies the condition

$$\mathbf{dU} >_1 \mathbf{0} \quad (\mathbf{d} \in D). \quad (1)$$

The following informal algorithm shows in detail that a unimodular matrix with this property can always be constructed.

**Algorithm 3** Given a perfect nest  $\mathbf{L}$  of  $m$  loops, as shown in Fig. 3, with a set of distance vectors  $D$ , this algorithm finds an  $m \times m$  unimodular matrix  $\mathbf{U} = (u_{rt})$  that transforms  $\mathbf{L}$  into an equivalent loop nest  $\mathbf{L}'$ , such that the inner loops  $L'_2, L'_3, \dots, L'_m$  of  $\mathbf{L}'$  can all run in parallel.

1. If  $D = \emptyset$ , then all loops of  $\mathbf{L}$  can execute in parallel; take for  $\mathbf{U}$  the  $m \times m$  unit matrix and exit. Otherwise, go to step 2.
2. Condition (1) is equivalent to the following system of inequalities

$$d_1 u_1 + d_2 u_2 + \dots + d_m u_m \geq 1 \quad (\mathbf{d} \in D), \quad (2)$$

where  $\mathbf{d} = (d_1, d_2, \dots, d_m)$  and the fixed second subscript of  $u_{r1}$  has been dropped for convenience.

For each  $r$  in  $1 \leq r \leq m$ , define the set

$$D_r = \{\mathbf{d} \in D : \mathbf{d} >_r \mathbf{0}\}.$$

At least one of these sets is nonempty. Since  $d_1 = d_2 = \dots = d_{r-1} = 0$  for each  $\mathbf{d} \in D_r$ , one can break up the system (2) into a sequence of subsystems of the following type:

$$\left. \begin{array}{l} d_m u_m \geq 1 \quad (\mathbf{d} \in D_m) \\ d_{m-1} u_{m-1} + d_m u_m \geq 1 \quad (\mathbf{d} \in D_{m-1}) \\ \vdots \\ d_1 u_1 + d_2 u_2 + \dots + d_{m-1} u_{m-1} + d_m u_m \geq 1 \quad (\mathbf{d} \in D_1). \end{array} \right\}$$

Since  $d_r > 0$  for  $\mathbf{d} \in D_r$ , this sequence can be rewritten as

$$\left. \begin{array}{l} u_m \geq 1/d_m \quad (\mathbf{d} \in D_m) \\ u_{m-1} \geq (1 - d_m u_m)/d_{m-1} \quad (\mathbf{d} \in D_{m-1}) \\ \vdots \\ u_1 \geq (1 - d_2 u_2 - \dots - d_m u_m)/d_1 \quad (\mathbf{d} \in D_1). \end{array} \right\} \quad (3)$$

3. If  $D_m = \emptyset$ , then take  $u_m = 0$ . Otherwise, take  $u_m = 1$ . Suppose  $u_m, u_{m-1}, \dots, u_{r+1}$  have been chosen, where  $1 \leq r < m$ . If  $D_r = \emptyset$ , then take  $u_r = 0$ . Otherwise,  $u_r$  has a set of lower bounds of the form:

$$u_r \geq (1 - d_{r+1} u_{r+1} - d_{r+2} u_{r+2} - \dots - d_m u_m)/d_r \quad (\mathbf{d} \in D_r).$$

Take for  $u_r$  the smallest nonnegative integer that would work:

$$u_r = \left[ \max_{\mathbf{d} \in D_r} \{(1 - d_{r+1} u_{r+1} - d_{r+2} u_{r+2} - \dots - d_m u_m)/d_r\} \right]^+.$$

4. Find  $s$  in  $1 \leq s \leq m$  such that  $u_s$  is the first nonzero element in the sequence:  $u_m, u_{m-1}, \dots, u_1$ . Note that  $u_s = 1$ . Set

$$\mathbf{U} = \begin{pmatrix} u_1 & 1 & \cdots & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ u_{s-1} & 0 & \cdots & 1 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & 0 & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & 0 & \cdots & 1 \end{pmatrix},$$

such that row  $s$  of  $\mathbf{U}$  is  $(1, 0, 0, \dots, 0)$ , its first column is  $(u_1, u_2, \dots, u_m)$ , and the submatrix obtained by deleting row  $s$  and the first column of  $\mathbf{U}$  is the  $(m-1) \times (m-1)$  unit matrix. Since  $\det \mathbf{U} = 1$ ,  $\mathbf{U}$  is unimodular.

5. Note that the inverse of  $\mathbf{U}$  is given by

$$\mathbf{U}^{-1} = \begin{pmatrix} 0 & \cdots & 0 & 1 & 0 & \cdots & 0 \\ 1 & \cdots & 0 & -u_1 & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 1 & -u_{s-1} & 0 & \cdots & 0 \\ 0 & \cdots & 0 & 0 & 1 & \cdots & 0 \\ \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & 0 & 0 & \cdots & 1 \end{pmatrix},$$

such that column  $s$  is  $(1, -u_1, \dots, -u_{s-1}, 0, \dots, 0)$ , row 1 is  $(0, \dots, 0, 1, 0, \dots, 0)$ , and the submatrix obtained by deleting column  $s$  and the first row is the  $(m-1) \times (m-1)$  unit matrix. From the equation  $(I_1, I_2, \dots, I_m) = (K_1, K_2, \dots, K_m)\mathbf{U}^{-1}$ , it follows that

$$\left. \begin{array}{lcl} I_1 & = & K_2 \\ & \vdots & \\ I_{s-1} & = & K_s \\ I_s & = & K_1 - u_1 K_2 - \dots - u_{s-1} K_s \\ I_{s+1} & = & K_{s+1} \\ & \vdots & \\ I_m & = & K_m. \end{array} \right\}$$

In the system of inequalities

$$p_r(I_1, \dots, I_{r-1}) \leq I_r \leq q_r(I_1, \dots, I_{r-1}) \quad (1 \leq r \leq m),$$

substitute for each  $I_r$  the corresponding expression in  $K_1, K_2, \dots, K_m$ . Get the loop limits  $\alpha_r(K_1, \dots, K_{r-1})$  and  $\beta_r(K_1, \dots, K_{r-1})$  of Fig. 4 by

solving this system using Fourier's method of elimination.

6. Now each distance vector  $\mathbf{d}$  of  $\mathbf{L}$  satisfies the condition  $\mathbf{d}\mathbf{U} >_1 \mathbf{0}$ . Hence, the transformed nest  $\mathbf{L}'$  of Fig. 4 created by this matrix  $\mathbf{U}$  is equivalent to the original nest  $\mathbf{L}$ , and the inner loops of  $\mathbf{L}'$  can all execute in parallel.

*Remark 1* There exist infinitely many vectors  $\mathbf{u} = (u_1, u_2, \dots, u_m)$  satisfying (3) and  $\gcd(u_1, u_2, \dots, u_m) = 1$ . For each such vector  $\mathbf{u}$ , there exist infinitely many unimodular matrices with  $\mathbf{u}$  as the first column. (See Sect. 3.3 in [2].) Any such matrix will satisfy the goal of Algorithm 3. Among all possible choices for  $\mathbf{u}$ , an ideal vector is one that minimizes the number of iterations  $(\beta_1 - \alpha_1 + 1)$  of the outermost loop  $L'_1$  that must run sequentially. This poses an optimization problem; see Chap. 3 in [3] for details.

Since  $\mathbf{K} = \mathbf{IU}$  and  $(u_1, u_2, \dots, u_m)$  is the first column of  $\mathbf{U}$ , one has  $K_1 = u_1 I_1 + u_2 I_2 + \dots + u_m I_m$ . An equation of the form  $K_1 = c$ , where  $c$  is a constant, represents a hyperplane in the vector space  $\mathbf{R}^m$  with coordinate axes  $I_1, I_2, \dots, I_m$ . The integral values of  $K_1$  from  $\alpha_1$  to  $\beta_1$  then represent a packet of parallel hyperplanes through the index space of the loop nest  $\mathbf{L}$ , perpendicular to the vector  $\mathbf{u}$ . Geometrically speaking, Algorithm 3 finds a sequence of parallel hyperplanes, such that the planes are taken sequentially, and iterations for all index points on each plane are executed in parallel. This algorithm is derived from Lamport's 1974 CACM paper [8]. The name *Hyperplane Method*, often used to describe it, also comes from [8].

*Example 1* To better understand how Algorithm 3 creates the matrix  $\mathbf{U}$  from a given set of distance vectors  $D$ , consider a loop nest  $\mathbf{L} = (L_1, L_2, L_3, L_4)$  with the set:

$$D = \{(0, 0, 0, 2), (0, 3, 1, -2), (0, 4, -6, 0), (1, -5, 3, 1), (2, 1, 0, 0), (3, 0, -2, 1)\}.$$

The only loop that carries no dependence is  $L_3$ . Hence, only  $L_3$  can run in parallel. The goal is to find a unimodular matrix  $\mathbf{U}$  that will transform  $\mathbf{L}$  into an equivalent loop nest  $\mathbf{L}'$ , where all the inner loops can execute in parallel. The first column  $(u_1, u_2, u_3, u_4)$  of  $\mathbf{U}$  must satisfy the inequality

$$d_1 u_1 + d_2 u_2 + d_3 u_3 + d_4 u_4 \geq 1$$

for each  $(d_1, d_2, d_3, d_4) \in D$ . After simplification, one gets a set of six inequalities:

$$\left. \begin{array}{l} u_4 \geq 1/2 \\ u_2 \geq (1 - u_3 + 2u_4)/3 \\ u_2 \geq (1 + 6u_3)/4 \\ u_1 \geq 1 + 5u_2 - 3u_3 - u_4 \\ u_1 \geq (1 - u_2)/2 \\ u_1 \geq (1 + 2u_3 - u_4)/3. \end{array} \right\}$$

For each  $u_r$ , select the smallest possible nonnegative integral value that will work. So, take  $u_4 = 1$ . Since  $D_3 = \emptyset$  (i.e., there is no distance vector  $\mathbf{d}$  with  $\mathbf{d} >_3 \mathbf{0}$ ), take  $u_3 = 0$ . The constraints on  $u_2$  are then  $u_2 \geq 1$  and  $u_2 \geq 1/4$ . Take  $u_2 = 1$ . Finally, the lower bounds on  $u_1$  are given by  $u_1 \geq 5$ ,  $u_1 \geq 0$ , and  $u_1 \geq 0$ , so that one takes  $u_1 = 5$ . The unimodular matrix  $\mathbf{U}$  as constructed in Step 4 of Algorithm 3 is

$$\mathbf{U} = \begin{pmatrix} 5 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{pmatrix}.$$

Here  $s = 4$ . Row 4 of  $\mathbf{U}$  is  $(1, 0, 0, 0)$ , its first column is  $(u_1, u_2, u_3, u_4) = (5, 1, 0, 1)$ , and the submatrix obtained by deleting the fourth row and the first column is the  $3 \times 3$  unit matrix. The set of distance vectors of the equivalent loop nest  $\mathbf{L}' = (L'_1, L'_2, L'_3, L'_4)$  is the set of vectors  $\mathbf{d}\mathbf{U}$  for  $\mathbf{d} \in D$ , that is, the set

$$\{(2, 0, 0, 0), (1, 0, 3, 1), (4, 0, 4, -6), (1, 1, -5, 3), (11, 2, 1, 0), (16, 3, 0, -2)\}.$$

None of the inner loops  $L'_2, L'_3, L'_4$  carries a dependence, and hence they can all run in parallel.

### Outer Loop Parallelization

For a given  $m \times n$  matrix  $\mathbf{A} = (a_{ij})$ , the rows are denoted by  $\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m$  and the columns by  $\mathbf{a}^1, \mathbf{a}^2, \dots, \mathbf{a}^n$ . Note that the proof of the following theorem uses both the set  $D$  of distance vectors and the distance matrix  $\mathbf{D}$  of  $\mathbf{L}$ , while the previous algorithm used only  $D$ .

**Theorem 1** Consider a nest  $L$  of  $m$  loops. Let  $D$  denote the distance matrix of  $L$  and  $\rho$  the rank of  $D$ . Then there exists a valid unimodular transformation  $L \Rightarrow L'$  such that the outermost  $(m - \rho)$  loops and the innermost  $(\rho - 1)$  loops of  $L'$  can execute in parallel.

*Proof* Let  $D$  denote the set of distance vectors of  $L$ . A unimodular matrix  $U$  will induce a valid transformation  $L \Rightarrow L'$  if and only if  $\mathbf{d}U > \mathbf{0}$  for each  $\mathbf{d} \in D$ . After a valid transformation by  $U$ , the distance vectors of  $L'$  are the vectors  $\mathbf{d}U$ , where  $\mathbf{d} \in D$ . The outermost  $(m - \rho)$  loops and the innermost  $(\rho - 1)$  loops of  $L'$  can execute in parallel, if and only if  $\mathbf{d}U >_r \mathbf{0}$  is false for each  $\mathbf{d} \in D$  when  $r \neq m - \rho + 1$ . Let  $n = m - \rho$ . Then each  $\mathbf{d} \in D$  must satisfy  $\mathbf{d}U >_{n+1} \mathbf{0}$ .

The transpose  $D'$  of  $D$  has  $m$  rows and its columns are the distance vectors of  $L$ . By [Algorithm 1](#), find an  $m \times m$  unimodular matrix  $V$  and an echelon matrix  $S$  such that  $VD' = S$ . ( $S$  and  $D'$  have the same size.) The number of nonzero rows of  $S$  is the rank  $\rho$  of  $D$ , and the number of zero rows is  $n = m - \rho$ . Since the lowest  $n$  rows of  $S$  are zero vectors, it follows that each of the lowest  $n$  rows of  $V$  is orthogonal to each  $\mathbf{d} \in D$ .

Next, find an  $m$ -vector  $u$  by [Algorithm 3](#) such that  $\mathbf{d}u > 0$  for each  $\mathbf{d} \in D$ . Let  $A$  denote the  $m \times (n + 1)$  matrix where the columns  $a^1, a^2, \dots, a^n$  are the lowest  $n$  rows of  $V$ , and  $a^{n+1} = u$ . Then each  $\mathbf{d} \in D$  satisfies the equations:

$$\mathbf{d}a^1 = 0, \mathbf{d}a^2 = 0, \dots, \mathbf{d}a^n = 0, \mathbf{d}a^{n+1} > 0. \quad (4)$$

By [Algorithm 2](#), find an  $m \times m$  unimodular matrix  $U$  and an  $m \times (n + 1)$  echelon matrix

$$T = \begin{pmatrix} t_{11} & t_{12} & t_{13} & \cdots & t_{1n} & t_{1,n+1} \\ 0 & t_{22} & t_{23} & \cdots & t_{2n} & t_{2,n+1} \\ 0 & 0 & t_{33} & \cdots & t_{3n} & t_{3,n+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & t_{nn} & t_{n,n+1} \\ 0 & 0 & 0 & \cdots & 0 & t_{n+1,n+1} \\ 0 & 0 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 0 \end{pmatrix},$$

such that  $A = UT$  and the diagonal element  $t_{n+1,n+1}$  is nonnegative. The unimodular transformation  $L \Rightarrow L'$  induced by  $U$  satisfies the theorem.

After writing the relation  $A = UT$  in the form

$$(a^1, a^2, \dots, a^n, a^{n+1}) = (u^1, u^2, \dots, u^n, u^{n+1}, u^{n+2}, \dots, u^m) \cdot T,$$

it becomes clear that

$$\left. \begin{aligned} a^1 &= t_{11}u^1 \\ a^2 &= t_{12}u^1 + t_{22}u^2 \\ &\vdots \\ a^n &= t_{1n}u^1 + t_{2n}u^2 + \cdots + t_{nn}u^n \\ a^{n+1} &= t_{1,n+1}u^1 + \cdots + t_{n,n+1}u^n + t_{n+1,n+1}u^{n+1}. \end{aligned} \right\} \quad (5)$$

Since  $a^1, a^2, \dots, a^n$  form distinct rows of a unimodular matrix  $V$ , they are linearly independent. Hence, the diagonal elements  $t_{11}, t_{22}, \dots, t_{nn}$  of  $T$  must be nonzero. Multiply the equations of (5) by any  $\mathbf{d} \in D$  and use (4) to get

$$\left. \begin{aligned} t_{11}(\mathbf{d}u^1) &= 0 \\ t_{12}(\mathbf{d}u^1) + t_{22}(\mathbf{d}u^2) &= 0 \\ &\vdots \\ t_{1n}(\mathbf{d}u^1) + t_{2n}(\mathbf{d}u^2) + \cdots + t_{nn}(\mathbf{d}u^n) &= 0 \\ t_{1,n+1}(\mathbf{d}u^1) + \cdots + t_{n,n+1}(\mathbf{d}u^n) + t_{n+1,n+1}(\mathbf{d}u^{n+1}) &> 0. \end{aligned} \right\}$$

Since  $t_{11}, t_{22}, \dots, t_{nn}$  are all nonzero and  $t_{n+1,n+1} \geq 0$ , this implies

$$\mathbf{d}u^1 = 0, \mathbf{d}u^2 = 0, \dots, \mathbf{d}u^n = 0, \mathbf{d}u^{n+1} > 0,$$

that is,  $\mathbf{d}U >_{n+1} \mathbf{0}$ , for each  $\mathbf{d} \in D$ . This completes the proof. ■

*Example 2* Consider a loop nest  $L = (L_1, L_2, L_3)$  whose distance matrix  $D$  and its transpose  $D'$  are given by

$$D = \begin{pmatrix} 6 & 4 & 2 \\ 0 & 1 & -1 \\ 1 & 0 & 1 \end{pmatrix} \quad \text{and} \quad D' = \begin{pmatrix} 6 & 0 & 1 \\ 4 & 1 & 0 \\ 2 & -1 & 1 \end{pmatrix}.$$

Here  $m = 3$ . By [Algorithm 1](#), find two matrices

$$\mathbf{V} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & -2 \\ 1 & -1 & -1 \end{pmatrix} \quad \text{and} \quad \mathbf{S} = \begin{pmatrix} 2 & -1 & 1 \\ 0 & 3 & -2 \\ 0 & 0 & 0 \end{pmatrix},$$

such that  $\mathbf{V}$  is unimodular,  $\mathbf{S}$  is echelon, and  $\mathbf{VD}' = \mathbf{S}$ . Then  $\rho = 2$  and  $n = 1$ . Since the bottom row of  $\mathbf{S}$  is zero, it follows that the bottom row  $(1, -1, -1)$  of  $\mathbf{V}$  is orthogonal to each column of  $\mathbf{D}'$ , that is, to each distance vector  $\mathbf{d}$  of  $\mathbf{L}$ . This will be the first column of a  $2 \times 3$  matrix  $\mathbf{A}$  that is being constructed.

Next, one needs a vector  $\mathbf{u}$  such that  $\mathbf{du} > 0$ , or equivalently,  $\mathbf{du} \geq 1$  for each distance vector  $\mathbf{d}$ . The set of inequalities to be satisfied is:

$$\left. \begin{array}{l} 6u_1 + 4u_2 + 2u_3 \geq 1 \\ u_2 - u_3 \geq 1 \\ u_1 + u_3 \geq 1 \end{array} \right\}$$

or

$$\left. \begin{array}{l} u_2 \geq 1 + u_3 \\ u_1 \geq (1 - 4u_2 - 2u_3)/6 \\ u_1 \geq 1 - u_3. \end{array} \right\}$$

[Algorithm 3](#) returns the vector  $\mathbf{u} = (1, 1, 0)$ . This will be the second column of the matrix  $\mathbf{A}$ . Thus,

$$\mathbf{A} = \begin{pmatrix} 1 & 1 \\ -1 & 1 \\ -1 & 0 \end{pmatrix}.$$

By [Algorithm 2](#), find two matrices

$$\mathbf{U} = \begin{pmatrix} -1 & 1 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \text{and} \quad \mathbf{T} = \begin{pmatrix} -1 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix},$$

such that  $\mathbf{U}$  is unimodular,  $\mathbf{T}$  is echelon (with a nonnegative diagonal element on second row), and  $\mathbf{A} = \mathbf{UT}$ . Since

$$(6, 4, 2)\mathbf{U} = (0, 10, 6), \quad (0, 1, -1)\mathbf{U} = (0, 1, 0),$$

$$\text{and } (1, 0, 1)\mathbf{U} = (0, 1, 1)$$

are all positive vectors, the transformation  $(L_1, L_2, L_3) \Rightarrow (L'_1, L'_2, L'_3)$  induced by  $\mathbf{U}$  is valid. The distance vectors of  $(L'_1, L'_2, L'_3)$  are  $(0, 10, 6)$ ,  $(0, 1, 0)$  and  $(0, 1, 1)$ . Since the loops  $L'_1$  and  $L'_3$  do not carry a dependence, they can run in parallel.

### Echelon Transformation

Some background needs to be prepared before echelon transformations can be defined. Let  $N$  denote the number of distance vectors of the loop nest  $\mathbf{L}$  of [Fig. 3](#), and  $\mathbf{D}$  its distance matrix. Apply [Algorithm 2](#) to the  $N \times m$  matrix  $\mathbf{D}$  to find an  $N \times N$  unimodular matrix  $\mathbf{V}$  and an  $N \times m$  echelon matrix  $\mathbf{S} = (s_{tr})$  with nonnegative rows, such that  $\mathbf{D} = \mathbf{VS}$ . Let  $\rho$  denote the number of positive rows of  $\mathbf{S}$ , so that  $\rho = \text{rank}(\mathbf{D})$ .

The top  $\rho$  rows of  $\mathbf{S}$  are positive rows and the bottom  $(N - \rho)$  rows are zero rows. Let  $\widehat{\mathbf{S}}$  denote the  $\rho \times m$  submatrix of  $\mathbf{S}$  consisting of the positive rows, and  $\widehat{\mathbf{V}}$  the  $N \times \rho$  submatrix of  $\mathbf{V}$  consisting of the leftmost  $\rho$  columns. Then,  $\mathbf{D}$  can be written in the form:

$$\mathbf{D} = \widehat{\mathbf{V}} \widehat{\mathbf{S}}. \quad (6)$$

**Lemma 1** *The rows of  $\widehat{\mathbf{V}}$  are positive vectors.*

*Proof* Let  $\mathbf{v}$  denote any row of  $\widehat{\mathbf{V}}$ . Then  $\mathbf{v}\widehat{\mathbf{S}} = \mathbf{d}$ , where  $\mathbf{d}$  is a distance vector. Since  $\mathbf{d}$  must be positive,  $\mathbf{v}$  cannot be the zero vector. Hence, it has the form  $\mathbf{v} = (0, \dots, 0, v_t, \dots, v_\rho)$ , where  $1 \leq t \leq \rho$  and  $v_t \neq 0$ . Let  $\ell = \ell_t$  denote the column number of the leading (first nonzero) element on row  $t$  of  $\widehat{\mathbf{S}}$ . Then,  $s_{t\ell} > 0$ , column  $\ell$  of  $\widehat{\mathbf{S}}$  has the form  $(s_{1\ell}, s_{2\ell}, \dots, s_{t\ell}, 0, \dots, 0)$ , and each column  $j$  for  $1 \leq j < \ell$  has the form  $(s_{1j}, s_{2j}, \dots, s_{t-1,j}, 0, \dots, 0)$ . Hence, the product  $\mathbf{v}\widehat{\mathbf{S}}$  has the form  $(0, \dots, 0, v_t s_{t\ell}, \dots)$ . Now,  $v_t s_{t\ell} \neq 0$  since  $v_t \neq 0$  and  $s_{t\ell} > 0$ . However, being the leading element of a distance vector,  $v_t s_{t\ell}$  must be positive. This means  $v_t > 0$ , since  $s_{t\ell} > 0$ . Thus,  $\mathbf{v}$  is a positive vector.  $\square$

**Lemma 2** *For  $1 \leq t \leq \rho$ , let  $\ell_t$  denote the column number of the leading element on row  $t$  of  $\widehat{\mathbf{S}}$ . For each  $\mathbf{I} \in \mathbf{Z}^m$ , there exists a unique  $\mathbf{Y} \in \mathbf{Z}^m$  and a unique  $\mathbf{K} \in \mathbf{Z}^\rho$ , such that*

$$0 \leq Y_{\ell_t} \leq s_{t\ell_t} - 1 \quad (1 \leq t \leq \rho) \quad (7)$$

and

$$\mathbf{I} = \mathbf{Y} + \mathbf{KS}. \quad (8)$$

*Proof* Note that the leading elements  $s_{t\ell_t}$  are all positive by construction. Let  $\mathbf{I} = (I_1, I_2, \dots, I_m) \in \mathbf{Z}^m$ . Define  $\mathbf{K} = (K_1, K_2, \dots, K_\rho) \in \mathbf{Z}^\rho$  by

$$\begin{aligned} K_1 &= \lfloor I_{\ell_1} / s_{1\ell_1} \rfloor \\ K_2 &= \lfloor (I_{\ell_2} - s_{1\ell_1} K_1) / s_{2\ell_2} \rfloor \\ &\vdots \\ K_\rho &= \lfloor (I_{\ell_\rho} - s_{1\ell_1} K_1 - s_{2\ell_2} K_2 - \dots - s_{\rho-1,\ell_{\rho-1}} K_{\rho-1}) / s_{\rho\ell_\rho} \rfloor. \end{aligned}$$

After defining  $\mathbf{K}$ , define  $\mathbf{Y} \in \mathbf{Z}^m$  by  $\mathbf{Y} = \mathbf{I} - \mathbf{KS}$ . Then  $\mathbf{Y}$  and  $\mathbf{K}$  are well defined and (8) holds.

For any real number  $x$ , one has  $0 \leq x - \lfloor x \rfloor < 1$ . If  $I$  and  $s$  are integers with  $s > 0$ , then  $0 \leq I/s - \lfloor I/s \rfloor < 1$  implies  $0 \leq I - s\lfloor I/s \rfloor \leq s - 1$ . Hence, if  $I = Y + s\lfloor I/s \rfloor$ , then  $0 \leq Y \leq s - 1$ . Since (8) implies

$$\begin{aligned} I_{\ell_1} &= Y_{\ell_1} + s_{1\ell_1} K_1 \\ I_{\ell_2} - s_{1\ell_1} K_1 &= Y_{\ell_2} + s_{2\ell_2} K_2 \\ &\vdots \\ I_{\ell_\rho} - s_{1\ell_1} K_1 - s_{2\ell_2} K_2 - \dots - s_{\rho-1,\ell_{\rho-1}} K_{\rho-1} &= Y_{\ell_\rho} + s_{\rho\ell_\rho} K_\rho, \end{aligned}$$

it follows from the definition of  $(K_1, K_2, \dots, K_\rho)$  that  $Y_{\ell_1}, Y_{\ell_2}, \dots, Y_{\ell_\rho}$  satisfy (7).  $\square$

The index variables  $I_1, I_2, \dots, I_m$  of the loop nest of Fig. 3 satisfy the constraints:

$$p_r(I_1, I_2, \dots, I_{r-1}) \leq I_r \leq q_r(I_1, I_2, \dots, I_{r-1}) \quad (1 \leq r \leq m).$$

For  $I_1, I_2, \dots, I_m$  in these inequalities, substitute the corresponding expressions in  $Y_1, Y_2, \dots, Y_m, K_1, K_2, \dots, K_\rho$  from (8). Add (7) to that system to get a system of inequalities in  $Y_1, Y_2, \dots, Y_m, K_1, K_2, \dots, K_\rho$ . Apply Fourier's method to the combined system and eliminate the variables

(in this order) to get bounds of the form:

$$\begin{aligned} \alpha_1 &\leq Y_1 \leq \beta_1 \\ \alpha_2(Y_1) &\leq Y_2 \leq \beta_2(Y_1) \\ &\vdots \\ \alpha_m(Y_1, Y_2, \dots, Y_{m-1}) &\leq Y_m \leq \beta_m(Y_1, Y_2, \dots, Y_{m-1}) \\ \alpha_{m+1}(Y) &\leq K_1 \leq \beta_{m+1}(Y) \\ \alpha_{m+2}(Y, K_1) &\leq K_2 \leq \beta_{m+2}(Y, K_1) \\ &\vdots \\ \alpha_{m+\rho}(Y, K_1, K_2, \dots, K_{\rho-1}) &\leq K_\rho \leq \beta_{m+\rho}(Y, K_1, K_2, \dots, K_{\rho-1}), \end{aligned}$$

where  $\mathbf{Y} = (Y_1, Y_2, \dots, Y_m)$ . For each index point  $\mathbf{I}$  of  $\mathbf{L}$ , there is a unique  $(m + \rho)$ -vector  $(\mathbf{Y}, \mathbf{K})$  satisfying these constraints, and conversely. The nest  $\mathbf{L}'$  of  $(m + \rho)$  loops shown in Fig. 5, where  $\mathbf{I} = \mathbf{Y} + \mathbf{KS}$  and  $H'(\mathbf{Y}, \mathbf{K}) = H(\mathbf{I})$ , has the same set of iterations as  $\mathbf{L}$ , but the order of execution is different. The transformation  $\mathbf{L} \Rightarrow \mathbf{L}'$  is called the *echelon transformation* of the loop nest  $\mathbf{L}$ .

Two iterations  $H(\mathbf{i})$  and  $H(\mathbf{j})$  in  $\mathbf{L}$  become iterations  $H'(\mathbf{y}, \mathbf{k})$  and  $H'(\mathbf{z}, \mathbf{l})$ , respectively, in  $\mathbf{L}'$ , where  $\mathbf{i} = \mathbf{y} + \mathbf{kS}$  and  $\mathbf{j} = \mathbf{z} + \mathbf{lS}$ . The transformed nest  $\mathbf{L}'$  is *equivalent* to the original nest  $\mathbf{L}$ , if whenever  $H(\mathbf{j})$  depends on  $H(\mathbf{i})$  in  $\mathbf{L}$ ,  $H'(\mathbf{y}, \mathbf{k})$  precedes  $H'(\mathbf{z}, \mathbf{l})$  in  $\mathbf{L}'$ , that is,  $(\mathbf{y}, \mathbf{k}) \prec (\mathbf{z}, \mathbf{l})$ .

**Theorem 2** *The loop nest  $\mathbf{L}'$  obtained from a nest  $\mathbf{L}$  by echelon transformation is equivalent to  $\mathbf{L}$ , and the  $m$  outermost loops of  $\mathbf{L}'$  can run in parallel.*

*Proof* To prove the equivalence of  $\mathbf{L}'$  to  $\mathbf{L}$ , consider two iterations  $H(\mathbf{i})$  and  $H(\mathbf{j})$  of  $\mathbf{L}$ , such that  $H(\mathbf{j})$  depends on  $H(\mathbf{i})$ . Let  $(\mathbf{y}, \mathbf{k})$  denote the value of  $(\mathbf{Y}, \mathbf{K})$  corresponding to the value  $\mathbf{i}$  of  $\mathbf{I}$ , and  $(\mathbf{z}, \mathbf{l})$  the value corresponding to  $\mathbf{j}$ . Since  $\mathbf{d} = \mathbf{j} - \mathbf{i}$  is a distance vector of  $\mathbf{L}$ , it follows from (6) that  $\mathbf{d} = \mathbf{v}\widehat{\mathbf{S}}$  for some row  $\mathbf{v}$  of  $\widehat{\mathbf{V}}$ .

$$\begin{aligned} L'_1: & \text{ do } Y_1 = \alpha_1, \beta_1 \\ & \vdots \\ L'_m: & \text{ do } Y_m = \alpha_m, \beta_m \\ L'_{m+1}: & \text{ do } K_1 = \alpha_{m+1}, \beta_{m+1} \\ & \vdots \\ L'_{m+\rho}: & \text{ do } K_\rho = \alpha_{m+\rho}, \beta_{m+\rho} \\ & H'(\mathbf{Y}, \mathbf{K}) \end{aligned}$$

$$K_\rho, K_{\rho-1}, \dots, K_1, Y_m, Y_{m-1}, \dots, Y_1$$

Loop Nest Parallelization. Fig. 5 Echelon Transformation

Then

$$\mathbf{j} = \mathbf{i} + \mathbf{d} = \mathbf{y} + \mathbf{k}\widehat{\mathbf{S}} + \mathbf{v}\widehat{\mathbf{S}} = \mathbf{y} + (\mathbf{k} + \mathbf{v})\widehat{\mathbf{S}}.$$

Since  $\mathbf{y}$  satisfies (7),  $(\mathbf{y}, \mathbf{k} + \mathbf{v})$  is the image of  $\mathbf{j}$  under the mapping  $\mathbf{I} \mapsto (\mathbf{Y}, \mathbf{K})$ . But the image of  $\mathbf{j}$  is also  $(\mathbf{z}, \mathbf{l})$  by assumption. Since this mapping is well defined, it follows that  $\mathbf{z} = \mathbf{y}$  and  $\mathbf{l} = \mathbf{k} + \mathbf{v}$ . Hence,

$$(\mathbf{z}, \mathbf{l}) - (\mathbf{y}, \mathbf{k}) = (\mathbf{z} - \mathbf{y}, \mathbf{l} - \mathbf{k}) = (\mathbf{0}, \mathbf{v}).$$

Since  $\mathbf{v}$  is positive by Lemma 2, this implies  $(\mathbf{y}, \mathbf{k}) \prec (\mathbf{z}, \mathbf{l})$ . Hence,  $\mathbf{L}'$  is equivalent to  $\mathbf{L}$  by definition.

It is clear from the above discussion that the distance vectors of the nest  $\mathbf{L}'$  are of the form  $(\mathbf{0}, \mathbf{v})$ , where  $\mathbf{v}$  is a row of  $\widehat{\mathbf{V}}$ . This means the  $m$  outermost  $Y$ -loops carry no dependence, and hence they can run in parallel.  $\square$

**Corollary 1** *In  $\mathbf{L}'$ , the distance matrix of the innermost nest of  $K$ -loops is  $\widehat{\mathbf{V}}$ .*

*Example 3* Consider the loop nest  $\mathbf{L}$ :

```
L1 : do I1 = 1,100
L2 : do I2 = 1,200
L3 : do I3 = I1,300
 X(I1,I2,I3) = X(I1-1,I2-3,I3) +
 X(I1-2,I2-10,I3) + X(I1-1,I2+1,I3)
```

whose distance matrix is

$$\mathbf{D} = \begin{pmatrix} 1 & 3 & 0 \\ 2 & 10 & 0 \\ 1 & -1 & 0 \end{pmatrix}.$$

By Algorithm 2, find two matrices

$$\mathbf{V} = \begin{pmatrix} 1 & 1 & 0 \\ 2 & 3 & 1 \\ 1 & 0 & 0 \end{pmatrix} \quad \text{and} \quad \mathbf{S} = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 4 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

such that  $\mathbf{V}$  is unimodular,  $\mathbf{S}$  is echelon, and  $\mathbf{D} = \mathbf{VS}$ . The leading elements of nonzero rows of  $\mathbf{S}$  are positive. It is clear that  $\rho = \text{rank}(\mathbf{D}) = \text{rank}(\mathbf{S}) = 2$ . The submatrix  $\widehat{\mathbf{S}}$  of  $\mathbf{S}$  consisting of its nonzero rows is given by

$$\widehat{\mathbf{S}} = \begin{pmatrix} 1 & -1 & 0 \\ 0 & 4 & 0 \end{pmatrix}.$$

Here  $s_{1\ell_1} = 1$  and  $s_{2\ell_2} = 4$ . Define a mapping  $(I_1, I_2, I_3) \mapsto (Y_1, Y_2, Y_3, K_1, K_2)$  of the index space of  $\mathbf{L}$  into  $\mathbf{Z}^5$  by the equation

$$(I_1, I_2, I_3) = (Y_1, Y_2, Y_3) + (K_1, K_2) \cdot \begin{pmatrix} 1 & -1 & 0 \\ 0 & 4 & 0 \end{pmatrix}, \quad (9)$$

and the constraints

$$0 \leq Y_1 \leq 0 \quad \text{and} \quad 0 \leq Y_2 \leq 3. \quad (10)$$

Equation (9) is equivalent to the system:

$$\left. \begin{array}{lcl} I_1 & = & Y_1 + K_1 \\ I_2 & = & Y_2 - K_1 + 4K_2 \\ I_3 & = & Y_3. \end{array} \right\} \quad (11)$$

Substituting for  $I_1, I_2, I_3$  from (11) into the constraints defining the loop limits of  $\mathbf{L}$ , one gets the following set of inequalities:

$$\left. \begin{array}{lcl} 1 & \leq & Y_1 + K_1 & \leq & 100 \\ 1 & \leq & Y_2 - K_1 + 4K_2 & \leq & 200 \\ Y_1 + K_1 & \leq & Y_3 & \leq & 300. \end{array} \right\} \quad (12)$$

Eliminate the variables  $K_2, K_1, Y_3, Y_2, Y_1$  from (10) and (12) by Fourier's method:

$$\left. \begin{array}{lcl} \lceil (1 - Y_2 + K_1)/4 \rceil & \leq & K_2 & \leq & \lfloor (200 - Y_2 + K_1)/4 \rfloor \\ 1 - Y_1 & \leq & K_1 & \leq & \min(100 - Y_1, Y_3 - Y_1) \\ 1 & \leq & Y_3 & \leq & 300 \\ 0 & \leq & Y_2 & \leq & 3 \\ 0 & \leq & Y_1 & \leq & 0. \end{array} \right\}$$

Using the fact that  $Y_1 = 0$ , simplify expressions and get the following loop nest  $\mathbf{L}'$  equivalent to  $\mathbf{L}$ :

```
L2 : do Y2 = 0,3
L3 : do Y3 = 1,300
L4 : do K1 = 1, min(100, Y3)
L5 : do K2 = \lceil (1 - Y2 + K1)/4 \rceil,
 \lfloor (200 - Y2 + K1)/4 \rfloor
```

$$\begin{aligned} X(K_1, Y_2 - K_1 + 4K_2, Y_3) = & \\ & X(K_1 - 1, Y_2 - K_1 + 4K_2 - 3, Y_3) + \\ & X(K_1 - 2, Y_2 - K_1 + 4K_2 - 10, Y_3) + \\ & X(K_1 - 1, Y_2 - K_1 + 4K_2 + 1, Y_3) \end{aligned}$$

In  $L'$ , the  $Y_2$  and the  $Y_3$  loops can run in parallel. (The  $Y_1$ -loop with a single iteration has been omitted.)

The distance matrix of the nest of  $K$ -loops is the submatrix consisting of the two leftmost columns of  $V$ , that is, the matrix:

$$\widehat{V} = \begin{pmatrix} 1 & 1 \\ 2 & 3 \\ 1 & 0 \end{pmatrix}.$$

Since the  $K_2$ -loop carries no dependence, it can run in parallel.

*Remark 2* When  $\rho = m$ , no valid unimodular transformation can give a parallel outer loop (see Corollary 1 to Theorem 3.8 in [3]). A simple example would be a nest of two loops with two distance vectors  $(2, 0)$  and  $(0, 3)$ , for which  $\rho = 2 = m$ . However, echelon transformation of this nest will yield a parallel  $Y_1$ -loop with 2 iterations and a parallel  $Y_2$ -loop with 3 iterations.

If both transformations are available, the best strategy would be to apply the echelon transformation first to get a nest of  $m$  parallel outermost  $Y$ -loops and  $\rho$  sequential innermost  $K$ -loops. Then apply [Algorithm 3](#) to the nest of  $K$ -loops to get one sequential outermost loop followed by  $(\rho - 1)$  parallel inner loops.

## Bibliographic Notes and Further Reading

*Unimodular Transformation.* Research on this topic goes back to Leslie Lamport's paper in 1974 [8], although he did not use this particular term. This essay is based on the theory of unimodular transformations as developed in the author's books on loop transformations [2, 3]. The general theory grew out of the theory of unimodular transformations of double loops described in [1]. (Watch for some notational differences between these references and the current essay.) The paper by Michael Wolf and Monica Lam [13] covers many useful aspects of unimodular transformations. See also

Michael Dowling [5], Erik H. D'Hollander [4], and François Irigoin and Rémi Triolet [6, 7].

Consider a sequential loop nest where each iteration (other than the first) depends on the previous one. The Hyperplane method would still transform it into a nest where the outermost loop is sequential and all inner loops are parallel. There is no great surprise here. It simply means that each inner loop in the new nest will have a single iteration. (Such a loop can run in parallel according to the definition given.) See [13] for the case when there are too many distance vectors.

*Echelon Transformation.* In his PhD thesis [9], David Padua developed the greatest common divisor method for finding a partition of the index space. Peir and Cytron [10] described a partition based on minimum dependence distances. Shang and Fortes [12] offered an algorithm for finding a maximal independent partition. D'Hollander's paper [4] builds on and incorporates these approaches. The general theory of echelon transformations presented here is influenced by these works. See also Polychronopoulos [11].

See [3] for details on unimodular, echelon, and other transformations used in loop nest parallelization, and more references.

### Synonyms

[Doall loops](#); [Forall loops](#)

### Definition

Parallel loops are one of the most widely used concepts to express parallelism in parallel languages and libraries. In general, a parallel loop is a loop whose iterations are executed at least partially concurrently by several threads or processes. There are several different kinds of parallel loops with different semantics, which will be discussed below. The most prominent kind is the Doall loop, where the iterations are completely independent.

### Discussion

#### Introduction

In a task parallel program, where the execution of different pieces of code is distributed to parallel processors,

there are two principal ways of specifying parallel activities. The first one is to specify several *different* code regions, i.e., tasks, which should be executed in parallel. This construct is typically called *parallel regions* or *parallel case*. It offers only a very limited scalability, since the maximum degree of parallelism is determined by the number of regions. The second way is to use *parallel loops*. In a parallel loop, the parallel processors execute the *same* code region, namely, the loop body, but with different data. Thus, parallel loops are a special kind of SPMD programming. Typically, parallel loops are used within a shared memory programming model, for example, OpenMP and Intel's Threading Building Blocks. However, they have also been included in some distributed memory programming models, for example, Occam.

In a sequential loop, the loop body is executed for each element in the loop's index domain in a fixed order implied by the domain. For example, in

```
for (i=0; i<N; i++)
 s[i] = sin(PI*i/N);
```

the assignments to *s* occur in the order *s*[0], *s*[1], ..., *s*[*N*], although there is obviously no particular reason which mandates this order of the loop iterations. In a parallel loop, the restrictions on the ordering of the loop iterations are relaxed, which allows the iterations to execute – at least partially – in parallel. In the example, all iterations can execute in parallel, since they are completely independent of each other.

#### Types of Parallel Loops

Today's parallel programming interfaces offer different constructs for parallel loops, which typically fall into one of the following classes which are described by Polychronopoulos [7] and Wolfe [10]: First, there are parallel loops which can be viewed as sequential loops extended by additional properties. A *Doall loop* assures that its iterations can be executed completely independently, while a *Doacross loop* may contain forward dependences. These loops can also be executed sequentially without changing their semantics. In addition, some parallel languages offer a *Forall loop*; however, the term is used with a nonuniform meaning. For example, the Forall loop in Vienna Fortran [3] is actually a Doall loop, while in High Performance Fortran (HPF)

and Fortran95, it has a special nonsequential execution semantics, which is described below.

### Doall Loops

In a Doall loop, every iteration can be executed independently from any other iteration. This means that the iterations can be executed in any sequential order or concurrently.

More formally, a Doall loop is not allowed to contain loop carried dependences. This means that when  $W(i)$  denotes the set of variables the loop's body writes to in some iteration  $i$  and  $R(i)$  denotes the set of variables read in iteration  $i$  the following conditions, often called Bernstein's conditions, must hold for any two different iterations  $i_1$  and  $i_2$  of the loop:

$$\begin{aligned} W(i_1) \cap W(i_2) &= \emptyset \text{ and} \\ R(i_1) \cap W(i_2) &= \emptyset \text{ and } W(i_1) \cap R(i_2) = \emptyset \end{aligned}$$

In this context, the term variable means either a scalar variable or an element of an array or some other structured data type. As an example, consider the following loops:

```
for (i=0; i<N; i++) {
 b[i] = sin(PI*i/N);
 a[i] = a[i] + b[i];
}

for (i=0; i<N; i++) {
 b[i] = sin(PI*i/N);
 a[i] = a[i-1] + b[i];
}
```

Here, the first loop is a Doall loop, while the second one is not. For the first loop,  $W(i) = \{a[i], b[i]\}$  and  $R(i) = \{a[i], b[i], i\}$ . Thus, for different iterations  $i_1$  and  $i_2$ , the write and read sets never overlap. On the other hand, for the second loop,  $W(i) = \{a[i], b[i]\}$  and  $R(i) = \{a[i-1], b[i], i\}$  which leads to  $W(i_1) \cap R(i_2) = \{a[i_1]\}$  for  $i_2 = i_1 + 1$ .

As an additional requirement, the iteration domain of a Doall loop must be fixed when the loop is entered, that is, the loop body is neither allowed to exit the loop prematurely nor to change the loop variable or its upper bound.

When a Doall loop is to be executed by a fixed number of processors (or threads), the iterations can be arbitrarily scheduled to the processors without changing the loop's computational results. However, the scheduling can have a large impact on the performance. With today's cache-based memory systems, it is beneficial if each processor executes a contiguous block of loop iterations since this will maximize the locality of the memory accesses on each processor. For example, when a loop iterating from 1 to 100 is executed by four processors, the first one would execute iterations 1–25, the second one 26–50, and so on. This situation is visualized in Fig. 1.

The blockwise scheduling works well, however, only when all iteration have approximately the same execution time. When the execution time differs largely between iterations, blockwise scheduling can lead to a poor performance. A typical example for this situation is a triangular loop nest, where the outer loop is parallel:

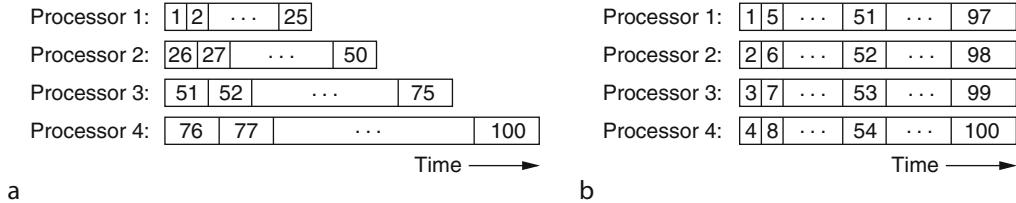

```
for (i=1; i<=100; i++)
 for (j=1; j<=i; j++)
 a[i][j] = some_computation(i, j);
```

With a blockwise scheduling, processor 4 gets the largest amount of work. Since there is typically a global synchronization (barrier) between all processors at the end of a parallel loop, the other three processors will have to wait, which results in a load imbalance. In such cases, a cyclic schedule, where single iterations are assigned to processors in a round-robin fashion offers a better load balancing, as it is shown in Fig. 2. However, the cache performance of such an execution may be poor. As a compromise between cache performance and load balancing, blocks of iterations may be assigned to the processors in a cyclic manner.

|              |    |    |     |     |
|--------------|----|----|-----|-----|
| Processor 1: | 1  | 2  | ... | 25  |
| Processor 2: | 26 | 27 | ... | 50  |
| Processor 3: | 51 | 52 | ... | 75  |
| Processor 4: | 76 | 77 | ... | 100 |

Time →

**Loops, Parallel. Fig. 1** Blockwise schedule for a simple parallel loop

**Loops, Parallel.** Fig. 2 Blockwise and cyclic schedule for a triangular loop (a) blockwise schedule, (b) cyclic Schedule

In addition to the static scheduling discussed above, dynamic scheduling may be used when the iterations' execution times vary irregularly. In this case, each processor fetches an iteration from a global work pool, executes it, and then fetches the next one, until the work pool is empty. Dynamic scheduling achieves very good load balancing at the price of the additional overhead for the synchronized access to the global work pool. Like in the static case, processors may fetch contiguous blocks of iterations from the pool in order to increase the cache performance and to decrease the overhead.

### Doacross Loops

A Doacross loop is a parallel loop, where individual iterations are scheduled to the processors in a round-robin fashion, either dynamically or statically. The iterations are started in the same order as in a sequential loop and then execute overlappingly in a pipelined fashion. This allows Doacross loops to possess forward dependences between iterations.

The following example shows a best case for a Doacross loop:

```
for (i=1; i<N; i++) {
 a[i] = f(i);
 b[i] = a[i] - a[i-1];
}
```

Although this loop contains a flow dependence, since the value of  $a[i]$  written in iteration  $i$  is read by  $a[i-1]$  in the following iteration  $i+1$ , it can be executed in parallel with optimal scalability. Figure 3 shows an execution under the assumption that the first statement of the loop body always needs two time units to execute, while the second one needs just one. Of course, in practice, some synchronization statements must be added to the loop in order to ensure the correct temporal order of the dependent statements:

```
for (i=1; i<N; i++) {
 a[i] = f(i);
 signal(i);
 wait(i-1);
 b[i] = a[i] - a[i-1];
}
```

Here, the operation `wait(i-1)` waits until the corresponding `signal(i-1)` has been executed, which indicates that the assignment to `a[i-1]` has finished.

There are also loops, called *serial loops*, where without code restructuring dependences in the loop body can completely inhibit any parallelism, for example,

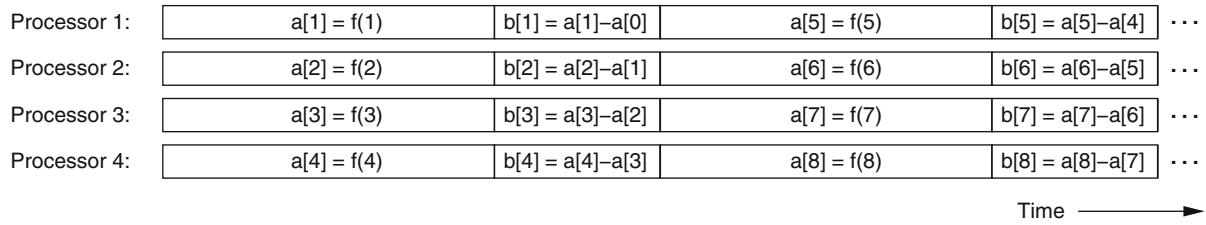

```
for (i=1; i<N; i++) {
 a[i] = b[i-1];
 b[i] = f(i);
}
```

As the schedule in Fig. 3 shows, the loop iterations cannot overlap due to the dependence, since the first statement of iteration  $i+1$  depends on the last statement of iteration  $i$ . However, in this special case, the two statements could be swapped, enabling nearly perfect parallelism. This kind of reorganization is typically performed by interactive restructuring tools or autoparallelising compilers.

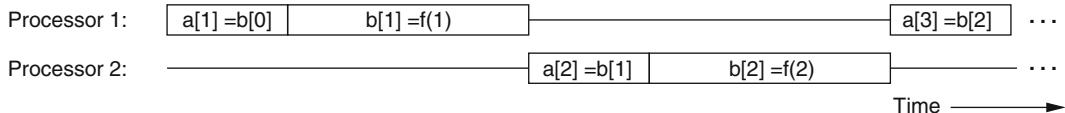

### Forall Loops

The Fortran D language [5] introduced a parallel loop, called *FORALL*, which deals with dependences in a special way: A read operation on a variable will return a new value only if that value was assigned in the current loop iteration, otherwise, it returns the old value of the variable at the time the loop was entered. Thus, conceptually each iteration works on its own copy of the data space.

In High Performance Fortran (HPF) [4], this construct was inherited with some modifications under the

**Loops, Parallel.** Fig. 3 Best case execution of a Doacross loop: full overlap

**Loops, Parallel.** Fig. 4 Worst case execution of a Doacross loop: no overlap

name *FORALL construct*, which was later included into the Fortran 95 language standard. The statements inside a FORALL construct are executed in their sequential order; however, each statement is executed for all elements of the index domain by first performing all read operations and only afterward doing the write operations. For example, in the construct

```
FORALL (i=2:n-1)
 a(i) = a(i-1) + a(i+1)
 b(i) = a(i)
END FORALL
```

first the expression  $a(i-1) + a(i+1)$  will be evaluated for all values of  $i$ , and only afterward all the assignments to  $a(i)$  will occur. Then, the second statement is executed in a similar way to copy  $a$  into  $b$ . Thus, the FORALL construct in HPF and Fortran 95 actually is rather a convenient way to express a sequence of vectorizable and/or parallelizable array assignments than a (parallel) loop.

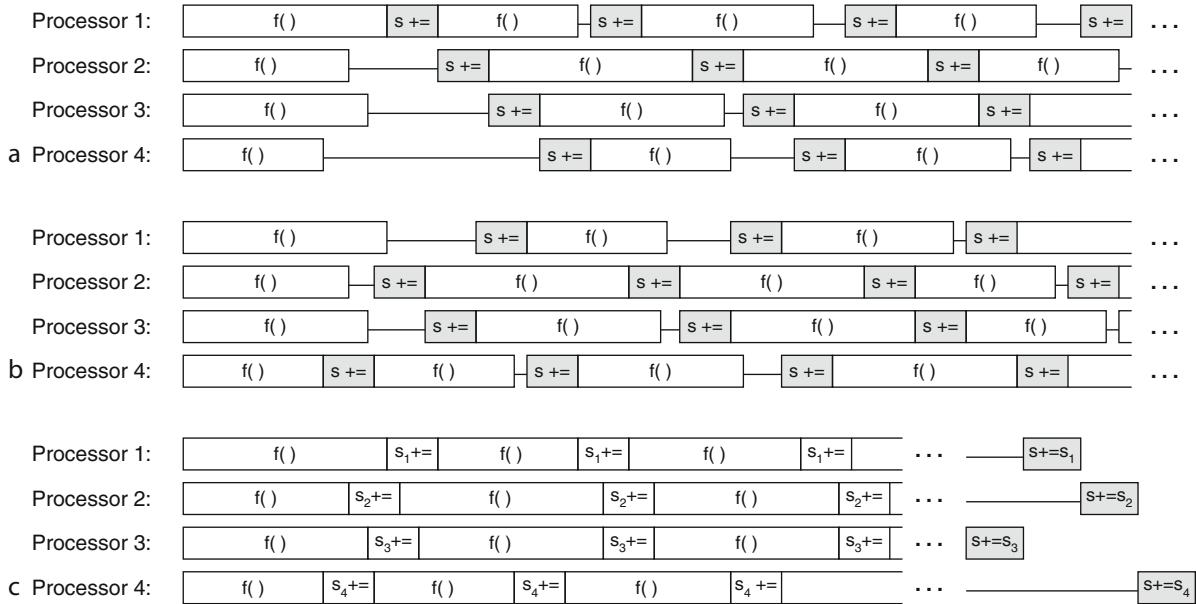

### Variables in Parallel Loops

In a shared memory environment, variables in a parallel loop may either be shared between all threads executing the loop or they may be private, which means that each thread has its own copy of the variable. Typically, the data the loop is working on is shared, while the loop variables of the parallel loop and all its inner loops must be private. Private variables can also be used to compute thread local intermediate results inside a loop, which are combined only after the loop terminated.

A special case of this situation is a reduction variable. A reduction variable is a variable  $v$  such that each assignment in the loop has the form  $v = v \oplus \dots$ , with  $\oplus$  being an associative operator, and  $v$  is not otherwise read in the loop. A typical example is the computation of the integral of a function:

```
double s = 0;
for (i=0; i<N; i++)
 s += f((i+0.5)/N) / N;
```

Strictly, this loop can only be executed in parallel as a Doacross loop, where the exact ordering of the summation is preserved. This is shown in Fig. 5a, where it is assumed that the execution time of  $f()$  shows some variation. If the reduction operation is associative and commutative, which is true for integer arithmetic, but due to rounding errors typically not for floating point arithmetic, the order of the summation may be changed arbitrarily without changing the result. In this case, the loop may be executed as a Doall loop, provided that the concurrent updates to the shared variable  $s$  are protected by a proper synchronisation for mutual exclusion. Fig. 5b shows that although the loop performs better than the Doacross loop, the degree of parallelism is still rather limited. A nearly optimal parallelization can be achieved using a private reduction variable. As indicated in Fig. 5c, each thread first computes a partial sum in its private instance of the variable. At the end of the loop, the partial sums are added to the global sum within a small critical section. Parallel programming interfaces typically allow to mark reduction variables in

**Loops, Parallel.** Fig. 5 Three ways of implementing a parallel reduction (a) Doacross loop, (b) Doall loop, (c) Doall loop with local summation

parallel loops and transparently introduce a local reduction variable as outlined above. A code example using OpenMP is given in the next section.

## Parallel Loops in OpenMP

OpenMP is a parallel programming model for shared memory computers, which extends traditional sequential languages with directives controlling the parallel execution. The main construct is the parallel region, which indicates that the region's code should be executed by a prespecified number of threads. Inside such a parallel region, loops may be designated as parallel loops, resulting in the loop iterations being distributed across the available threads. In C and C++, this is done using the directive

```
#pragma omp for
```

when the loop is already contained in a parallel region, or the combined directive

```
#pragma omp parallel for
```

which additionally creates a parallel region around the loop. These directives must be placed immediately before the loop. OpenMP puts a couple of restrictions on a parallel loop: it must be a `for`-loop with an

integer loop variable, constant increment, and a simple termination test. The loop must not exit prematurely, for example, via a `break` or `return` statement or an exception. In addition, the loop body must neither modify the loop variable nor the loop bounds.

The detailed behavior of the loop can be controlled by a number of optional clauses, which may be appended to the directive:

- The `schedule` clause controls how loop iterations are scheduled to threads. The default behavior is a static blockwise schedule as shown in Fig. 1. Using the clause `schedule(static, size)`, a fixed size for the blocks may be specified. The blocks then are assigned to threads in a round-robin fashion. Thus, for example, `schedule(static, 1)` results in a cyclic schedule like in Fig. 2b. It is also possible to specify a dynamic scheduling, again with an optional block size. The `schedule type guided` uses dynamic scheduling with exponentially decreasing block sizes, which can help to improve the load balancing while keeping the overhead reasonably. Finally, the definition of the `schedule type` can be postponed to the runtime, in order to quickly experiment with different schedules.

- Several other clauses concern the variables used inside the loop. The `shared` and `private` clauses explicitly define variables as being shared between threads or being thread private. The loop variable and all local variables declared inside the loop body are always private. Variables declared outside the loop are shared by default, although this behavior can be changed by using the `default` clause.

The value of a private variable is undefined at the beginning of the loop and is lost at its end. The clauses `firstprivate` and `lastprivate` allow the initialization and finalization of the value, respectively.

The `reduction` clause is used to specify a reduction variable together with the operation used in the reduction. The reduction will then be implemented as shown in Fig. 5c.

- Finally, two clauses control the synchronisation. By default, at the end of each parallel loop, all threads synchronize using a barrier. The `nowait` clause instructs OpenMP to omit this synchronization.

The `ordered` clause indicates that the loop contains an `ordered` directive, which is discussed below.

OpenMP executes parallel loops as Doall loops. However, OpenMP does not check whether the iterations are independent, thus, parallel loops in OpenMP may actually contain dependences. It is the responsibility of the programmer to ensure that the results of the parallel execution are correct. A means to achieve this is the use of synchronization constructs inside the loop. For mutually exclusive access to shared variables, OpenMP provides the `omp critical` and `omp atomic` directives, where the latter is an optimized form for statements like `x += expr`. Another synchronization directive is `omp ordered`, which ensures that the statement(s) controlled by the directive are executed in the same order as in the sequential loop. This directive can only be used in loops having an `ordered` clause and roughly results in the loop behaving like a Doacross loop. Such a loop should always use a `(static, 1)` schedule to achieve a reasonable performance.

In order to illustrate the usage of the mentioned directives, the following code examples show how the

parallel reduction outlined before can be implemented using OpenMP.

(a) As Doacross loop:

```
double s = 0;
#pragma omp parallel for \
ordered schedule(static,1)
for (i=0; i<N; i++) {
 double h = f((i+0.5)/N) / N;
#pragma omp ordered
 s += h;
}
```

(b) As Doall loop:

```
double s = 0;
#pragma omp parallel for
for (i=0; i<N; i++) {
 double h = f((i+0.5)/N) / N;
#pragma omp critical
 s += h;
}
```

(c) Local summation using the reduction clause:

```
double s = 0;
#pragma omp parallel for \
reduction(+: s)
for (i=0; i<N; i++)
 s += f((i+0.5)/N) / N;
```

(d) Explicit local summation:

```
double s = 0;
#pragma omp parallel
{
 double ls = 0;
#pragma omp for
 for (i=0; i<N; i++)
 ls += f((i+0.5)/N) / N;
#pragma omp atomic
 s += ls;
}
```

In the code examples (a) and (b), a private auxiliary variable is used in order to allow the calls to `f()` being executed in parallel. In example (d), `ls` is a private variable, since it is declared inside the parallel region. The execution behavior of these loops is exactly as outlined in Fig. 5.

## Parallel Loops in Intel(R) Threading Building Blocks

The Threading Building Blocks (TBB) are a template library for ISO C++, which includes a variety of constructs supporting the parallel programming with shared memory. Among these constructs are two different kinds of Doall loops, as well as a reduction operation. Since TBB is just a library and does not require any compiler support, parallel loops must be expressed by calling a library function which receives the loop body in the form of a functor, that is, a function object.

For example, the body of the Doall loop shown in the beginning of this entry can be expressed in a class like this:

```
class Body1 {
 double *a;
 double *b;
public:
 void operator()(const tbb::blocked_range<int>& r) const {
 for (int i=r.begin(); i<r.end(); i++) {
 b[i] = sin(PI*i/N);
 a[i] = a[i] + b[i];
 }
 }
 Body1(double *arg_a, double
 *arg_b) { a = arg_a; b = arg_b; }
};
```

The class must define an ()-operator, which must execute the loop body for the index range specified by its parameter. In addition to the class `blocked_range` for a contiguous one-dimensional interval, TBB also provides classes for two- and three-dimensional ranges. A parallel for-loop with the specified body is then written as a function call, for example,

```
tbb::parallel_for(tbb::blocked_range<int>(0,N), Body1(a,b));
```

Here, `a` and `b` are the two array variables, which are shared between the threads executing the loop. Since the loop body is instantiated as an object, pointers to the shared data must be passed to the constructor and stored in attributes of the body class. TBB executes the loop by recursively splitting the index range into a set of subranges, for which the ()-operator will be

invoked. The execution of each subrange forms a task, which is dynamically scheduled to one of the available worker threads. By default, their number is one less than the number of CPU cores, thus reserving one core for the manager thread. The way how the index range is partitioned can be controlled by passing a partitioner as an optional argument to the `parallel_for` function. The default partitioner uses a heuristics to determine a suitable size of the subranges. It can be fine-tuned using an optional parameter in the constructor of `blocked_range`, which allows to specify a minimum size for the subranges. In order to achieve a good speedup, it should be chosen such that the ()-operator executes at least some 10,000 instructions. For parallel loops which are executed repeatedly, TBB provides an additional partitioner that tries to improve cache affinity.

A second kind of parallel loop construct available in TBB implements loops based on C++ iterators. Iterators are extensively used in C++ class libraries in order to iterate over all elements of a collection, for example, a linked list. Although the `parallel_do` loop must usually fetch the work items serially, since most iterators only support a strictly sequential traversal of a collection, the processing of these work items in the loop body may be initiated in an arbitrary order. Thus, also `parallel_do` implements a Doall loop where all iterations must be independent. However, the body of a `parallel_do` is allowed to extend the iteration space by inserting items into the collection. This is illustrated in the following example:

```
class Body2 {
public:
 void operator()(Item& item, tbb::parallel_do_feeder<Item>& feed)
const {
 // may generate a new item
 Item res = processItem(item);
 if (res != NULL) {
 // add item to collection
 feed.add(res);
 }
}
...
std::list<Item> l;
... // initialize list
```

```
tbb::parallel_do(l.begin(),
l.end(), Body2());
```

The loop iterates over all elements of a linked list and invokes the function `processItem` on each of these elements. The processing of an item may result in a new item being generated, which is added to the collection via a `parallel_do_feeder` object passed as an optional argument to the `()`-operator. Since TBB makes extensive use of templates, the items may have an arbitrary data type.

Besides independent loops, TBB allows to implement parallel loops with reductions by using the `parallel_reduce` function. Reduction loops are executed by recursively splitting the index range into subranges, computing the local values for the leaf subranges, and then recursively combining these local results into the global one. Since the initialization of the local result and the combining operation depend on the concrete loop, the class defining the loop's body must provide an additional constructor and a join operation. The following code implements the integration used as an example before:

```
class Sum {
public:
 double sum;
 void operator()(const tbb::
blocked_range<int>& r) {
 for (int i=r.begin(); i<r.end(); i++)
 sum += f((i+0.5)/N) / N;
 }
 // splitting constructor
 Sum(const Sum& s, tbb::split) {
 sum = 0;
 }
 // combining operation
 void join(const Sum& s) {
 sum += s.sum;
 }
 Sum() { sum = 0; }
};

Sum s;
tbb::parallel_reduce(tbb::
blocked_range<int>(0,N), s);
```

The dummy argument of type `tbb::split` is used to distinguish the splitting constructor from a copy constructor.

## Bibliographic Notes and Further Reading

In the 1980s, many parallel and vector supercomputers, for example, Cray X-MP or Alliant FX/8, started to offer parallel loops as a programming construct, which was implemented by their proprietary compilers. Karp [6] provides an overview of the state of the art of parallel programming at that time, including a discussion of parallel loops.

Since parallel loops are typically supported by a compiler, either by the use of directives like in OpenMP, or by autoparallelization, in-depth discussions can be found in books on parallelizing compilers. Wolfe presents a very good overview on data dependences and techniques for loop parallelization in [10]. In [7], Polychronopoulos discusses different methods for scheduling parallel loops in detail.

Since Fortran is the predominant language in the area of numerical computations, there have been many research efforts to integrate parallel loops into this language, most of them addressing distributed memory parallel computers. The group around Ken Kennedy at Rice University developed Fortran D [5], while in parallel Hans Zima and his coworkers devised Vienna Fortran [3]. Both languages influenced the High Performance Fortran language, whose first specification appeared as a special issue of the Scientific Computing journal [4].

Programming with OpenMP is discussed in ample detail in several books [1, 2, 9]. There is also a textbook [8] about the Intel Threading Building Blocks, which

contains many examples. Additional information about OpenMP and TBB can be found in the related entries of this encyclopedia.

## Definition

Massive-scale analytics refers to a combination of mathematical methods and high-performance computational methods for the analysis of vast amounts of data in order to gain crucial insights and facilitate decision making across a broad spectrum of application domains, sometimes in an automated data-driven fashion. This requires a unified approach that addresses the two key dimensions of massive-scale analytics: data and computation.

## Discussion

### Introduction

The volumes of data available to various organizations throughout society over the past many years have been growing at an explosive rate. Important advances in computer sciences and technologies have made this possible, which in turn have resulted in the development and growth of data warehouses and reporting capabilities to view information concerning various aspects of an enterprise. These basic reporting capabilities have helped organizations improve the accuracy and timeliness of the data used for the purposes of enterprise decision making. However, significantly increasing the rewards for investments in data collection and data warehouse construction well beyond basic reporting requires the development of massive-scale analytics that provide deeper insights and understanding of the enterprise and optimization of its performance. The overall goal of massive-scale analytics is to enable organizations with data-driven decision-making capabilities based on a combination of advanced mathematical and computational methods, including automated tools and applications.

There are many challenges to realizing the full benefits of massive-scale analytics. This includes important challenges along the two key dimensions of applying massive-scale analytics against huge volumes of data, namely the data dimension which involves machine

learning, knowledge discovery, and data management, together with the computational dimension which involves high-performance and massively parallel computing. The main challenges for the data dimension entail extracting knowledge and insight from complex queries against massive data sets in an efficient and effective manner. The main challenges for the computational dimension entail efficient access to massive data sets and efficient parallel algorithms for computing advanced analytics over these data sets. Far too often, massive-scale analytics are pursued solely from the perspective of one of these dimensions. However, it is only through a general approach which simultaneously addresses these two key dimensions in a unified fashion that the full potential of massive-scale analytics can be realized. In addition to leveraging and combining solutions along both dimensions for creating and developing predictive models, this general massive-scale analytics approach includes the stochastic analysis and optimization of such predictive models to support decision making, scenario analysis, and optimization across a wide variety of applications in a domain-specific manner. This additional aspect of massive-scale analytics raises a number of important challenges to obtain scalable solutions for complex multidimensional stochastic models and decision processes.

Some of the application areas where massive-scale analytics are being actively pursued include advertising and marketing, business intelligence, energy (power grid), health care (genomics, public health), natural sciences (biology), security (internet, national), social networks, workforce management, and transportation. The list of such applications continues to grow at a rapid pace and this trend is expected to endure for the foreseeable future.

## Data Dimension

The massive scale analytics challenge along the data dimension is to provide knowledge and insight on data sets using methods that can gracefully scale with increasing data set sizes. Research on this front has been conducted in the following distinct areas.

## Platforms for Scalable Data Management and Analysis

Successfully processing and analyzing massive data sets requires a platform that can store and allow one to

process data efficiently. Early platforms for scalable data management were provided through database systems. Database systems typically provide a relational data model for data representation, a system for data storage and indexing, and a query processor that can answer queries against the data stored in the system. Parallel database systems improve performance through parallelization of various operations, such as loading data, building indexes, and evaluating queries [11]. Although data may be stored in a distributed fashion, the distribution is governed solely by performance considerations. Such systems improve processing by using multiple CPUs and disks in parallel. Additional programmability is afforded through *user defined functions* – these allow users to embed their custom parallel computations inside a database system. Parallel database systems have been successfully used in the scalable implementation of analytics solutions that go beyond simple database queries [27]. More recently, researchers have also delved into the problem of building database systems that are optimized for data warehouse workloads [31] rather than transactional workloads.

While parallel relational database systems work very well for structured data, more recently, with the advent of applications that need to digest unstructured data (such as plain text, webpages, XML files, RSS feeds) and the need for increased programmability, there has been the development of new systems, programming abstractions, and query languages to store, process, and analyze such data. An example of such an effort is the increasingly popular Apache Hadoop project that uses the MapReduce programming model [10] to provide a simplified means of processing large files on a parallel system through user-defined *Map* and *Reduce* primitives. A MapReduce job consists of two phases – a Map phase and a Reduce phase. During the Map phase, the user-defined *Map* primitive transforms the input data into *(key, value)* pairs in parallel. These pairs are stored and then sorted by the system so as to accumulate all *values* for each *key*. During the Reduce phase, the user-defined *Reduce* primitive is invoked on each unique *key* with a list of all the *values* for that *key*; usually, this phase is used to perform aggregations. Finally, the results are output in the form of *(key, value)* pairs. Each *key* can be processed in parallel during the Reduce phase. A user can implement a variety of parallel analytics computations by submitting one or more MapReduce jobs to

the system. Such systems have been designed to run on large commodity clusters and recover from both data as well as compute node failures. For many domains, the MapReduce paradigm is too low level and there has been the development of custom data management and analysis platforms on top of MapReduce ranging from key-value stores like Cassandra to machine learning platforms such as System-ML [15].

### Algorithms for Scalable Knowledge Discovery and Data Mining

Spurred by advances in data collection technologies, the field of data mining has emerged, merging ideas from statistics, machine learning, databases, and high performance computing. The main challenge in data mining is to extract knowledge and insight from massive data sets in a fast and efficient manner. Data mining methods must scale near-linearly with the data set size. Thus, as data set sizes increase, these techniques must allow one to process increasing volumes of data and at the same time provide a reasonable response time by employing parallelism. Data mining commonly involves four classes of tasks: association rule mining, classification, clustering, and regression. Classification, clustering, and regression have been well studied in the machine learning and statistics communities, but the algorithms were not always designed to scale linearly with the data set size. Over the past 2 decades, the data mining community has borrowed methods from these communities and devised new methods to provide actionable knowledge from large data sets efficiently. Parallel solutions have also been devised that scale using data parallelism. Furthermore, when data parallelism is not an option, techniques that learn on partitions of the data independently and then use the resulting models collectively as an ensemble have also been devised [12]. The reader can look at the entry on parallel data mining for further details.

### Approximate Data Processing and Mining

An alternate strategy to deal with increasing data set sizes is to develop approximate versions of existing algorithms. The approximation should be tunable in the sense that the process should take less time if one can make do with a less accurate answer. This allows one to process increasingly larger data sets in the same amount of time by requesting a less accurate answer.

Database and data mining researchers have developed a suite of approximation techniques to process very large data sets in linear and sometimes even sub-linear time. These techniques make use of summary structures and/or sampling to provide approximate answers, oftentimes with a deterministic or probabilistic error bound. Approximate data processing and mining techniques have also been extended to process data streams where one can only perform one pass over the data. Examples of data streams include computer network traffic, phone conversations, ATM transactions, web searches, and sensor data. The reader can refer to the papers by Garofalakis et al. [13] and Babcock et al. [3] for an introduction to approximate query processing techniques and the application of these techniques to processing data streams, respectively, and the book by Charu Aggarwal [1] for an introduction to issues and solutions related to data stream mining.

### Computational Dimension

#### Architectural Resources

The peak computational ability of systems has been growing at a rate greater than that indicated by Moore's Law, doubling more frequently than every 18 months. For example, the fastest disclosed computer in the world was running just over one teraflop ( $10^{12}$  FLOPS) in 1997 according to the TOP500 list [33]. In 2008 the analogous system at the top of this list broke the petaflop ( $10^{15}$  FLOPS) barrier [23]. Thus, for traditional scientific computations, e.g., physics simulations, floating-point arithmetic is a bountiful resource. As analytics, even deep analytics, applications are rarely more computationally intensive than such scientific computations, it is unlikely that these algorithm's performance will be limited by floating-point resource availability. Memory tends to be the bottleneck for analytics, as it is often the limiting factor for scientific applications. On large HPC systems memory access has a complex characterization. On any system, the standard performance measures of memory are the latency to access and the bandwidth available and both characteristics tend to degrade as one's focus moves from the on-chip cache to the larger main memory and the attached high-capacity nonvolatile memory (typically a hard disk drive). With large, distributed-memory systems, off-chip, off-node, and off-rack memory characteristics come into play. It

is typically the case that as one increases the working set of the problem under consideration it is necessary to use the memory systems of other nodes and to carry out implicit or explicit message passing between those nodes to share data. It is usually the case that the larger the domain under consideration, the greater the latency and the lower the bandwidth available. However, this relationship is not always true. For example, the bandwidth of a hard drive system, especially when viewed as the shared resource that it is almost assured to be, can be lower than the intranode network on a large HPC system. Further, there are architectural features that can ameliorate the situation. Examples include massive multithreading and out-of-order execution, which both tend to greatly mask issues related to high-latency accesses.

### Software and Programmability

In order to efficiently utilize high performance computing resources for analytics the algorithms employed must be parallel. Software that is already executing in parallel, through automatically (compiler) extracted parallelism, lightweight explicit parallelism (e.g., OpenMP, HPF, and X10 [6, 7, 19]), or somewhat intrusive and highly orchestrated parallelism (e.g., Pthreads and MPI [17, 25]) must be extended to encompass larger (higher thread and node count) systems. This can present significant challenges as most analytics codes contain sequential portions (due to the complexity of the algorithm or assumptions about resources available, such as the amount of memory available in a single coherence domain). There is also a good deal of analytics software designed and written for strictly sequential execution. For the most part, this software must be heavily redesigned and the algorithms employed, rethought. As the number of processes increases, Amdahl's law makes it necessary to parallelize an ever-increasing percentage of the overall algorithm. Thus, in either case, a good deal of work is likely required in order to enable analytics software for this domain. This has motivated research into such enabling technologies as the Parallel Global Address Space (PGAS) languages [32] as well as investment in creating software tools in this space (e.g., IBM's High Performance Computing Toolkit [8] and Intel's Parallel Studio [20]).

### HPC System Utilization Modes

There are two fundamental ways in which large HPC systems are currently leveraged for analytics applications. It is usually the case that a small part of a larger system is devoted to a single program execution. This allows analytics to leverage high performance computing systems using current software and, given the nature of stochastic modeling, is an excellent way to leverage such systems. More rarely, analytics codes are rewritten to take advantage of highly parallel (1,000-way and beyond) systems in a unified fashion. This usually requires new algorithmic insights or the revival of algorithms that were once dismissed as impractical (due to their serial performance) as well as significant software engineering [16, 18].

### Stochastic Decomposition

In addition to deep insights and understanding of the enterprise, a unified approach that addresses both data and computational dimensions of massive-scale analytics will provide an organization with predictive modeling, scenario analysis, and decision-making capabilities. This involves the stochastic analysis and optimization of an underlying mathematical representation of such predictive models and decision processes. The multidimensional aspects of these underlying stochastic processes are a major source of complexity, often involving various dependencies and dynamic interactions among the different dimensions of the multidimensional process. Hence, the stochastic analysis and optimization of predictive models and decision processes in a scalable manner as part of massive-scale analytics will often need to leverage a number of additional mathematical and computational methodologies. This includes Monte Carlo methods, a class of computational algorithms based on the use of repeated probabilistic sampling to compute the results of interest; the reader is referred to the entry on Monte Carlo methods for further details. Another related general methodology is based on stochastic decomposition, which essentially consists of decomposing the complex multidimensional stochastic process into a combination of various forms of simpler processes with reduced dimensionality. All of the mathematical and computational methodologies that support stochastic analysis and optimization

for massive-scale analytics can also provide benefits to and exploit benefits from the areas covered in sections ▶Data Dimension and ▶Computational Dimension.

### Nearly Completely Decomposable Systems

One general class of stochastic decomposition approaches is based on the theory of nearly completely decomposable stochastic systems. Consider a discrete-time Markov process with transition probability matrix such that block submatrices along the main diagonal consist of relatively large probability mass, while the elements of the remaining block submatrices are very small in comparison. Stochastic matrices of this type are called nearly completely decomposable [9], in which case the transition probability matrix can be written in a form comprised of stochastic and completely decomposable micro (conditional) models and stochastic macro (unconditioning) models. When the system size is very large, computing the stationary distribution (as well as functionals of the stationary distribution) directly from the transition probability matrix can be prohibitively expensive in both time and space. On the other hand, the overall solution for nearly completely decomposable stochastic matrices can be efficiently computed based on extensions of the Simon-Ando approximations for the stationary distribution of the corresponding Markov process. As a specific example, Aven, Coffman, and Kogan [2] consider model instances where the functional of the stationary distribution represents the stationary page fault probability for a stochastic computer program model and a finite storage capacity. A solution for instances of such computer storage models arising in parallel computing environments, where standard nearly completely decomposable methods breakdown and yield improper solutions, is derived by Peris et al. [26] and Squillante [28] based on first passage times, recurrence times, taboo probabilities and first entrance methods.

### Fixed-Point Based Solutions

Another general class of stochastic decomposition approaches is based on models of each dimension of the multidimensional process in isolation together with a

set of fixed-point equations to capture the dependencies and dynamic interactions among the multiple dimensions. One of the most well-known examples of this general approach is the Erlang fixed-point approximation developed to address the computational complexity of the exact product-form solution for the classical Erlang loss model. This approximate solution is based on a stochastic decomposition in which the multidimensional exact solution is replaced by a system of nonlinear equations in terms of an exact solution for each dimension in isolation. It is well known that there exists a solution of the Erlang fixed-point equations and that this solution converges to the exact solution of the original Erlang loss model in the limit as the number of dimensions grow large under a certain type of scaling; refer to, e.g., Kelly [22]. The corresponding capacity planning problem to optimize an objective function of the stationary loss probabilities and capacities has also been considered within this context by Kelly [22]. The asymptotic exactness of the Erlang fixed-point approximation and optimization based on this approximation is an important aspect of this general decomposition approach for the analysis and optimization of complex multidimensional stochastic processes.

M

### Exploiting Priority Structural Properties

Yet another general class of stochastic decomposition approaches is based on exploiting various priority structural properties to reduce the dimensionality of the stochastic process in a recursive manner. Although this general approach was originally developed for single-server queueing systems with multiple queues under a priority scheduling discipline (see, e.g., [14, 21]), it has been extended and generalized in many different ways for the stochastic analysis and optimization of multidimensional stochastic systems. The basic idea consists of a recursive mathematical procedure starting with the two highest priority dimensions of the process that involves: (a) analyzing the probabilistic behavior of the so-called completion-time process, which characterizes the intervals between consecutive points of interaction between the starts of busy periods for the lower priority dimension; (b) obtaining the distributional characteristics of related busy-period processes through an analysis of associated stochastic processes and modified dimensional probability distributions in isolation; and

(c) determining the solution of the two-dimensional priority process from a combination of these results. These steps are repeated to obtain the solution for the  $(n+1)$ -dimensional priority process using the results for the  $n$ -dimensional priority process, until reaching the final solution for the original multidimensional stochastic process. Several related extensions of this general approach have been developed for the stochastic analysis and optimization of various parallel computing environments. These approaches generally exploit distinct priority structures in the underlying multidimensional stochastic process together with the probabilistic behavior of dependence structures and dynamics resulting from the complex massively parallel computing environment; for one such example, refer to [30].

## Maude

JOSÉ MESEGUER

University of Illinois at Urbana-Champaign, Urbana, IL, USA

### Synonyms

Rewriting logic

### Definition

Maude [4, 5] is a declarative language whose modules are theories in rewriting logic [13], and whose computation is logical deduction by concurrent rewriting modulo the equational structural axioms of each theory. Since virtually all models of concurrent computation can be naturally and easily expressed as rewrite theories [12–14], Maude and its tool environment can be used both as a parallel language, and as a flexible *semantic framework* to define, execute, formally analyze, and implement other parallel languages.

### Discussion

#### Rewriting Logic and Maude in a Nutshell

Many different models of concurrency have been proposed and used: Petri nets, parallel functional programming, Actors, the  $\pi$ -calculus and other process calculi, and so on. Rewriting logic [13] is not just one more model of concurrency. It is instead a *logical framework* for concurrency in which different models and different parallel languages can be formally specified, executed, and analyzed as *rewrite theories*. This can be done without imposing a *representational bias* that favors some specific concurrency model, and without complex *encodings* that distort and obscure the specific features of each model.

The reasons why this natural expression of different concurrency models within rewriting logic is possible are essentially twofold, namely, the ease and generality with which: (1) different kinds of *distributed states* and (2) different kinds of *local concurrent transitions* can be specified. A *rewrite theory*  $(\Sigma, E, R)$  consists of an equational theory  $(\Sigma, E)$  and a set of rewrite rules  $R$ , and specifies a concurrent system. The distributed states of such a system are specified by the equational theory

## Matrix Computations

► Linear Algebra, Numerical

$(\Sigma, E)$ , where  $\Sigma$  is a collection of typed operators which includes the *state constructors* that build up a distributed state out of simpler state components, and where  $E$  specifies the algebraic identities that such distributed states enjoy. That is, the distributed states are specified as an *algebraic data type* defined as the initial algebra semantics (see, e.g., [15]) of the equational theory  $(\Sigma, E)$ . Concretely, this means that a distributed state is mathematically represented as an  $E$ -equivalence class  $[t]_E$  of terms (i.e., algebraic expressions) built up with the operators declared in  $\Sigma$ , *modulo* provable equality using the equations  $E$ , so that two state representations  $t$  and  $t'$  describe the *same* state if and only if one can prove the equality  $t = t'$  using the equations  $E$ . Instead, the *local concurrent transitions* of the concurrent system specified by  $(\Sigma, E, R)$  are described by its set  $R$  of *rewrite rules*. Each rewrite rule in  $R$  has the form  $t \rightarrow t'$ , where  $t$  and  $t'$  are algebraic expressions in the syntax of  $\Sigma$ . The lefthand side  $t$  describes a *local firing pattern*, and the righthand side  $t'$  describes a corresponding *replacement pattern*. That is, any fragment of a distributed state which is an instance of the firing pattern  $t$  can perform a local concurrent transition in which it is replaced by the corresponding instance of the replacement pattern  $t'$ . Both  $t$  and  $t'$  are typically *parametric* patterns, describing not single states, but parametric families of states. The parameters appearing in  $t$  and  $t'$  are precisely the *mathematical variables* that  $t$  and  $t'$  have, which can be instantiated to different concrete expressions by a mapping  $\theta$ , called a *substitution*, sending each variable  $x$  to a term  $\theta(x)$ . The instance of  $t$  by  $\theta$  is then denoted  $\theta(t)$ .

The most basic *logical deduction steps* in a rewrite theory  $(\Sigma, E, R)$  are precisely atomic concurrent transitions, called *atomic rewrites*, corresponding to applying a rewrite rule  $t \rightarrow t'$  in  $R$  to a state fragment that is an instance of the firing pattern  $t$  by some substitution  $\theta$ . That is, up to  $E$ -equivalence, the state is of the form  $C[\theta(t)]$ , where  $C$  is the rest of the state not affected by this atomic transition. Then the resulting state is precisely  $C[\theta(t')]$ , so that the atomic transition has the form  $C[\theta(t)] \rightarrow C[\theta(t')]$ . Rewriting is *intrinsically concurrent*, because many other atomic rewrites can potentially take place in the rest of the state  $C$  (and in the substitution  $\theta$ ), at the same time that the local atomic transition  $\theta(t) \rightarrow \theta(t')$  happens. That is, in general one may have complex concurrent transitions of the form  $C[\theta(t)] \rightarrow C'[\theta'(t')]$ , where the rest of the state  $C$  has evolved to  $C'$  and the substitution  $\theta$  has evolved to  $\theta'$

by other (possibly many) atomic rewrites simultaneous with the atomic rewrite  $\theta(t) \rightarrow \theta(t')$ . The rules of deduction of rewriting logic [2, 13] (which in general allow rules in  $R$  to be *conditional*) precisely describe all the possible, complex concurrent transitions that a system can perform, so that concurrent computation and logical deduction *coincide*.

Maude [4, 5] is a language and system implementation directly based on rewriting logic so that: (1) a Maude Module is exactly a rewrite theory  $(\Sigma, E, R)$  satisfying some simple executability conditions that make it easy to compute with the rules  $R$  modulo the equations  $E$  (see [5] for details) and (2) computation in Maude is logical deduction by rewriting.

*A Simple Example.* All the ideas discussed above can be illustrated by means of a simple example of a concurrent object-based system specified in Maude. Maude's syntax is user-definable; therefore, all state-building operators can be declared by the user with any desired “mixfix” syntax. A concurrent state made up of objects and messages can be thought of as a “soup” in which objects and messages are freely floating and can come into contact with each other in communication events. Mathematically, this means that the concurrent state, called a *configuration*, is modeled as a *multiset* or *bag* built up by a multiset union operator which satisfies the axioms of *associativity* and *commutativity*, with the empty multiset as its *identity element*. In Maude one can, for example, choose to express multiset union with *empty syntax*, that is, just by *juxtaposition*. One can achieve this by declaring the type (called a *sort*) Configuration of configurations, which contains the sorts Object and Msg as *subsorts*, and the empty configuration, say none, and the configuration union operator by the declarations:

```
sorts Object Msg Configuration .
subsorts Object Msg < Configuration .
op none : -> Configuration [ctor] .
op _ _ : Configuration Configuration ->
Configuration
[ctor config assoc comm id: none] .
```

Each operator is declared with the *op* keyword, followed by its syntax, the list of its argument sorts, an arrow  $->$ , and its result sort. And all declarations are finished by a space and a period. In the case of the configuration union operator, there are two argument positions, which are marked by underbars. Before and/or after such underbars, any desired syntax

tokens can be declared. In this case an empty syntax (juxtaposition) has been chosen, so that no tokens at all are declared. If, instead, one wanted to describe configurations as comma-separated collections of objects and messages, one could give the alternative syntax declaration:

```
op _,_ : Configuration Configuration ->
 Configuration
 [ctor config assoc comm id: none] .
```

Note that constants like `none` are viewed as *operators with no arguments*. The keyword `config` declares that this is a union operator for configurations of objects and messages. This allows Maude to execute such configurations with an object and message fair strategy, so that all objects having messages addressed to them do eventually process such messages. The `assoc comm id: none` declarations declare the associativity axiom  $(x y) z = x (y z)$ , the commutativity axiom  $x y = y x$ , and the identity axiom  $x \text{ none} = x$ . Maude then supports rewriting *modulo* such axioms, so that a rule can be applied to a configuration regardless of parentheses, and regardless of the order of arguments. The `ctor` keyword declares that both `none` and `_ _` are state-building *constructors*, as opposed to functions defined on constructors such as, for example, a cardinality function, say `|_|`, that counts the total number of objects and messages present in a configuration, and which could be defined with the following syntax and equations:

```
op |_| : Configuration -> Nat .
var O : Object . var M : Msg . var C :
 Configuration .
eq | none | = 0 .
eq | O C | = 1 + | C | .
eq | M C | = 1 + | C | .
```

where `Nat` is the sort of natural numbers in the `NAT` module. Note that the above equations are applied by Maude modulo the associativity, commutativity, and identity axioms for `_ _`. For example, by instantiating `C` to `none`, the second equation defines the cardinality of a single object `O` to be  $1 + | \text{none} | = 1$ .

Consider an object-based system containing three classes of objects, namely, `Buffer`, `Sender`, and `Receiver` objects, so that a sender object sends to the corresponding receiver a sequence of values (say natural numbers) which it reads from its own buffer, while the receiver stores the values it gets from the sender in its

own buffer. In Maude's Full Maude language extension (see Part II of [5]), such object classes can be declared as subsorts of the `Object` sort in *class declarations*, which specify the names and sorts of the *attributes* of objects in the class. The above three classes can be defined with class declarations:

```
class Buffer | q : NatList, owner : Oid .
class Sender | cell : Nat?, cnt : Nat,
 receiver : Oid .
class Receiver | cell : Nat?, cnt : Nat .
```

An object of a class `C1` declared with attributes `a1` of sort `A1`, ..., `an` of sort `An`, is a record-like structure of the form:

```
< oid : C1 | a1 : v1, ... , an : vn >
```

where each `vi` is a term of sort `Ai`. For example, assuming that one uses quoted identifiers as object identifiers (by importing the `QID` module and giving the subsort declaration `Qid < Oid`), and that the supersort `Nat?` of `Nat` containing an empty value `mt`, and the sort `NatList` of lists of natural numbers have been declared as:

```
sorts Nat? NatList .
subsorts Nat < Nat? NatList .
op mt : -> Nat? [ctor] .
op nil : -> NatList [ctor] .
op _,_ : NatList NatList ->
 NatList [ctor assoc id: nil] .
```

then the following is an initial configuration of a sender and a receiver object, each with their own buffer, and each with their cell currently empty:

```
< 'a : Buffer | q : 1 . 2 . 3 , owner : 'b >
< 'b : Sender | cell : mt , cnt : 0 ,
 receiver : 'd >
< 'c : Buffer | q : nil , owner : 'd >
< 'd : Receiver | cell : mt , cnt : 1 >
```

A sender object can send messages to its corresponding receiver object. The programmer has complete freedom to define the format of such messages by declaring an operator of sort `Msg`, using the `msg` keyword instead of the more general `op` keyword to emphasize that the resulting terms are messages. For example, one can choose the following format:

```
msg to_:_from_cnt_ : Oid Nat Oid Nat -> Msg.
```

where a message, say, `to 'd' : 3 from 'b' cnt 1`, means that '`b`' sends to '`d`' the data item 3, with counter 1,

indicating that this is the *first* element transmitted. This last information is important, since message passing in a configuration is usually asynchronous, so that messages could be received out of order. Therefore, receiver objects need to use the counter information to properly reassemble a list of transmitted data. Of course, out-of-order communication is just *one* possible situation that can be modeled. If, instead, one wanted to model in-order communication, the distributed state could contain *channels*, similar for example to the buffer objects, so that axioms of associativity and identity are satisfied when inserting messages into a channel, but *not commutativity*, which is the axiom allowing out-of-order communication in an asynchronous configuration of objects and messages. All that has been done up to now is to define the *distributed states* of this object-based system as the algebraic data type associated to an equational theory, namely, the equational theory  $(\Sigma, E)$ , where  $\Sigma$  is the signature whose sorts have been declared with the `sort` (and `class`) keywords, with subsort relations declared with the `subsort` keyword, and whose operators have been declared with the `op` (or `msg`) keywords. And where the equations  $E$  have been declared in one of two ways: (1) either as explicit equations, specified with the `eq` keyword, or as (2) *equational axioms* of associativity and/or commutativity and/or identity associated to specific operators, declared with the `assoc`, `comm` and `id:` keywords.

What about the concurrent *transitions* for buffers, senders, and receivers? As already mentioned, they are specified by a set  $R$  of rewrite rules which describe the local concurrent transitions possible in the system. One can, for example, define such transitions by the following four rewrite rules (note that object attributes not changed by a rule need not be mentioned in it):

```

vars X Y Z : Oid . vars N E : Nat .
vars L L' : NatList .

rl [read] : < X : Buffer | q : L . E ,
owner : Y > < Y : Sender | cell : mt,
cnt : N >
=> < X : Buffer | q : L, owner : Y >
< Y : Sender | cell : E, cnt : N + 1 > .

rl [write] : < X : Buffer | q : L , owner :
Y > < Y : Receiver | cell : E >
=> < X : Buffer | q : E . L , owner : Y >
< Y : Receiver | cell : mt > .

```

```

rl [send] : < Y : Sender | cell : E , cnt :
N , receiver : Z >
=> < Y : Sender | cell : mt, cnt : N >
(to Z :: E from Y cnt N) .

rl [receive] : < Z : Receiver | cell : mt ,
cnt : N > (to Z :: E from Y cnt N)
=> < Z : Receiver | cell : E , cnt :
N + 1 > .

```

That is, senders can read data from the buffer they own and update their count; and receivers can write their received data in their own buffer. Also, each time a sender has a data element in its cell, it can send it to its corresponding receiver with the appropriate count; and a receiver with an empty cell can receive a data item from its sender, provided it has the correct counter. Note that rewriting is intrinsically concurrent; for example, '`b`' could be sending the next data item to '`d`' at the same time that '`d`' is receiving the previous data item or is writing it into its own buffer. Note also that the rules `send` and `receive` describe the *asynchronous message passing* communication between senders and receivers typical of the Actor model [1]. Instead, the `read` and `write` rewrite rules describe *synchronization events*, in which a buffer and its owner object synchronously transfer data between each other. This illustrates the flexibility of rewriting logic as a semantic framework: No assumption of either synchrony or asynchrony is built into the logic. Instead, many different styles of concurrency and of in-order or out-of-order communication can be directly modeled without any difficulty.

The behavior of the above system can be simulated by means of Maude's `rewrite` (abbreviated `rew`) command. For example, one can see the result of a terminating execution of the initial configuration described above by giving to Full Maude the following command:

```

Maude> (rew < 'a : Buffer | q : 1 . 2 . 3 ,
owner : 'b >
< 'b : Sender | cell : mt , cnt : 0 ,
receiver : 'd > < 'c : Buffer | q :
nil , owner : 'd >
< 'd : Receiver | cell : mt , cnt : 1 > .)
result Configuration :
< 'a : Buffer | owner : 'b,q : nil >
< 'b : Sender | cell : mt,cnt :
3,receiver : 'd >
< 'c : Buffer | owner : 'd,q :(1 . 2 . 3)>
< 'd : Receiver | cell : mt,cnt : 4 >

```

Since a concurrent system can be non-terminating, a `rewrite` command may never terminate; for this reason, the `rewrite` command can be given an extra numerical parameter, indicating the maximum number of rewrite steps that should be simulated. Furthermore, a concurrent system can often be highly non-deterministic, so that the result of a `rewrite` command provides just *one* fair simulation of the system among possibly many others. Instead, functions defined by *equations* with the `eq` keyword (as opposed to the concurrent transitions defined by *rules* with the `r1` keyword) should have a single final result. The evaluation of functional expressions to their unique final result using the module's equations from left to right is supported by a different command, namely, the `reduce` (abbreviated `red`) command. For example, one can compute the cardinality of the above initial configuration by giving to Full Maude the command:

```
Maude> (red | < 'a : Buffer | q : 1 . 2 . 3 ,
 owner : 'b >
< 'b : Sender | cell : mt , cnt : 0 ,
 receiver : 'd > < 'c : Buffer | q : nil ,
 owner : 'd >
< 'd : Receiver | cell : mt , cnt : 1 > | ..)

result NzNat :
 4
```

Simulating a system with the `rewrite` command is useful but insufficient. One would like, for example, to verify that for *all* behaviors some undesired situation (for example a deadlock) does not happen; or one might like to find what different states of a certain kind (final states, or states satisfying a certain pattern and/or condition) can be reached from a given initial state. This can be achieved by using Maude's `search` command, which performs breadth-first search from an initial state looking for states specified by a *pattern* (a constructor term with variables, so that the desired states are instances of it), and possibly by an additional semantic condition specified with the `such that` keyword. For example, one may wish to check the invariant that all states reachable from our initial configuration exhibit *in-order reception* of the list `1 . 2 . 3` of numbers initially stored in the sender's buffer; that is, that any list stored in the receiver's buffer is always a *postfix* of the list `1 . 2 . 3`. This can be done by first equationally defining a `postfix` predicate on pairs of lists as follows:

```
op postfix : NatList NatList -> Bool .
eq postfix(L,L' . L) = true .
eq postfix(L,L') = false [owise] .
```

where an equation declared with the “otherwise” (`owise`) keyword abbreviates a conditional equation that is applied only when all other equations defining the same function cannot be applied (see Sect. 4.5.4 of [5]). One can then give the following `search` command to Full Maude to verify the desired invariant by searching for a state violating such an invariant (note Maude's support for on-the-fly introduction of mathematical variables by appending to a variable's name a colon and the sort of the variable, as done below for `C:Configuration` and `L:NatList`):

```
Maude> (search < 'a : Buffer | q : 1 . 2 . 3 ,
 owner : 'b >
< 'b : Sender | cell : mt , cnt : 0 ,
 receiver : 'd > < 'c : Buffer | q : nil ,
 owner : 'd >
< 'd : Receiver | cell : mt , cnt : 1 >
=>* C:Configuration < 'c : Buffer | q :
L:NatList , owner : 'd > such that
postfix(L:NatList,1 . 2 . 3) = false .)
```

No solution.

In this example, the number of reachable states from the initial configuration is finite, so that the `search` command can exhaustively search all reachable states. However, the `search` command can be given even when the number of reachable states is infinite. It will then return all the states it finds satisfying the given pattern and semantic condition. In particular, if one searches for the violation of an invariant and the invariant is indeed violated, it will find such a violation in finite time.

Besides the possibility of using the `search` command for verifying invariants, whenever the set of states reachable from an initial state is finite, Maude also provides the possibility of *model checking* any desired linear-time logic (LTL) formula. This can be easily done by equationally defining the desired state predicates used as atomic propositions in the given LTL formula, importing Maude's `MODEL-CHECKER` module, and then giving a command to model check the desired formula from the given initial state. For example, for the above initial configuration one may wish to model check the liveness property that all system behaviors eventually terminate with the sender's buffer empty, the sender's and receiver's cells empty, and the receiver's buffer containing the list originally stored in the sender's

buffer. A detailed description of Maude’s LTL model checking capabilities can be found in Chap. 13 of [5].

## Rewriting Logic Semantics of Programming Languages

The flexibility of rewriting logic to naturally express many different models of concurrency can be exploited not just at the theoretical level, for expressing such models both deductively, and denotationally in the model theory of rewriting logic [13, 14]: It can also be applied to give *formal definitions of concurrent programming languages* by specifying the concurrent model of a language  $\mathcal{L}$  as a rewrite theory  $(\Sigma_{\mathcal{L}}, E_{\mathcal{L}}, R_{\mathcal{L}})$ , where: (1) the signature  $\Sigma_{\mathcal{L}}$  specifies both the syntax of  $\mathcal{L}$  and the types and operators needed to specify semantic entities such as the store, the environment, input-output, and so on; (2) the equations  $E_{\mathcal{L}}$  can be used to give semantic definitions for the *deterministic* features of  $\mathcal{L}$  (a sequential language typically has only deterministic features and can be specified just equationally as  $(\Sigma_{\mathcal{L}}, E_{\mathcal{L}})$ ); and (3) the rewrite rules  $R_{\mathcal{L}}$  are used to give semantic definitions for the concurrent features of  $\mathcal{L}$  such as, for example, the semantics of threads. By specifying the rewrite theory  $(\Sigma_{\mathcal{L}}, E_{\mathcal{L}}, R_{\mathcal{L}})$  as a Maude module, it becomes not just a mathematical definition but an *executable* one, that is, an *interpreter* for  $\mathcal{L}$ . Furthermore, one can leverage Maude’s generic search and LTL model checking features to automatically endow  $\mathcal{L}$  with powerful *program analysis capabilities*. For example, the search command can be used in the module  $(\Sigma_{\mathcal{L}}, E_{\mathcal{L}}, R_{\mathcal{L}})$  to detect any violations of invariants, e.g., a deadlock or some other undesired state, of a program in  $\mathcal{L}$ . Likewise, for terminating concurrent programs in  $\mathcal{L}$  one can model check any desired LTL property. All this can be effectively done not just for toy languages, but for real ones such as Java and the JVM, and with performance that compares favorably with state-of-the-art tools such as Java PathFinder [10, 11]. There are essentially three reasons for this surprisingly good performance. First, rewriting logic’s distinction between equations  $E_{\mathcal{L}}$ , used to give semantics to deterministic features of  $\mathcal{L}$ , and rules  $R_{\mathcal{L}}$ , used to specify the semantics of concurrent features, provides in practice an enormous *state space reduction*. Note that a state of  $(\Sigma_{\mathcal{L}}, E_{\mathcal{L}}, R_{\mathcal{L}})$  is, by definition, an  $E_{\mathcal{L}}$ -equivalence class  $[t]_{E_{\mathcal{L}}}$ , which in practice is represented as the state of the program’s execution after all deterministic execution steps possible at a given

stage have been taken. That is, the equations  $E_{\mathcal{L}}$  have the effect of “fast forwarding” such an execution by skipping all intermediate deterministic steps until the next truly concurrent interaction is reached. For example, for  $\mathcal{L} = \text{Java}$ ,  $E_{\text{Java}}$  has hundreds of equations, but  $R_{\text{Java}}$  has just 5 rules. The second reason is of course that the underlying Maude implementation is a high-performance one that can reach millions of rewrite steps per second. The third reason is that the intrinsic flexibility of rewriting logic means that it does not prescribe a fixed style for giving semantic definitions. Instead, *many different styles*, for example, small-step or big-step semantics, reduction semantics, CHAM-style semantics, or continuation semantics, can all be naturally supported [20]. But not all styles are equally efficient; for example, small-step semantics makes heavy use of conditional rewrite rules, insists on modeling every single computation step as a rule in  $R_{\mathcal{L}}$ , and is in practice horribly inefficient. Instead, the continuation semantics style described in [20] and used in [10] is very efficient.

The good theoretical and practical advantages of using rewriting logic to give semantic definitions to programming languages have stimulated an international research effort called the *rewriting logic semantics project* (see [16, 17, 20] for some overview papers). Not only have semantic definitions allowing effective program analyses been given for many real languages such as Java, the JVM, Scheme, and C, for hardware description languages such as ABEL and Verilog, and for software modeling languages such as MOF, Ptolemy and AADL: It has also been possible to build a host of sophisticated program analysis tools for real languages based on different kinds of *abstract semantics*. The point is that instead of a “concrete semantics”  $(\Sigma_{\mathcal{L}}, E_{\mathcal{L}}, R_{\mathcal{L}})$ , describing the actual execution of programs in a language  $\mathcal{L}$ , one can just as easily define an “abstract semantics”  $(\Sigma_{\mathcal{L}}^A, E_{\mathcal{L}}^A, R_{\mathcal{L}}^A)$  describing any desired abstraction  $A$  of  $\mathcal{L}$ . To give just two examples, one can give an abstract semantics for type checking by replacing operations on concrete values by operations on their corresponding types [9]; and one can likewise give an abstract semantics to scientific programs by operating not on their numerical values, but on their intended *units of measurement* [3]. All this means that many different forms of program analysis, much more scalable than the kind of search and model checking based on a language’s concrete semantics,

become available essentially for free by using Maude to execute and analyze one's desired abstract semantics  $(\Sigma_L^A, E_L^A, R_L^A)$ .

Two further developments of the rewriting logic semantics project, both pioneered by Grigore Roșu with several collaborators, are worth mentioning. One is the K *semantic framework* for programming language definitions [19], which provides a very concise and highly modular notation for such definitions. The K-Maude tool then automatically translates language definitions in K into their corresponding rewrite theories in Maude for execution and program analysis purposes. Another is *matching logic* [18], a program verification logic with substantial advantages over both Hoare logic and separation logic which uses a language's rewriting logic semantics, including the possibility of using patterns to symbolically characterize sets of states, to mechanize the formal verification of programs, including programs that manipulate complex data structures using pointers.

## Maude's Implementation and Formal Environment

Maude is implemented in C++ as a high-performance semi-compiled interpreter. Both equations and rules are (semi-)compiled into matching and replacement automata [7, 8]. This makes it possible to *trace* every single step of rewriting with both equations and rules. In the sequential Maude implementation, the execution of concurrent systems is *simulated* by the `rewrite` or `frewrite` commands, which each apply a module's rules with a specific fair strategy [5]. However, because of its built-in support for sockets (see Sect. 11.4 in [5]), Maude is also a *parallel language*, which can be used to program in a declarative, high-level way interesting distributed applications, for example, mobile languages (see Chap. 16 of [5]). Using sockets, a concurrent configuration of objects and messages, which at the sequential level would be represented by a single multiset data structure, can now be distributed and executed over several machines, where each machine holds its own *local configuration* of objects and messages as a multiset, and rewrites it sequentially in a fair way. Objects in a local configuration can send messages not only to other objects in the same local configuration, but to remote objects in other machines using sockets. The fact that the rewriting of objects and messages is automatically fair for each object means that

*no explicit scheduling is needed*; that is, by the intrinsic fairness with which rewriting of objects and messages is implemented, all objects in the different local configurations always get to process the messages sent to them either from other objects in the same local configuration or from remote objects. An upcoming next generation of Maude, currently under development at SRI International and the University of Illinois, will add to the present capabilities of Maude for distributed computing the additional ability of exploiting the finer parallelism provided by multicore machines. This means that the local configurations of objects and messages running in each multicore machine will themselves also be executed concurrently, with different objects in the same local configuration executing on different cores.

Besides the search and LTL model checking features directly supported by the Maude implementation, which allow reachability analysis and LTL formal verification of Maude programs, Maude also has a *formal environment* of tools supporting other types of formal verification, including: (1) inductive theorem proving for equational theories (called *functional modules* in Maude) using its ITP tool; (2) proofs of termination using its MTT tool; (3) proofs of local confluence for equations with its CRC tool (which ensure that functional evaluations with equations using the `reduce` command are deterministic), and of coherence of rules with respect to equations with its ChC tool (which ensure that execution of equations and of rules "commutes" in an appropriate sense); (4) proofs of *sufficient completeness* in its SCC tool, ensuring that enough equations have been given to fully define each non-constructor function symbol; and (5) execution and model checking analysis of real-time systems with its Real-Time Maude tool. A common feature of all these tools (and also of the Full Maude language extension, see Part II of [5]) is their systematic use of *reflection* to manipulate the Maude modules that they analyze as terms within rewriting logic itself. This powerful form of logical reflection is based on the fact that rewriting logic and equational logic are both reflective logics [6], and is efficiently supported by Maude's META-LEVEL module (see Chaps. 14–15 of [5]). Besides the formal tools used to analyze Maude modules, Maude can likewise be used to build domain-specific tools for specific languages or logical systems, including the already-mentioned tools for programming languages.

Some of these other tools, as well as the Maude formal tools, are discussed in Chap. 21 of [5]. Maude itself, its documentation, and its formal tools are all freely available at [maude.cs.uiuc.edu](http://maude.cs.uiuc.edu).

## Definition

Meiko was a UK-based parallel computer company that was founded in 1985 by six employees of Inmos. It

grew to a peak of 150 employees based in Bristol and Boston Massachusetts. It ceased to trade in 1996; shortly afterward, some of the communications technology and a small engineering team were transferred to Quadrics.

## Discussion

Meiko machines were all distributed memory clusters. There were three distinct machine generations during the 10 years of Meiko's life: Transputer systems, hybrids that used Transputers for communication and an Intel i860 or SPARC processor, and, finally, SPARC systems in which the Transputers had been replaced by Meiko designed communications ASICs.

At the time of their construction, the takeover of high performance computing by cluster machines had yet to take place, the fastest machines at the time being vector supercomputers from Cray and Japanese vendors. Meiko machines contributed to the demonstration that it was possible to use cluster machines with no shared memory for high performance computing.

## Customers

Meiko had over 400 different customers, some of the more important are mentioned here.

## HPC Users

Major users of Meiko machines for high performance scientific computing included

- CERN who used the machines in the NA48 experiment data recording (a project continued by Quadrics)
- Edinburgh Parallel Computer Centre who used the machines for general scientific supercomputing, and QCD calculations
- Hewlett Packard printer division who used the machines for simulation of inkjet printer heads
- Lawrence Livermore National Laboratory who used the machines in the stockpile stewardship program
- Southampton University who used the machines in the EECS department
- Toyota who used the machines for producing photo-realistic, ray traced images of cars from design data

Many other customers in Europe also used the machines, some of which were funded as part of

the EEC's Esprit program, the GPMIMD project in particular.

## Transputer-Based Machines

Meiko's first-generation machines, known as "The Computing Surface," were based on the Inmos T414 Transputer. Early systems consisted of up to 160 32-bit integer processors connected by 20MBit/s serial links. They were programmed in Occam. With the 1987 introduction of the Inmos T800 Transputer, which had an integrated FPU, floating point performance increased to 2MFlops per CPU, 320 MFlops for the system as a whole. Customers wanted to be able to program these machines in conventional programming languages, so that existing codes could be more easily ported to the machine. Recognizing this, Meiko produced Fortran 77 and C compilers for the Transputer. In these languages, communication was achieved by calls to message passing libraries that mapped directly onto the underlying Transputer hardware channel communication instructions.

These early machines were normally connected to a host (a DEC micro-VAX, or Sun server), which booted the user program directly into the Computing Surface, and provided I/O. These machines were therefore really attached compute servers, rather than stand-alone computers.

In the initial T414 machines, the topology of the Transputer link network was set by plugging wires in the back of the machine. Later machines used a Meiko designed ASIC to allow the link configuration and hence the network topology to be changed between jobs. The topology of the machine was, however, fixed for the duration of a single job – Inmos added adaptive routing support to later generations of product. Since Transputers had no memory protection, or operating system, multitasking was achieved by physically partitioning the machine and running separate jobs on separate processors.

## Hybrid Machines

When Intel released the i860 (80860) processor in 1989, Meiko built boards that used these in conjunction with Transputers. The main program executed on the i860, with communication handled by the Transputers. While the peak performance of the system was high (60-80 MFlops per processor) achieving this proved

difficult, with some hand coded assembler routines achieving 30–40 MFlops but most compiled code getting less than 10.

Meiko also produced SPARC boards with Transputer communications. These were normally used to replace an external host machine, running SunOS (and later Solaris). These boards could all be used in machines with Transputers as nodes, providing a simple upgrade path for existing customers.

Inmos' follow up Transputer design, the T9000, was not a success and Meiko switched to designing its own interconnect for use with conventional microprocessors.

### Sun SPARC-Based Machines

In 1993, Meiko introduced the “Computing Surface 2” (CS-2) machines. These were based on 40 MHz SPARC processors with Meiko's own interconnect, using two custom ASICs, the Elan network interface and the Elite switch. The CS-2 system had an asymptotic bandwidth of 42 MBytes per second per link, a put latency of 10 µs and a message passing latency of 80 µs.

The communication network used by the CS-2 was built from Elite switches, each of which was a sixteen-way full crossbar. Since the links were unidirectional, these provided an eight-way bidirectional crossbar. The network was source routed, with each NIC being able to select at random (or in round robin order) from a table of four possible routes to each destination. Packets in the network were routed by byte-stripping, each Elite stripping the first byte from the incoming message and using that to determine the outgoing route. The Elite chip also included the ability to broadcast an incoming message to a contiguous range of outgoing links, and to combine acknowledgments from a range of links into a single message.

In the CS-2 machine, the Elite switches were connected in a full fat-tree configuration to provide a scalable interconnect with linear increase in bisectional bandwidth and logarithmic increase in latency as the machine size increased.

In addition to the SPARC boards, Meiko produced a board using a SPARC processor and a pair of Fujitsu vector processors. The node had a double precision peak performance of 100 MFlop with 128 MBytes of

memory and 1.2 GB/s of memory bandwidth per vector unit (three words per flop!) and an additional 800 MB/s port shared by the SPARC and the Elan. The high peak performance was attractive (particularly to LLNL, the first customer) but the node design complicated the programming model – a new vectorizing compiler was developed by The Portland Group. In the initial design, the vector processors were not cache coherent with the SPARCs, despite sharing memory with them. This made programming hard, or forced the SPARC processor to execute with most of the memory marked as uncachable. Of course, this slowed the non-vectorizable portions of the code, making overall performance poor. (A simple application of Amdahl's Law with a slowdown applied to the non-vectorized component shows that if the slowdown is  $S$ , even with an infinitely fast vector system a proportion  $(1 - 1/S)$  of the program must vectorize to achieve parity with the scalar system; for a slowdown of  $10\times$  this leads to a requirement that more than 90% of the computation vectorizes). Later versions implemented cache coherence, but the complexity of the logic and PCB manufacture required made the design uneconomic. Meiko had a competing board design that used four SPARC CPUs. It was lower cost, much easier to program and generally sustained higher performance, but it lacked the high floating point peak and only sold to a small number of customers.

The CS-2 system pictured comprised 24 modules each with four boards. It was typically configured with either 64 vector or 256 scalar nodes together with I/O card and switching. The largest system shipped (to LLNL) consisted of five such racks with a total of 224, mostly vector, nodes.

A fourth-generation system based on SPARC processors and a new network was under development in 1995 when the company ran out of money. Significant elements of this design were used in QsNet, although Quadrics moved away from the SPARC/MBUS design to the recently standardized PCI host interface. Ever since then, network adapters for HPC systems have been on “wrong side” of a commodity host interface with reduced bandwidth and increased latency as a consequence.

M

## Uses Outside High Performance Computing

Meiko worked with Oracle to port their database (Oracle 7 Parallel Server) to the CS-2, and a number of database server machines were sold late in the life of the company. These systems were used on early data warehousing applications by UK retailers including WH Smiths and Bass Taverns. Sales data was transferred from the company mainframe overnight enabling marketing users to develop and test complex decision support queries on recent data. Other users ran a mix of online transaction processing (OLTP) and decision support on their CS-2 systems. Meiko was unable to capitalize on this product – customers for database systems of its class were not generally willing to buy them from a small UK company.

## Influence

The experience of the Meiko designs has spread widely. In 2009, ex-employees of Meiko are to be found at companies such as AMD, Cray, HP, Intel, and Sun. They

have influenced designs as diverse as AMD’s “HyperTransport” interconnect, current database machines, and parallel file system design. For instance, the technical lead for the Lustre parallel file system product at Sun is one of the founders of Meiko who led the parallel Oracle project 15 years earlier.

## Contributions

### Direct User Space Communication

The Meiko CS-2 machine was one of the first machine designs to implement direct, cache-coherent, secure multi-user communication from user address space to user address space with no OS intervention. Other contemporary machines like the Thinking Machines CM-5 (also based on SPARC chips with a “fat-tree” interconnect) allowed only single user use of the compute nodes, did not execute a full OS on the node, and used the CPU to transfer data.

Avoiding OS intervention on message passing is critical if low latency is to be achieved, as simply entering and leaving kernel mode is expensive. Since

most message passing codes have many small messages, achieving high compute performance requires low-latency message passing.

OS intervention is normally required in I/O operations for these reasons

- Protection: to ensure that the user is not attempting to transmit (or receive into) parts of their address space which are unmapped, or that the user is not attempting to access a device which they have no permission to access.
- Pinning: to ensure that the physical address of data which is being communicated does not change while the communication is occurring, since DMA I/O devices traditionally deal with physical addresses.
- Device Sharing: to ensure that multiple users do not incorrectly interleave access to the same physical device, all access is serialized through the OS device driver.

The Elan communications interface was designed to avoid these issues. The protection and pinning issues were avoided by giving the Elan its own set(s) of page tables, so that all requests (both local and remote) could be made in terms of user virtual addresses. The Elan could then convert these into physical addresses, or (if the page was not present), raise a local page fault to cause the OS to load the page (if it was paged out), or kill the process (if the access was invalid). The page tables in the Elan were maintained by the Solaris kernel as it modified its own page tables.

Device sharing and security were achieved by giving the Elan multiple, duplicate, copies of its control registers at different physical addresses. When a process initially requested access to the Elan, the resource manager would allocate a set of control registers to the process, and map them directly into the process' address space. It would also program the Elan so that it knew which page tables to use when it received a request through that set of control registers, and what global identifier it should use to identify incoming and outgoing messages from that process. Thus when a remote request arrived at the Elan it could match the global identifier and route it into the correct local process' address space with no OS intervention.

The Elan chip sat on the SPARC MBUS, so could participate in the cache-coherency traffic in the local node. There was therefore no requirement that data to

be transmitted be flushed to memory, or that data must be received into uncached store.

To eliminate the involvement of the CPU in processing message protocols, the Elan include its own processor (which executed a subset of the SPARC instruction set) and its own DMA engine. Using the techniques already outlined, this processor could execute code in the context of a user process, without requiring that the code be in a kernel-space device driver. Thus, each parallel job in the system could use whatever protocol it wished, the code to implement it being loaded as a normal shared library.

### **Remote Memory Access**

The fundamental communication primitive provided by the Elan was a remote memory access (put or get). This allows a less synchronized style of communication than message passing, since communication occurs when the initiator of the request requires it, it does not require any cooperation from the target. This leads to a programming style similar to that of the partitioned global address space languages today (UPC, Co-Array Fortran, Titanium), rather than a message passing style.

The message passing libraries (such as MPI) were built on top of the remote memory access, rather than building remote memory access on top of message passing, as one would do in an active message style system.

However, the model here differs from a fully shared memory system because remote memory is not available to the local processor directly through normal load and store operations. Rather accesses to remote memory must be explicitly requested from the network interface. Communication here is thus explicit, whereas in a shared memory system it is implicit in normal memory accesses.

This model fits well with the “partitioned global address space” languages, since there the compiler always knows whether a memory access is local or remote, and can generate appropriate code to fetch remote data as required.

### **Network Collective Operations**

The Elite chip was designed to support network collective operations, broadcasting packets to a contiguous range of links, combining the results and returning a single answer to the initiating process. This technique

was used to implement fast broadcast and barrier functions, without the use of a separate network as in the CM-5. The combining operation could be used, for instance, to test whether all processes had the same value at a specific virtual address, by sending a single message and receiving a single acknowledgment. The aggregation of the result occurring in the network, rather than requiring aggregation up a tree of processors, with each one combining results from those below it. The root process performed network conditionals until it received the acknowledgment that all processes had entered the barrier. It then broadcast a completion notification. These techniques were developed by Quadrics in future generations of Elite router.

## Software

### Development Tools

For the Transputer machines, Meiko implemented their own development environment, which allowed user code to configure the machine topology and then load code into it.

For the SPARC-based machines, Meiko ported the TotalView debugger at the request of LLNL, and enhanced it to interact with the resource manager of the CS-2. The SPARC systems included an early parallel filesystem implemented as a Solaris virtual filesystem.

Meiko pioneered development of C and Fortran compilers for Transputers and later HPF compilers for the SPARC systems. It supported PVM and PARMACS on the CS-2, contributed to the MPI standard, and the MPICH MPI implementation.

### Operating System

Meiko implemented kernel patches to the Solaris operating system to maintain the Elan page tables in synchrony with the kernel page tables. Quadrics continued to develop these for Linux, and their ultimate descendant was finally adopted into Linus' kernel in 2008.

## Memory Consistency Models

### ► Memory Models

## Memory Models

SARITA V. ADVE<sup>1</sup>, HANS J. BOEHM<sup>2</sup>

<sup>1</sup>University of Illinois at Urbana-Champaign, Urbana, IL, USA

<sup>2</sup>HP Labs, Palo Alto, CA, USA

### Synonyms

Fences; Memory consistency models; Memory ordering

### Definition

In the context of shared-memory systems, the memory model specifies the values that a shared-memory read in a program may return. It is part of the interface between

a shared-memory program and any hardware or software that may transform that program – it both specifies the possible behaviors of the memory accesses for the programmer and constrains the legal transformations and executions for the implementer.

For high-level language programs, the memory model describes the behavior of accesses to shared variables or heap objects, while for machine code, the memory model describes the behavior of hardware instructions that access shared memory. Without an unambiguous memory model, it is not possible to reason about the correctness of a shared-memory program, compiler, dynamic optimizer, or hardware.

## Discussion

### Sequential Consistency

In a single-threaded program, a read is expected to return the value of the last write to the same address, where last is uniquely defined by the program text or program order. This allows the programmer to view the memory accesses as occurring one at a time (atomically) in program order. It also allows the hardware or compiler to aggressively reorder memory accesses as long as program order is preserved between a write and other accesses to the same address as the write.

A natural extension for shared-memory programs is the sequential consistency memory model [12] which offers simple interleaving semantics. With sequential consistency, all memory accesses appear to be performed in a single total order preserving the program order of each thread. Each read access to a memory location yields the value stored by the last preceding write access to the same memory location. Although sequential consistency appears to be an appealing programming model, it suffers from two deficiencies:

- It can be difficult or inefficient to implement. Hardware often makes memory accesses visible to other threads out of order, for example, by buffering stores. Compilers often do the same, for example, by moving an access to a loop-invariant variable out of the loop. Unlike with single-threaded programs, these optimizations can be observed by the program, and may thus violate sequential consistency for multi-threaded programs.

- The definition of sequential consistency is based on the interleaving of individual memory accesses, and is thus only meaningful if the programmer understands how memory is accessed, for example, a byte versus a word at a time. This is sensible at the machine architecture level, but may not be realistic at the programming language level.

### Relaxed Memory Models

Recognizing the limitations of sequential consistency, more relaxed or weak memory models have been proposed. Until the late 1990s, most of this work was in the context of hardware instruction set architectures and implementations. These implementation-centric models are mostly driven by specific optimizations desirable for hardware. The most common class relaxes the program order requirement of sequential consistency. For example, the SPARC Total Store Order (TSO) [18] and the x86 models [11] allow reordering a write followed by a read (to a different location) in program order. The IBM PowerPC memory model [9] allows reordering both reads and writes (to different locations). Such models additionally provide various forms of fence instructions to enable programmers to explicitly impose program orders not guaranteed by default. Other optimizations exploited by such models include subtle relaxations of the memory model to allow writes from multiple threads to become visible in inconsistent orders to different observer threads, as well as the ability to make memory references visible to other threads out of order even if a data- or control dependence exists between the references. Although most of the work on this genre of implementation-centric models is in the context of hardware, some programming environments such as OpenMP 3.0 [16] also express their memory models in terms of fence instructions to ensure explicit program ordering.

These relaxed models provide performance benefits over sequential consistency (through both hardware and compiler optimizations), but are inappropriate as programming interfaces. They often require description of subtle interactions and/or are not well-matched to software requirements, making them too complex to reason and/or suboptimal for performance.

## The Data-Race-Free Memory Models

The data-race-free models [1, 4] (also referred to as properly labeled models [8]) take a programmer-centric approach. They observe that good programming practice requires programs to be well synchronized or data-race-free. In such programs, concurrent non-read-only accesses to the same variable are either explicitly marked as synchronization or are separated by explicit synchronization. This ensures that no thread can ever observe another thread between synchronization points, allowing the implementation to aggressively transform code between synchronization points while still maintaining the appearance of sequential consistency.

The data-race-free models formally define the notion of data-race-free programs and guarantee sequential consistency only for those programs. For full implementation flexibility, they do not provide any guarantees for programs that contain data races. This approach allows nearly standard optimizations, while providing a simple model for programmers and was the approach adopted by the Ada programming language [17] and the POSIX standard [10] (albeit informally).

## State-of-the-art in 2010

In the last decade, there has been much work to standardize high-level language programming models, specifically in the context of Java and C++. There is now convergence toward data-race-free as the model of choice. For all practical purposes, the Java memory model [13, 14] and the upcoming C and C++ standards [6, 7] provide the data-race-free model, but with two unfortunate caveats.

First, Java's safety and security properties require that some semantics need to be provided for all programs, including programs with data races. It has been extraordinarily difficult to develop reasonable semantics for racy programs, while still preserving full implementation flexibility. The current formal specification of the Java memory model is therefore quite complex and has an unresolved bug.

Second, although data-race-free maps well to current implementation-centric hardware models for most purposes, there are useful programming idioms where available hardware-level fences are too heavyweight for

language-level synchronization mechanisms. For this reason, Java and C++ provide low-level synchronization constructs that provide potentially better performance on some current hardware, but at the cost of significant complexity to the programming model.

Although most language specifications are converging to the data-race-free model, current implementations often lag. In particular, it is still quite common for C and C++ compilers to effectively introduce copies of an otherwise unmodified variable to itself, for example, by overwriting adjacent structure fields when a small field is modified [5]. These can introduce visible data races, and are hence incompatible with the model.

In summary, although data-race-free provides the best trade-off between performance and ease-of-use today, it falls short for safe languages and current implementations.

## Bibliographic Notes and Further Reading

A more complete overview and retrospective on memory models is provided in [2]. It also surveys some possible approaches for overcoming the deficiencies of current data-race-free models. A tutorial on hardware-oriented relaxed memory models can be found in [3]. A description of the x86 hardware memory model, together with a discussion of some of the issues arising in precisely defining such models, is given in [15].

[Data starvation crisis](#)

## Definition

The memory wall describes implications of the processor/memory performance gap that has grown steadily

over the last several decades. If memory latency and bandwidth become insufficient to provide processors with enough instructions and data to continue computation, processors will effectively always be stalled waiting on memory. The trend of placing more and more cores on chip exacerbates the situation, since each core enjoys a relatively narrower channel to shared memory resources. The problem is particularly acute in highly parallel systems, but occurs in platforms ranging from embedded systems to supercomputers, and is not limited to multiprocessors.

## Discussion

### Introduction

The term memory wall was coined in a short, controversial note that William A. Wulf and Sally A. McKee published in a 1995 issue of the *ACM SIGArch Computer Architecture News* (“Hitting the Memory Wall: Implications of the Obvious” [1]). At the time, most computer architects focused entirely on increasing processor speed, believing that improving and creating more latency tolerating techniques would suffice to keep these ever-faster processors fed with instructions and data. The High Performance Computing (HPC) community had already recognized the problem, but 5 years after John Ousterhout published an article entitled “Why Aren't Operating Systems Getting Faster As Fast as Hardware?” [5], the mainstream computing community still believed that out-of-order execution, wider instruction issue widths, non-blocking caches, and increased speculation would continue to deliver performance improvements through increased Instruction Level Parallelism (ILP) and latency tolerance. Even Richard Sites's article in the popular magazine *Microprocessor Report* (“It's the Memory, Stupid!”) [7] failed to change common opinion.

In the memory wall article, the authors make the point that if the entire memory hierarchy, and not just the caches, were not improved in tandem with the microarchitecture, computer performance would cease to improve. They assume that every fifth instruction is a memory reference and that the number of cycles required to fill a cache line grows over time (looking at two different ratios of processor versus DRAM speedups, cache hit of 90% up to 99.8%, and two initial cache miss/hit cost ratios). By graphing the number of cycles it takes to perform a cacheline

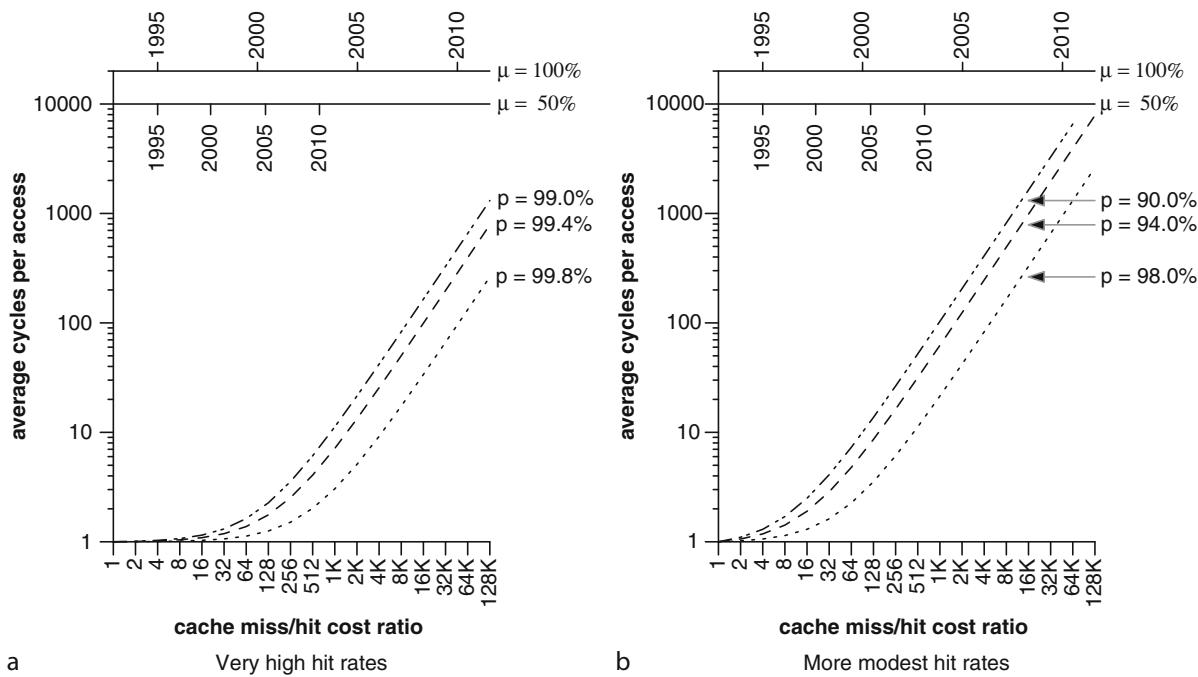

fill, they show that even at impossibly high hit rates and a less aggressive speed growth differential, processor improvements would soon no longer matter, since the cores would find themselves almost always waiting on memory. Their analysis necessarily contains many simplifying assumptions, but the four-page note eventually had impact, and memory wall has become a common term.

Figures 1 and 2 show the average number of cycles required per memory access as cache miss/hit cost ratios rise. The  $x$  axis marks increases in these cost ratios assuming given starting points (i.e., a cache for which fills cost four times as much as hits, and one for which fills cost 16 times as much). The log-based  $y$  axis indicates cycles per access. The curves in each graph indicate average access costs for different (unrealistic) cache hit rates from 90.0% to 99.8%. The lines at the top of each graph indicate where on the cycle-cost curves we would be at different points in time, where the top line marks years for an aggressive improvements (100%) in processor speed every 18 months, and the bottom marks years for a more modest improvement rate (50%). As the original article says, “the specific values won’t change the basic conclusion of this note, namely that we are

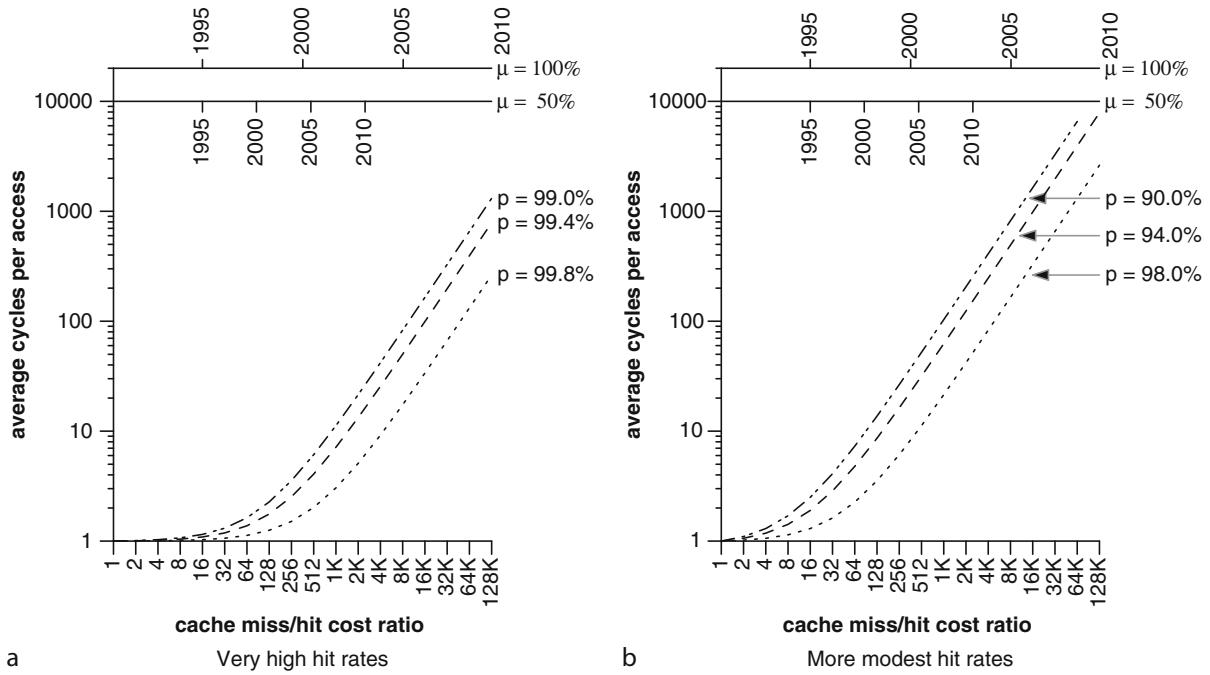

going to hit a wall in the improvement of system performance unless something basic changes” [11].

The memory wall also has a bandwidth component. One aspect of that is the limited number of pins that can be placed on ever-shrinking chips (formerly on the perimeter [1], now on the surface). The 1995 note focuses on latency aspects of the memory wall, but latency and bandwidth are two sides of the same coin, and cannot be teased apart. Denali CEO Sanjay K. Srivastava again stated the obvious in a 2001 interview with Wall Street Reporter: “There has been a growing disparity between the bandwidth needs of the processing elements and the ability of the memory elements to deliver that bandwidth. This ‘data starvation crisis’ is now being recognized as the main bottleneck for all electronic system designs” [8].

Depending on application characteristics and the architectures on which the applications run, current programs may or may not experience a memory wall. Data access locality on many levels is important to good performance. Applications that access sparse data structures, exhibit random (as opposed to structured) access patterns, or have huge working sets that prevent them from enjoying high cache hit rates suffer most.

**Memory Wall.** Fig. 1 Trends for a 1995 cache miss/hit cost ratio of four [11]

**Memory Wall.** Fig. 2 Trends for a 1995 cache miss/hit cost ratio of sixteen [11]

## DRAM Basics

Dynamic Random Access Memory (DRAM) is used in almost all main memories, as opposed to Static Random Access Memory (SRAM), which is used in almost all caches in the memory hierarchy. The term DRAM was coined to indicate that the technology allowed any (random) access to be performed in about the same amount of time, in contrast to tape storage and disks. In spite of the name, some accesses take longer than others. Improvements in DRAMs have largely increased storage capacity, rather than increasing speed, hence the processor/memory performance gap.

DRAMs are organized into internal banks, and each bank, or storage array, is accessed by specifying a row and a column address. Separate wires are used to transmit commands, addresses, and data. When the memory controller issues a row address, the specified line is loaded from the storage array into a bank of sense amplifiers (also called a DRAM *page* or *hot row*) that boosts the signal but also behaves something like a line of cache. The data in the “open” page remains valid long enough to perform many accesses, and consecutive accesses that hit in the same row happen much faster than accesses to different rows. Exploiting reference

locality can thus improve memory performance in these Fast Page Mode (FPM) DRAMs. Reading the row from the storage array is destructive, and so before another row can be accessed, the current row must be written back, which is called “closing” the row. The sense amplifiers must then be recharged before another row can be read. Memory systems can be organized with either open or closed page policies. In the former, data are left in the sense amplifiers in hopes that subsequent accesses will exhibit enough locality to be satisfied by the open row. In the latter, the active page is closed after every access. Using a closed page policy is simpler and provides more predictable access times, and thus many memory controllers close the current page after every cacheline fill.

Memory performance can also be improved by increasing bandwidth and using more chips in parallel. Separate chips are referred to as ranks. One common current packaging format uses Dual Inline Memory Modules (DIMMs), which have separate electrical connections on both sides of the printed circuit boards containing the DRAM circuits. Since the basic DRAM storage technology changes little with time (a bit is simply a capacitance stored at the intersection

of wires in the array), most improvements in DRAM performance come from innovations in the interface through which the memory controller communicates with the chip. DRAM chips were originally asynchronous, requiring a handshake protocol to coordinate data transmission across the memory bus. Eliminating asynchrony (so each action must happen after a specified number of memory clock cycles) and pipelining commands allows multiple accesses to be in flight at a time in Synchronous DRAMs (SDRAMs). Extended Data Out (EDO) DRAMs allow slightly more parallelism: The data output of a read is maintained while the command for the next access is being sent. One of the biggest performance improvements comes from increasing the speed at which data are transmitted. Double Data Rate (DDR) DRAMs transmit data on both the rising and falling edges of the memory clock. DDR2 halves the clock cycle to provide four clock edges per memory clock cycle, and DDR3 divides it further.

Bruce Jacob et al. [2] provide a good reference for all levels of the memory hierarchy. The bottom line is that changing the DRAM interface to incorporate synchrony, pipelining of data and commands, and double data rate transmission have had a significant impact on the design of memory system back ends. In spite of these improvements, DRAMs still cannot deliver the performance required to keep cores from stalling frequently. Given that HPC applications suffer most seriously from the memory wall phenomenon, the rest of this discussion is presented in that context.

## HPC Software Implications of Memory Trends

Many types of applications suffer from inadequate memory performance, but the trends that created conditions leading to the memory wall have historically had the largest impact on HPC applications. These trends cause two broad categories of memory challenges. A confluence of economic and technological factors drives the use of less overall memory for a given amount of computation and the use of less memory bandwidth for the delivered computation *FLOPS* (Floating Point Operations per Second).

## Existing Model for HPC Applications

Shared memory paradigms such as OpenMP, UPC (Universal Parallel C), pthreads, Global Arrays, X10,

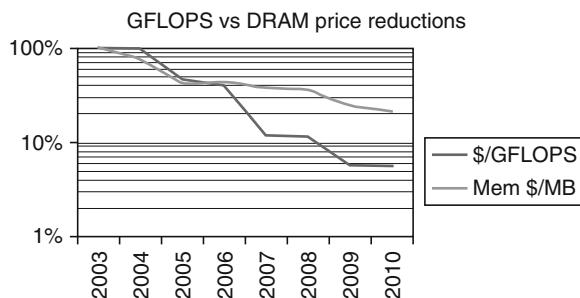

Fortress, and Charm++ are coming into greater use. Nonetheless, the predominant programming model remains single-threaded MPI (Message Passing Interface). Reduced amounts of memory combined with increased core counts cause the standard model of a single thread per MPI task to require re-examination, and the reduced bandwidth will in turn cause application programmers to redesign the algorithm decomposition of their problems. A common program structure used by MPI programs alternates between computation and communication phases. All tasks in the application synchronize via either reduction operations or explicit barriers. The tasks proceed through each of these phases in lock step. Two consequences of this model are pertinent to memory effects. These are highlighted here and explored in detail below.

The first consequence is that as memory per computation core is reduced, then for a given single-threaded MPI task, the amount of data on which that task can compute is reduced. This, in turn, can potentially imply that either the data needed by the algorithm decomposition no longer fit in memory, or that the amount of computation per phase is reduced. The reduction of computation per phase causes additional load balancing challenges: Tasks spend a greater percentage of time communicating instead of doing useful computation, thereby reducing the overall efficiency of the algorithm.

The second consequence is that as the ratio of memory bandwidth per FLOP shrinks, the percentage of time the application spends moving data to and from memory grows. Though communication/synchronization time is inevitable with decreasing bandwidth ratios, this limitation is imposed in part by the MPI model, which prevents the application from leveraging more efficient intra-node optimizations.

## Amount of Memory

Figure 3 shows the increasing cost of memory relative to the cost of computing. This trend has led to less available memory for a given amount of computation on large supercomputers. Although there are some technologies on the horizon that may provide a different cost point — for example, PCM (Phase Change Memory) — there will be challenges in effectively utilizing them. More importantly, even if designers can incorporate them, they will only provide a one-time improvement in the cost ratio. Overall, the community consensus holds that

**Memory Wall.** Fig. 3 Memory cost trends

even in the presence of occasional improvements in the memory/computation cost ratio, the general trend will continue, and the gap will widen.

### Memory Bandwidth

The trends in memory bandwidth are at least as problematic. Though improvements have been made in terms of the number of pins and later balls, there is still a physical limitation to the size and thus number of off-chip connections. As with the amount of memory there are a couple technologies on the horizon, such as chip stacking, that has a potential to provide a one time gain. However, as with the amount of memory, consensus among experts indicate that trend will continue. Though not memory bandwidth related, there is an increasing gap in communication bandwidth versus computation power. This trend leads to similar challenges. The effect of decreasing memory bandwidth per computation is examined in the next section.

### Future Directions

U.S. Department of Energy roadmaps project that the next generation of supercomputers will see  $O(1M)$  cores with the count climbing to a projected  $O(100M)$  cores in the exascale era near the end of the decade (2018–2019). One implication of all these memory trends is that the core algorithms in HPC applications must be redesigned to handle not just the challenges introduced by memory trends but also the scale of the supercomputers of coming generations. Although researchers recognize the necessity of doing this, it is a daunting task, and in many areas there has not been

significant progress. More work has been applied on the programming model front.

The trends provide a strong indication that most applications written in a flat (only MPI), single-threaded programming model will not be able to take advantage of the computing power that next-generation and coming exascale machines will offer. Many programmers have recognized this, and some are in the process of modifying applications. Many different avenues are being pursued, but most are based on executing more than a single software thread of execution within a node. This strategy directly attacks the challenge of amount of memory by providing many threads of computation per given memory. The most prevalent option is combining OpenMP with MPI. While this is a readily available model, researchers have already identified difficulties with the existing specification.

The ability to run multiple threads within a given MPI task indirectly addresses the memory bandwidth and communication bandwidth challenges. Such a strategy releases the threads running within the MPI task from being held to MPI algorithm limitations of interaction. For example, threads can take advantage of shared memory, and (more importantly) shared L2 or even L1 caches, or other intra-chip optimizations such as atomic operations. The disadvantage of this two-tiered or hybrid programming model is its increased complexity. Programming languages such as UPC, X10, Chapel, and Fortress have been introduced to address this complexity, providing an integrated programming model across the entire system. They explicitly support multiple levels of parallel execution, and recognize that memory access is non-uniform: Required data will be stored physically closer to some threads than others (and thus data locality becomes important on yet another level).

It seems likely that truly addressing all these trends and the challenges they impose will benefit from a new programming paradigm. The challenge is analogous to the transition to MPI: Changes must be embraced by the community at large. Porting applications to new programming models is extremely expensive, and will only be undertaken once sufficient confidence in an emergent programming model exists. Memory trends must be addressed in both hardware and software by a unified community.

## Bibliographic Notes and Further Reading

Publication of “Hitting the Memory Wall: Implications of the Obvious” inspired a flurry of responses, both in private email and in print. Most of these put forth arguments for why the memory wall did not and would

not exist (for example, see Maurice Wilkes’s “The Memory Wall and the CMOS End-Point” [10], also in *ACM SIGArch Computer Architecture News*). A simple online search yields many such articles, and it is interesting to review the numerous then-popular assumptions and to examine which ones have held over time.

Chun Liu et al. [3] discuss the problem in the context of the chip multiprocessors (CMPs) that began to emerge over the past decade. Thus, in spite of the community’s original skepticism about the very existence of the problem, a few researchers have continued to address different aspects of the memory wall, keeping the term in common computer parlance.

More recently, Richard Murphy [4] examines memory performance (both latency and bandwidth) for traditional and emerging supercomputer applications, finding that performance for both kinds of workloads is dominated by the memory system, but that the emerging applications are even more sensitive to memory latency and bandwidth limitations than their traditional counterparts. He notes that for massively parallel processors, the memory wall manifests itself due to the limited number of independent channels to memory compared to increases in numbers of cores. Thus, the problem predicted by Doug Burger et al. [1] in their 1996 article, “Memory Bandwidth Limitations of Future Microprocessors,” has been realized for this class of computers. Samuel K. Moore emphasizes Murphy’s findings with respect to informatics codes in a short *IEEE Spectrum* article, “Multicore Is Bad News for Supercomputers.” He quotes Sandia National Laboratory’s director of computation, James Peery: “After about eight cores, there’s no improvement.” Nonetheless, the debate regarding the conclusions of both articles continues: For example, see Ars Technica [9] for lengthy conversations on the memory wall for all types of CMP systems.

Brian Rogers et al. [6] developed an analytic model of CMP memory bandwidth to analyze constraints imposed by gap between increasing numbers of cores and limited memory bandwidth, and they used this model to assess the likely effectiveness of combinations of known techniques such as link compression, cache compression, DRAM caches, and stacked (3D) caches, concluding that by using appropriate combinations of approaches to reduce main memory bandwidth

requirements, the number of cores on chip is likely to reach 24–40 or higher (for future technology generations). The philosophy behind this work is the classic one that has allowed us to address the memory wall problem as well as we have thus far: We must use every technique available, and every combination thereof, to overcome the memory wall. Rogers et al. project that in this way, CMPs four technology generations from now may support over 180 cores. At that point, cost, power, and thermal considerations are likely to represent even larger walls. The interdependences of this confluence of problems place even greater constraints on how any individual component can be addressed: The memory wall is no longer just about latency and bandwidth, but about cost, power, area, and temperature, and thus will likely remain a prominent problem in computer system design for generations to come.

### Synonyms

Decomposition; Fill-reducing orderings; Graph partitioning; Load balancing; Mesh partitioning

### Definition

METIS and ParMETIS are serial and parallel software packages for partitioning and repartitioning large irregular graphs and unstructured meshes and for computing fill-reducing orderings of sparse matrices.

### Introduction

Algorithms that find a good partitioning of highly irregular graphs and unstructured meshes are critical for developing efficient solutions for a wide range of problems in many application areas on both serial and parallel computers. For example, large-scale numerical simulations on parallel computers, such as those based on finite element methods, require the distribution of the finite element mesh to the processors. This distribution must be done so that the number of elements assigned to each processor is the same, and the number of adjacent elements assigned on different processors is minimized. The goal of the first condition is to balance the computations among the processors. The goal of the second condition is to minimize the communication resulting from the placement of adjacent elements to different processors. Graph partitioning can be used to successfully satisfy these conditions by first modeling the finite element mesh by a graph, and then partitioning it into equal parts.

Graph partitioning algorithms are also used to compute fill-reducing orderings of sparse matrices. These fill-reducing orderings are useful when direct methods are used to solve sparse systems of linear equations. A good ordering of a sparse matrix dramatically reduces both the amount of memory and the time required to solve the system of equations. Furthermore, the fill-reducing orderings produced by graph partitioning

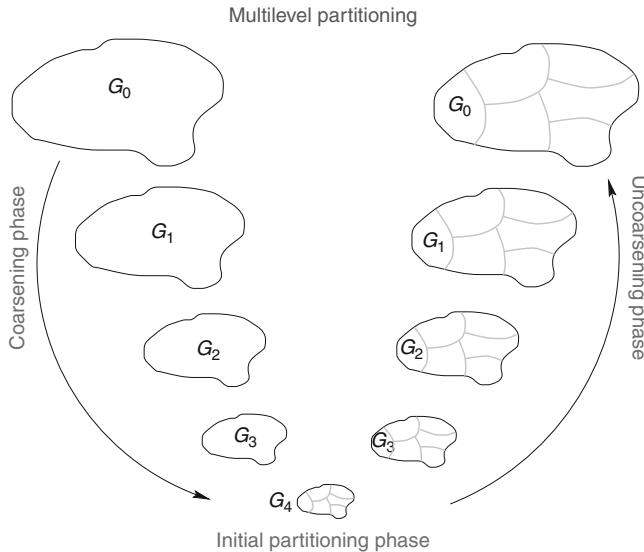

algorithms are particularly suited for parallel direct factorization as they lead to a high degree of concurrency during the factorization phase.

### METIS

METIS is a serial software package for partitioning large irregular graphs, partitioning large meshes, and computing fill-reducing orderings of sparse matrices. METIS has been developed at the Department of Computer Science and Engineering at the University of Minnesota and is freely distributed. Its source code can be downloaded directly from <http://www.cs.umn.edu/~metis>, and is also included in numerous software distributions for Unix-like operating systems such as Linux and FreeBSD.

The algorithms implemented in METIS are based on the multilevel graph partitioning paradigm [3, 4, 6], which has been shown to quickly produce high-quality partitions and fill-reducing orderings. The multilevel paradigm, illustrated in Fig. 1, consists of three phases: graph coarsening, initial partitioning, and uncoarsening. In the graph coarsening phase, a series of successively smaller graphs is derived from the input graph. Each successive graph is constructed from the previous graph by collapsing together a maximal size set of adjacent pairs of vertices. This process continues until the size of the graph has been reduced to just a few hundred vertices. In the initial partitioning phase, a partitioning of the coarsest and hence, smallest, graph is computed using relatively simple approaches such as the algorithm developed by Kernighan-Lin [8]. Since the coarsest graph is usually very small, this step is very fast. Finally, in the uncoarsening phase, the partitioning of the smallest graph is *projected* to the successively larger graphs by assigning the pairs of vertices that were collapsed together to the same partition as that of their corresponding collapsed vertex. After each projection step, the partitioning is refined using various heuristic methods to iteratively move vertices between partitions as long as such moves improve the quality of the partitioning solution. The uncoarsening phase ends when the partitioning solution has been projected all the way to the original graph.

METIS uses novel approaches to successively reduce the size of the graph as well as to refine the partition during the uncoarsening phase. During coarsening, METIS

**METIS and ParMETIS.** Fig. 1 The three phases of multilevel  $k$ -way graph partitioning. During the coarsening phase, the size of the graph is successively decreased. During the initial partitioning phase, a  $k$ -way partitioning is computed. During the multilevel refinement (or uncoarsening) phase, the partitioning is successively refined as it is projected to the larger graphs.  $G_0$  is the input graph, which is the finest graph.  $G_{i+1}$  is the next level coarser graph of  $G_i$ .  $G_4$  is the coarsest graph

employs algorithms that make it easier to find a high-quality partition at the coarsest graph. During refinement, METIS focuses primarily on the portion of the graph that is close to the partition boundary. These highly tuned algorithms allow METIS to quickly produce high-quality partitions and fill-reducing orderings for a wide variety of irregular graphs, unstructured meshes, and sparse matrices.

METIS provides a set of stand-alone command-line programs for computing partitionings and fill-reducing orderings as well as an application programming interface (API) that can be used to invoke its various algorithms from C/C++ or Fortran programs. The list of stand-alone programs and API routines of the current version of METIS (version 4.x) is shown in Table 1. The API routines allow the user to alter the behavior of the various algorithms and provide additional routines that partition graphs into unequal-size partitions and compute partitionings that directly minimize the total communication volume.

### Partitioning a Graph

METIS provides the pmetis and kmetis programs for partitioning an unstructured graph into a user-specified number of  $k$  equal-size parts. The partitioning algorithm used by pmetis is based on multilevel

recursive bisection described in [6], whereas the partitioning algorithm used by kmetis is based on multi-level  $k$ -way partitioning described in [4]. Both of these methods are able to produce high-quality partitions. However, depending on the application, one program may be preferable than the other. In general, kmetis is preferred when it is necessary to partition graphs into more than just a small number of partitions. For such cases, kmetis is considerably faster than pmetis. On the other hand, pmetis is preferable for partitioning a graph into a small number of partitions. The API routines corresponding to the pmetis and kmetis programs are METIS\_PartGraphRecursive and METIS\_PartGraphKway, respectively.

### Alternate Partitioning Objectives

The objective of the traditional graph partitioning problem is to compute a balanced  $k$ -way partitioning such that the number of edges (or in the case of weighted graphs the sum of their weights) that straddle different partitions is minimized. This objective is commonly referred to as the *edge-cut*. When partitioning is used to distribute a graph or a mesh among the processors of a parallel computer, the objective of minimizing the edge-cut is only an approximation of the true communication cost resulting from the partitioning [2].

**METIS and ParMETIS. Table 1** An overview of METIS' command-line and library interfaces

| Operation                   | Stand-alone program | API routine                |
|-----------------------------|---------------------|----------------------------|
| Partition a graph           | pmetis              | METIS_PartGraphRecursive   |
|                             | kmetis              | METIS_PartGraphKway        |
|                             |                     | METIS_PartGraphVKway       |
|                             |                     | METIS_mCPartGraphRecursive |
|                             |                     | METIS_mcPartGraphKway      |
|                             |                     | METIS_WPartGraphRecursive  |
|                             |                     | METIS_WPartGraphKway       |
|                             |                     | METIS_WPartGraphVKway      |
| Partition a mesh            | partnmesh           | METIS_PartMeshNodal        |
|                             | partdmesh           | METIS_PartMeshDual         |
| Compute a fill-reducing     | oemmetis            | METIS_EdgeND               |
| Ordering of a sparse matrix | onmetis             | METIS_NodeND               |
|                             |                     | METIS_NodeWND              |
| Convert a mesh into a graph | mesh2nodal          | METIS_MeshToNodal          |
|                             | mesh2dual           | METIS_MeshToDual           |

The communication cost resulting from a  $k$ -way partitioning generally depends on the following factors: (a) the total communication volume, (b) the maximum amount of data that any particular processor needs to send and receive; and (c) the number of messages a processor needs to send and receive. METIS' API provides the METIS\_PartGraphVKway and METIS\_WPartGraphVKway routines that can be used to directly minimize the total communication volume resulting from the partitioning (first factor). In addition, METIS also provides support for minimizing the third factor (which essentially reduces the number of startups) and indirectly (up to a point) reduces the second factor. This enhancement is provided as a refinement option for both the METIS\_PartGraphKway and METIS\_PartGraphVKway routines, and is the default option of kmetis and METIS\_PartGraphs Kway.

### Support for Multiphase and Multi-physics Computations

The traditional graph partitioning problem formulation is limited in the types of applications that it can effectively load balance because it specifies that only a single quantity be balanced. Many important types of multiphase and multi-physics computations require that multiple quantities be balanced simultaneously. This is because synchronization steps exist between the

different phases of the computations, and so, each phase must be individually load balanced. That is, it is not sufficient to simply sum up the relative times required for each phase and to compute a partitioning based on this sum. Doing so may lead to some processors having too much work during one phase of the computation (and so, these may still be working after other processors are idle), and not enough work during another. Instead, it is critical that every processor must have an equal amount of work from each phase of the computation.

METIS includes partitioning routines that can be used to partition a graph in the presence of such multiple balancing constraints. Each vertex is now assigned a vector of  $m$  weights and the objective of the partitioning routines is to minimize the edge-cut subject to the constraints that each one of the  $m$  weights is equally distributed among the domains. For example, if the first weight corresponds to the amount of computation and the second weight corresponds to the amount of storage required for each element, then the partitioning computed by the new algorithms will balance both the computation performed in each domain and the amount of memory that it requires. The multi-constraint partitioning algorithms and their applications are further described in [3]. The pmetis and kmetis programs invoke the multi-constraint partitioning routines whenever the input graph specifies more than one set of vertex weights. Support for multi-constraint

partitioning via METIS' API is provided by the `METIS_mCPartGraphRecursive` and `METIS_METIS_mCPartGraphKway` routines that are based on the multilevel recursive bisection and the multilevel  $k$ -way partitioning paradigms, respectively.

## Partitioning for Heterogeneous Parallel Computing Architectures

Heterogeneous computing platforms containing processing nodes with different computational and memory capabilities are becoming increasingly more common. METIS' API provides the `METIS_WPartGraphRecursive`, `METIS_WPartGraphKway`, and `METIS_WPartGraphVKway` routines, which are designed to partition a graph into  $k$  parts such that each part contains a prespecified fraction of the total number of vertices (or vertex weight). By matching the weights specified for each partition to the relative computational and memory capabilities of the various processors, these routines can be used to compute partitions that balance the computations on heterogeneous architectures.

## Partitioning a Mesh

METIS provides the `partnmesh` and `partdmesh` programs for partitioning meshes arising in finite element or finite volume methods. These programs take as input the element node array of the mesh and compute a  $k$ -way partitioning for both its elements and its nodes. METIS currently supports four different types of mesh elements that are triangles, tetrahedra, hexahedra (bricks), and quadrilaterals. These programs first convert the mesh into a graph, and then use `kmetis` to partition this graph. The difference between these two programs is that `partnmesh` converts the mesh into a nodal graph (i.e., each node of the mesh becomes a vertex of the graph), whereas `partdmesh` converts the mesh into a dual graph (i.e., each element becomes a vertex of the graph). In the case of `partnmesh`, the partitioning of the nodal graph is used to derive a partitioning of the elements. In the case of `partdmesh`, the partitioning of the dual graph is used to derive a partitioning of the nodes. Both of these programs produce partitioning of comparable quality, with `partnmesh` being considerably faster than `partdmesh`. However, in some cases, `partnmesh` may produce partitions that have higher load imbalance

than `partdmesh`. The API routines corresponding to the `partnmesh` and `partdmesh` programs are `METIS_PartMeshNodal` and `METIS_PartMeshDual`, respectively.

## Computing a Fill-Reducing Ordering of a Sparse Matrix

METIS provides two programs `ometis` and `onmetis` for computing fill-reducing orderings of sparse matrices. Both programs use multilevel nested dissection to compute a fill-reducing ordering [6]. The nested dissection paradigm is based on computing a vertex separator for the graph corresponding to the matrix. The nodes in the separator are moved to the end of the matrix, and a similar process is applied recursively for each one of the other two parts.

These programs differ on how they compute the vertex separators. The `ometis` program finds a vertex separator by first computing an edge separator using a multilevel algorithm, whereas the `onmetis` program uses the multilevel paradigm to directly find a vertex separator. The orderings produced by `onmetis` generally incur less fill than those produced by `ometis`. In particular, for matrices arising in linear programming problems the orderings computed by `onmetis` are significantly better than those produced by `ometis`. Furthermore, `onmetis` utilizes compression techniques to reduce the size of the graph prior to computing the ordering. Sparse matrices arising in many application domains are such that certain rows of the matrix have the same sparsity patterns. Such matrices can be represented by a much smaller graph in which all rows with identical sparsity pattern are represented by just a single vertex whose weight is equal to the number of rows. Such compression techniques can significantly reduce the size of the graph, whenever applicable, and substantially reduce the amount of time required by `onmetis`. However, when there is no reduction in graph size, `ometis` is about 20–30% faster than `onmetis`. Furthermore, for large matrices arising in three-dimensional problems, the quality of orderings produced by the two algorithms is quite similar.

METIS' API provides the `METIS_EdgeND`, `METIS_NodeND`, and `METIS_NodeWND` routines for computing fill-reducing orderings for sparse matrices. The first two routines provide the functionality

of the `oemetis` and `onmetis` programs, respectively; whereas, the third routine is designed to compute fill-reducing orderings of graphs whose vertices have weights corresponding to the number of rows in the original sparse matrix with identical sparsity structure.

### Converting a Mesh into a Graph

METIS provides two programs: `mesh2nodal` and `mesh2dual` for converting a mesh into the graph format used by METIS. In particular, `mesh2nodal` converts the element node array of a mesh into a nodal graph; that is, each node of the mesh corresponds to a vertex in the graph and two vertices are connected by an edge if the corresponding nodes are connected by lines in the mesh. Similarly, `mesh2dual` converts the element node array of a mesh into a dual graph; that is, each element of the mesh corresponds to a vertex in the graph and two vertices are connected if the corresponding elements in the mesh share a face. The API routines corresponding to these two programs are `METIS_MeshToNodal` and `METIS_MeshToDual`, respectively. Since METIS does not provide API routines that can directly compute a multi-constraint partitioning of a mesh or compute a partitioning that minimizes its overall communication cost, these routines can be used to first convert the mesh into a graph, which can then be used as input to METIS' graph partitioning routines to obtain such partitionings.

### ParMETIS

ParMETIS is an MPI-based parallel library that implements a variety of algorithms for partitioning and repartitioning unstructured graphs and meshes and for computing fill-reducing orderings of sparse matrices.

ParMETIS has been developed at the Department of Computer Science and Engineering at the University of Minnesota and is freely distributed. Its source code can be downloaded directly from <http://www.cs.umn.edu/~metis>. The algorithms in ParMETIS are based on the corresponding algorithms implemented in METIS. However, ParMETIS extends METIS' functionality by including routines that are especially suited for parallel computations and large-scale numerical simulations.

The complete list of operations that ParMETIS' routines can perform and the associated API routines of the current version of ParMETIS (version 3.x) is shown in Table 2. ParMETIS' partitioning and repartitioning routines provide support for single- and multi-constraint partitioning and for parallel computational platforms with heterogeneous computing capabilities. Note that unlike METIS, ParMETIS does not provide any stand-alone parallel programs for parallel partitioning and ordering.

### Partitioning a Graph

`ParMETIS_V3_PartKway` is the routine in ParMETIS that is used to partition unstructured graphs. This routine takes a graph and computes a  $k$ -way partitioning that minimizes the edge-cut. `ParMETIS_V3_PartKway` makes no assumptions on how the graph is initially distributed among the processors. It can effectively partition a graph that is randomly distributed as well as a graph that is well distributed. The parallel graph partitioning algorithm used in `ParMETIS_V3_PartKway` is based on the serial multilevel  $k$ -way partitioning algorithm (implemented by METIS' `kmetis` program and `METIS_Part`

**METIS and ParMETIS. Table 2** An overview of ParMETIS' API routine

| Partition                                                       | API routine                             |
|-----------------------------------------------------------------|-----------------------------------------|
| Partition a graph                                               | <code>ParMETIS_V3_PartKway</code>       |
|                                                                 | <code>ParMETIS_V3_PartGeom</code>       |
|                                                                 | <code>ParMETIS_V3_PartGeomKway</code>   |
| Partition a mesh                                                | <code>ParMETIS_V3_PartMeshKway</code>   |
| Repartition a graph corresponding to an adaptively refined mesh | <code>ParMETIS_V3_AdaptiveRepart</code> |
| Refine the quality of an existing partitioning                  | <code>ParMETIS_V3_RefineKway</code>     |
| Compute a fill-reducing ordering of a sparse matrix             | <code>ParMETIS_V3_NodeND</code>         |
| Convert a mesh into a graph                                     | <code>ParMETIS_V3_MeshToDual</code>     |

GraphKway API routine) and parallelized in [5, 7, 9, 10].

When coordinate information is available about the vertices of the graph (e.g., when the vertices correspond to mesh nodes or elements), ParMETIS provides two additional routines that can be used to compute the partitioning. The first is `ParMETIS_V3_PartGeom` that uses an approach based on space-filling curves. This routine is very fast but produces relatively low-quality solutions. The second is `ParMETIS_V3_PartGeomKway` that first computes an initial partitioning using the method based on space-filling curves, redistributes the graph according to this partitioning, and then calls `ParMETIS_V3_PartKway` to compute the final high-quality partitioning of the graph. Even though this approach computes two different partitionings, because the second partitioning is computed using a graph that is already well-distributed among the processors, it actually takes less time. Also, the quality of the final partitioning produced by `ParMETIS_V3_PartGeomKway` is comparable to that computed by `ParMETIS_V3_PartKway`.

Note that in most of ParMETIS' partitioning routines the number of sub-domains is decoupled from the number of processors. Hence, it is possible to use these routines to compute a  $k$ -way partitioning independent of the number of processors that are used.

### Partitioning Adaptively Refined Meshes

For large-scale scientific simulations, the computational requirements of techniques relying on globally refined meshes become very high, especially as the complexity and size of the problems increase. By locally refining and de-refining the mesh either to capture flow-field phenomena of interest or to account for variations in errors, adaptive methods make standard computational methods more cost effective. The efficient execution of such adaptive scientific simulations on parallel computers requires a periodic repartitioning of the underlying computational mesh. These repartitionings should minimize both the inter-processor communications incurred in the iterative mesh-based computation and the data redistribution costs required to balance the load.

Repartitioning algorithms fall into two general categories. The first category balances the computation by incrementally diffusing load from those sub-domains

that have more work to adjacent sub-domains that have less work. These schemes are referred to as *diffusive schemes*. The second category balances the load by computing an entirely new partitioning, and then intelligently mapping the sub-domains of the new partitioning to the processors such that the redistribution cost is minimized. These schemes are generally referred to as *remapping schemes*. Remapping schemes typically lead to repartitionings that have smaller edge-cuts, while diffusive schemes lead to repartitionings that incur smaller redistribution costs. However, since these results can vary significantly among different types of applications, it can be difficult to select the best repartitioning scheme for the job.

ParMETIS provides the `ParMETIS_V3_AdaptiveRepart` routine for repartitioning adaptively refined meshes. This routine assumes that the mesh is well distributed among the processors, but that (due to mesh refinement and de-refinement) this distribution is poorly load balanced. `ParMETIS_V3_AdaptiveRepart` is based on the Unified Repartitioning Algorithm [10, 12] and combines the best characteristics of remapping and diffusion-based repartitioning schemes. A key parameter used by this algorithm is the *ITR Factor* that describes the ratio between the time required for performing the inter-processor communications incurred during parallel processing compared to the time to perform the data redistribution associated with balancing the load. As such, it allows for the computation of a single metric that describes the quality of the repartitioning.

The underlying algorithm of `ParMETIS_V3_AdaptiveRepart` follows the multilevel partitioning paradigm but uses a technique known as *local coarsening* that only collapses together vertices that are located on the same processor. On the coarsest graph, an initial partitioning need not be computed, as one can either be derived from the initial graph distribution (in the case when sub-domains are coupled to processors), or else one needs to be supplied as an input to the routine (in the case when sub-domains are decoupled from processors). However, this partitioning does need to be balanced. The balancing phase is performed on the coarsest graph by using both remapping- and diffusion-based algorithms [11]. A quality metric for each of these partitionings is then computed (using the ITR Factor) and the partitioning with the highest quality is selected.

This technique tends to give very good points from which to start multilevel refinement, regardless of the type of repartitioning problem or the value of the ITR Factor. Note that the fact that the algorithm computes two initial partitionings does not impact its scalability as long as the size of the coarsest graph is suitably small. Finally, multilevel refinement is performed on the balanced partitioning in order to further improve its quality. Since `ParMETIS_V3_AdaptiveRepart` starts from a graph that is already well distributed, it is very fast.

Appropriate values for the ITR Factor can easily be determined depending on the times required to perform (a) all inter-processor communications that have occurred since the last repartitioning, and (b) the data redistribution associated with the last repartitioning/load balancing phase. Simply divide the first time by the second. The result is the correct ITR Factor. In case these times cannot be ascertained (e.g., for the first repartitioning/load balancing phase), our experiments have shown that values between 100 and 1,000 work well for a variety of situations.

`ParMETIS_V3_AdaptiveRepart` can be used to load balance the mesh either before or after mesh adaptation. In the latter case, each processor first locally adapts its mesh, leading to different processors having different numbers of elements. `ParMETIS_V3_AdaptiveRepart` can then compute a partitioning in which the load is balanced. However, load balancing can also be done before adaptation if the degree of refinement for each element can be estimated *a priori*. That is, if we know ahead of time into how many new elements each old element will subdivide, we can use these estimations as the weights of the vertices for the graph that corresponds to the dual of the mesh. In this case, the mesh can be redistributed before adaption takes place. This technique can significantly reduce data redistribution times.

### Improving the Quality of a Partitioning

ParMETIS provides the `ParMETIS_V3_RefineKway` routine that can be used to improve the quality of an existing partitioning. `ParMETIS_V3_RefineKway` can be used to improve the quality of partitionings that are produced by other partitioning algorithms. `ParMETIS_V3_RefineKway` can also be used repeatedly to further improve the quality

of a partitioning. However, each successive call to `ParMETIS_V3_RefineKway` will tend to produce smaller improvements in quality.

### Partitioning Meshes

ParMETIS provides the `ParMETIS_V3_PartMeshKway` routine for directly partitioning the elements of an unstructured (or structured) mesh. This partitioning is computed by first converting the mesh into a graph whose vertices are the elements of the mesh and then using `ParMETIS_V3_PartKway` to compute the actual partitioning. Note that in the case of adaptive computations, ParMETIS does not provide routines that can directly repartition adaptively refined meshes. However, an application can use the `ParMETIS_V3_MeshToDual` routine to construct in parallel the dual graph of the mesh, which can then be provided as input to the `ParMETIS_V3_AdaptiveRepart` routine.

### Computing Fill-reducing Orderings of Sparse Matrices

`ParMETIS_V3_NodeND` is the routine provided by ParMETIS for computing fill-reducing orderings of sparse matrices. The algorithm implemented by `ParMETIS_V3_NodeND` is similar to that implemented by METIS' `onmetis` stand-alone program and `METIS_NodeND` routine. To achieve high performance, `ParMETIS_V3_NodeND` first uses `ParMETIS_V3_PartKway` to compute a high-quality partitioning and redistributes the graph accordingly. Next it proceeds to compute the  $\log p$  levels of the elimination tree concurrently. When the graph has been separated into  $p$  parts (where  $p$  is the number of processors), the graph is redistributed among the processor so that each processor receives a single subgraph, and `METIS_NodeND` is used to order these smaller subgraphs.

## Bibliographic Notes and Further Readings

There is an extensive body of research related to the topic of graph and mesh partitioning and its applications to parallel and scientific computing. Schloegel et al. [13] and Devine et al. [1] provide comprehensive overviews of the various methods that have been developed and their applications to high performance scientific computing. In addition, besides METIS and ParMETIS, there are a number of other tools that have been developed and are actively maintained for serial and parallel graph partitioning.

## Metrics

ALLEN D. MALONY

University of Oregon, Eugene, OR, USA

## Synonyms

[Performance metrics](#)

## Definition

A metric is a quantitative measure used to characterize, evaluate, and compare parallel performance. Many performance metrics are defined based on the variety of performance data and other information that can be obtained from a measurement of a parallel execution. Metrics can be absolute as well as derived from other metrics. Parallel metrics are used to understand the relationship of scalability and performance.

## Discussion

### Introduction

Performance is at the heart of parallel computing. Qualitatively, performance embodies those aspects that motivate parallel computing research and development, such as delivering greater speed and solving larger problems. However, for purposes of scientific and engineering discussion, it is necessary to describe performance in more quantitative terms. Metrics make it possible to characterize, evaluate, and compare performance based on methods for performance data measurement and analysis. Metrics are determined from performance measures. Where a *measure* constitutes a quantity or degree of performance, and implies a means for ascertaining (measuring) it, a *metric* is a “standard of measure,” a semantic representation of performance. Metrics are the language of parallel performance science.

Metrics are mostly determined by the variety of performance data that can be obtained in measurements,

reflecting different features of interest in a parallel execution. Metrics can be of different types, depending on the purpose for their use. Where do metrics come from? What are the common metrics used in the parallel computing community? How are metrics applied? These are some of the questions discussed below.

## Standard Metrics

Performance metrics are based on measures of parallel operation. Two questions naturally follow. What are the features of parallel operation to quantify? How are those features measured in a real parallel program? The term “standard metric” is used here to reflect common performance data from measurement of parallel program execution.

## Time Metrics

Parallel computing is generally concerned with reducing the amount of time necessary to perform a computational task, whether that be the execution of single parallel application or the running of many jobs together on a parallel machine. Thus, the most fundamental performance metric of interest to parallel computing is *execution time*. A time metric is calculated in different ways depending on what is available for time measurement, and there can be different types of execution time to observe.

Time measurement requires a clock source (a clock reference), and different sources have different resolution and accuracy characteristics. *Wallclock time* regards the passage of real time as a clock basis, as one would use a clock on the wall. It is used often to quantify the actual time taken for a parallel execution to complete, from start to finish. One could use a watch to time a parallel program, but all operating systems provide some form of real time clock to keep track of time. The real time clock is created from a hardware source and can have a high degree of resolution.

However, there are different components of time reflecting different states of execution. Operating systems normally keep track of *CPU time*, *I/O time*, and the time spent *idle* for a process. CPU time is typically broken down into *user* and *system* time. User time is the time the process spends in execution of the program code and system time is the time the operating system spends executing on behalf of the process. The CPU time measure (with user and system components)

is commonly referred to as *process virtual time* since it is maintained on a process basis and the virtual clock advances only when the process is executing in either user or system mode.

Whereas it is helpful to see the breakdown of time for each individual process or thread of a parallel program, process virtual time cannot serve as a uniform time reference for the whole parallel execution, primarily because it ignores periods when the process is idle. In general, it is important to have a single, real time clock reference for measuring time on all processes to determine accurately the time from the beginning of the parallel computation to the end. The real time clock is also necessary to allow performance measurements of interactions between processes (threads). In practice, synchronized clocks are hard to achieve in a parallel machine, requiring local real time clocks to be used with software-based time correlation.

In summary, time metrics can apply to the parallel program as a whole, in which case it is necessary to have a common time basis. *Total execution time* is the metric used most often for reporting the performance of a parallel execution. It represents the elapsed time from the beginning of the parallel computation to the end. However, further breakdown of execution time across the processes / threads of the parallel program can be important for performance analysis, especially of synchronization and communication operations. Multiple methods of measuring time are used to compute time metrics of concern. Note, it is also useful to sum time metrics from individual processes to get a single metric representing total time consumed overall. For instance, adding the time processes spend doing real computation could represent total *work*. Similarly, adding the time processes spend in synchronization and communication could represent total *overhead*.

## OS and Hardware Metrics

Time is not the only metric used to characterize parallel execution. The operating system and processor hardware provide performance data that reflects how a program interacts with the parallel machine. From the operating system standpoint, it is possible to see information about virtual memory, paging, I/O, and networking. OS metrics typically captures performance data at the process level as counts of interesting events and other quantitative measures.

The availability of counters in modern computing hardware has made it possible to generate performance metrics about the operation of the processor, memory system, and other hardware components. All CPUs today have counters available covering a range of functionality from tracking instructions executed, to measuring cache operation, to basic timing. Access to the counters are made possible through the instruction set architecture, at the low level, and libraries such as the Performance API (PAPI) [3], at higher levels. Using the counter interfaces, it is possible to calculate metrics such as the number of floating point operations (*flops*), level 1 cache misses (data, instruction), translation lookaside buffer misses, and so on.

OS and hardware metrics are measured locally in a parallel system. For some, it makes sense to accumulate the performance data to compute a total value, as a way to convey an amount of work, such as in the case of total flops, or an average value, to elucidate an overall parallel inefficiency, as in the case of average cache misses per processor. Clearly, flops (typically reported as millions or billions of flops, *Mflops* or *Gflops*) is an important metric since it is used commonly to represent the amount of computational work in scientific applications.

### Derived Metrics

The types of metrics above one might regard as *raw metrics* since they come directly from measurement. New metrics can be calculated from other metrics to better characterize performance. A *derived metric* is the result of an arithmetic metric expression. The best known derived metric is flops per second rate (also referred to by the acronym *flops*), determined by dividing the total number of floating point operations performance by the execution (summed over all processes) by the total execution time. Flops rate is the primary derived metric reported for high-performance scientific computing.

Rate-based derived metrics are easily calculated from any raw metric. Any OS or hardware counter can be used to determine informative rate metrics, such as instructions per second, cache misses per second, or page faults per second. Sometimes it is necessary to instrument the program code to determine certain values. For instance, sustainable *memory bandwidth* and *communication bandwidth* in gigabytes per second

depends on knowing how much data is being referenced or transferred.

However, the derived metric expression can be anything. One important derived metric is the *computation-to-communication ratio*, computed in two ways:

1. The number of calculations (determined by some computation metric) divided by the number of communication messages (measured as number or bytes)
2. The time spent calculating divided by the time spent communicating

The computation-to-communication ratio is helpful in gauging the *efficiency* of a parallel execution. Lower ratios suggest more communication overhead in the parallel execution. The ratio could also reflect the differences in performance of the processing and communications infrastructure. Improving communication network bandwidth and latency would result in an increase in the ratio. This type of derived metric could be called a *relative metric* since it is describing one metric with respect to another, generally as a ratio. If time is the denominator, the relative metric becomes a rate.

Other expressions for deriving metrics might help in the aggregation or categorization of more specific performance, such as in summing the time spent in all MPI routines into a single MPI class.

### Parallelism Metrics

The metrics discussed above can be thought of as describing aspects of parallel execution performance where the parallelism degree, problem size, and other parameters are fixed. Such an execution instance is typically called a *performance experiment*. Obviously, standard metrics from multiple performance experiments can be captured and compared. In this regard, new *comparative metrics* can be created to highlight certain cross-experiment performance aspects. By definition, each performance experiment reflects differences in how the experiment was constructed, on what platform it executed, the input data sets, and many other parameters of performance interest. A comparative metric can analyze performance along one or several parameter dimensions.

A simple comparative metric would consider how a standard or derived performance metric varies for

changes in a single parameter. Consider varying the amount of calculations performed by a parallel program by increasing the size of the problem. The number of parallel processes used will remain fixed. This is a type of performance study called *problem size scaling*. After running the performance experiment for each problem size, the standard performance metrics can be compared with respect to the problem size choices. One problem size could be chosen as the base, for instance, and performance metrics for the other sizes normalized to the base metrics. Since the parallelism degree is fixed, the result of the comparative analysis gives insight to effects on performance due to the amount of computation, memory allocation, and other factors dependent on problem size.

The term “parallelism metrics” will be used generally to characterize performance effects as a result of changes in parallel execution parameters. As comparative metrics, parallelism metrics have implicit and explicit relevance to how parallelism is manifesting in performance variation.

## Speedup

A fundamental parallelism metric is *speedup*. Simply put, speedup expresses the performance improvement as parallelism increases. If  $T_s$  is the sequential execution time of a program and  $T_p$  is the execution time when the program is run in parallel on  $p$  processors, speedup is the simple expression:  $S = S_p = T_s/T_p$ . The speedup metric conveys performance improvement when  $S > 1$  and degradation when  $S < 1$ . *Ideal speedup* (also known as *ideal scaling*) is defined by  $S_p = p$ . *Superlinear speedup* is obtained when  $S_p > p$ .

However, there are two well-known speedup formulations, determined by how execution time is modeled. The first is taken from Amdahl's law [1] which is a method to find the maximum expected improvement to an overall system when only part of the system is improved. If the number of processors is increased for use in the parallel portion of an application's computation, Amdahl's law is a speedup expression that identifies the theoretical maximum performance improvement possible.

Let  $T_s$  be the execution time of a sequential computation. Let  $\alpha$  be the fraction of the computation that cannot be parallelized. If there are  $p$  processors, then the time of the parallel computation,  $T_p$ , can be written

as  $T_p = \alpha * T_s + (1 - \alpha) * T_s/p$ , assuming the parallel execution is ideal and does not result in any overheads. Now the speedup equation can be written as:  $S = T_s/T_p = \frac{1}{\alpha + (1-\alpha)/p}$ . Notice as  $p \rightarrow \infty$ ,  $S$  is bounded by  $\frac{1}{\alpha}$ . In other words, the sequential portion of the computation limits the speedup that can be achieved.

Speedup formulated in this manner is also known as *strong speedup* (or *strong scaling*), since the size of the computational work to be performed is defined by the sequential execution and does not change. The *sequential fraction* becomes a dominant, strong factor in the speedup metric. There was concern in the parallel computing community that large-scale parallel performance would be hard to achieve since even tiny portions of sequential execution place severe constraints on the actual speedup that can be obtained. For example, a 1% sequential fraction limits speedup to 100 maximum.

Suppose instead that the computational work is allowed to increase with increasing parallelism degree. This is the basis of Gustafson's Law [6]. Let  $n$  be the problem size,  $p$  be the number of processors, and  $T_p$  be the execution time on a parallel computer. We can write  $T_p = a(n) + b(n)$  where  $a(n)$  is the part that executes sequentially and  $b(n)$  is the part that executes in parallel. To determine execution time on a single processor, we just multiply the parallel component by the number of processors used:  $T_s = a(n) + p * b(n)$ . (Again, overheads are assumed to be zero.) If  $T_p$  is normalized to 1,  $a(n)$  and  $b(n)$  then represent sequential and parallel fractions of the total computation. The speedup equation can be written as:  $S = T_s/T_p = T_s = a(n) + p * (1 - a(n))$ .

Now assume increasing problem size. If the serial portion,  $a(n)$ , diminishes (as a fraction of the total computation) as  $n$  increases, speedup will be bounded by the number of processors,  $p$ :  $S \rightarrow p$  as  $n \rightarrow \infty$ . The term “weak speedup” (or “weak scaling”) is used to describe this speedup metric based on Gustafson's Law. The idea is that good speedups can be achieved with greater numbers of processors, as long as the amount of (relative) parallel work being done can be increased. This tends to be not difficult to do with many applications. As a result, the community became more confident that massively parallel computer systems could be productively utilized.

## Efficiency

Speedup metrics are calculations based on time metrics. How does speedup itself change as a result of parallelism degree? An *efficiency metric* can be defined as the ratio of speedup to the number of processors used to obtain it:  $E_p = \frac{S_p}{p}$ . Efficiency is an example of a *utilization metric*. In essence, it represents a return on investment in parallelism. For instance, a parallel program might achieve a speedup of 100, but it takes 1,000 processors to do it. Efficiency in this case is less than 10%.

Efficiency can change as a result of any performance factor that is influenced by parallelism degree. Returning to problem size, suppose performance experiments are conducted with varying problem size and parallelism. When all experiments are completed, efficiency can be computed for each. To quantify the effect of change problem size on parallel program efficiency, an *isoefficiency function* can be computed. Given a chosen level of efficiency, its purpose is to specify what size of problem must be solved on a given number of processors. Isoefficiency was created as a technique to analyze the scalability of parallel algorithms [5].

## Metric Use

Metrics form the basis of performance evaluation methodology and are used for purposes of benchmarking, characterization, performance problem diagnosis, and optimization. The particular performance evaluation problem will determine which metrics are best to use. Sometimes convention defines the metric(s) of choice.

## Peak Metrics

It has been standard practice to rate parallel machine performance by *peak speed*, usually defined for scientific computing in terms of maximum flops per second a parallel machine can possibly deliver. It is computed by summing up the maximum performance of every processor that can be executing in parallel. Of course, peak speed is never attained by a parallel application, since there are overheads involved and peak speed assumes only certain instructions are used. However, it has been applied as an upper-bound threshold for evaluating parallel execution efficiency. The term “percentage of peak” represents an efficiency metric where the total attained flops per second from a parallel application is divided

by peak flops. Because of the strong influence of processor components and system architecture, percentage of peak can differ from machine to machine for the same application. Clearly, different applications have different parallelism behavior and thus will vary in percentage of peak on the same machine. In general, it is not uncommon to see low percentages of peak for many parallel applications.

## Benchmark Metrics

Benchmarking is the process of conducting controlled experiments using a suite of programs to test performance factors associated with machine platform, compilers, libraries, and other parameters, including parallelism degree and problem size. In contrast to just comparing performance to some absolute measure, benchmarking is intended to allow more informed evaluation with respect to program properties. Benchmark codes are designed to exercise certain execution aspects, whether it be processor, memory, or networking performance, as well as to be representative of application code behavior. There is a long history to benchmarking of parallel machines, particularly for high-performance computing.

The most common metric used in scientific benchmarking is again *flops per second* or just *flops* for short. It is the primary metric in the LINPACK benchmark suite [4] and the basis for the High-Performance LINPACK (HPL) benchmark [10] version used to rank supercomputers in the TOP500 [9] list. The LINPACK benchmarks measure a system’s floating point computing power when solving a dense  $N \times N$  system of linear equations,  $Ax = b$ , using Gaussian elimination with partial pivoting. The number of floating point operations is known,  $\frac{2}{3} * N^3 + 2 * N^2$ , needing only execution time to be measured to determine flops.

To rank systems for the TOP500, HPL is run for different matrix sizes to find the maximal performance,  $R_{\max}$  at  $N_{\max} \times N_{\max}$  matrix size. The peak performance of the system,  $R_{\text{peak}}$ , is also reported. In addition to these, the metric  $N_{1/2}$  is calculated as the matrix dimension where half of the performance ( $R_{\max}/2$ ) is achieved. This metric is reminiscent of the famous  $N_{1/2}$  metric created by Hockney and Jesshope [7] to convey the efficiency of vector pipelined architecture. Here  $N_{1/2}$  refers to the vector length at which half of the theoretical peak vector pipeline performance is achieved.

Larger values mean the vector hardware has a harder time amortizing the pipeline startup costs.

There has been controversy over the years in the use of flops as a single overall parallel performance metric. Some argue that it overemphasizes the importance of floating point operations and obscures other factors more relevant to the resulting performance. There have also been questions about the use of LINPACK as a benchmark for ranking HPC machines because it represents only a particular type of parallel code. Such is the nature of benchmarking.

Other benchmarks have been created to address these concerns. The NAS parallel benchmarks [2] and the SPEC HPC benchmarks [11], among others, provide a variety of parallel codes for evaluation. They support *base* experiments and *tuned* experiments where different optimizations are allowed. The focus is on scientific computing and the primary metric is still flops. However, they also calculate what might be called *workload metrics* as a formula of the different benchmark results, for example, a geometric mean in the case of SPEC HPC.

The HPC Challenge benchmark [8] is different in that it was created to measure a broader spectrum of factors for performance evaluation. Certainly, flops is a metric for certain HPCC codes, but memory and communication bandwidth metrics are targeted with others, to gain a better sense of the capacity of the parallel system. To drill down more on memory performance, one benchmark code calculates billions of integer random updates to memory per second, called *GUPS*. Random memory performance is often a limiter to overall application performance because locality of reference is poor.

## Tuning Metrics

Metrics provide a means to characterize what, how, and where performance is manifested in parallel execution. Derivative and parallel metrics further quantify performance factors and give means to evaluate parallelism effects. As the goal of parallel computing is to deliver performance returns, there is strong interest optimizing applications. Tuning the performance of a parallel application is an iterative process consisting of several steps involving the identification and localization of inefficiencies, instigating their repair, and validating performance improvement.

The idea of *tuning metrics* is to represent the inefficiencies that result in performance degradation so that the critical ones can be targeted and tuning methods can be selected. It is typical to speak of these inefficiencies as *performance bottlenecks* and the process of characterizing and prioritizing bottlenecks as *bottleneck analysis*. Depending on the parallel computational model and parallel programming approach (e.g., shared memory multi-threading or distributed memory message passing), different performance bottlenecks will result. The goal is to find tuning metrics that help in bottleneck analysis.

For instance, tuning methods for task-based parallel programs might apply *critical path analysis* techniques to find the path of parallel execution events that takes the longest time to execute. If optimizations can be made along this critical path to reduce its overall execution time, the parallel performance overall will be improved. However, the critical path may change as a result, meaning that any further improvements with respect to the original path will be ineffective. Critical path analysis can be applied to multi-threaded and message passing programs [12].

Tuning metrics include synchronization overheads, communication delays, and other costs associated with parallel execution. Ordering of severity of these metrics can guide where optimization focus should be applied. Optimal large-scale parallel performance depends strongly on minimizing waiting time across the parallel system. Here, *load balance* is an important metric to consider, but it is a difficult one to actually measure directly.

It should be kept in mind that performance metrics used for tuning are representing complex interactions between multiple performance factors at the algorithm, software, hardware, and system levels. Diagnosing performance problems requires metrics to identify source of inefficiencies, and applying optimizations can change performance effects, requiring further tuning iterations.

## Summary

Parallel computing is an endeavor to improving performance through the use of parallel resources. To evaluate, characterize, diagnose, and tune parallel performance, it is necessary to quantify performance information in forms for critical review. This is the role of metrics.

## Definition

MILC is an acronym for MIMD Lattice Computation and is both the name of a long enduring physics collaboration, that is, the MILC Collaboration, and the code and the lattice gauge configurations that the MILC collaboration makes publicly available, that is, the MILC code and the MILC configurations, respectively.

## Discussion

### History of the Collaboration

The MILC collaboration was established in 1990. The original members of the collaboration were Claude Bernard, Thomas DeGrand, Carleton DeTar, Steven Gottlieb, Alex Krasnitz, Michael Ogilvie, Robert Sugar, and Doug Toussaint. Many postdocs and students have joined the collaboration, and more senior members joining later include Urs Heller, Jim Hetrick, and James Osborn. Additional members can be found at the collaboration Web site [1] or by consulting the list of publications [2].

### Physics Goals

Physicists know of four fundamental forces in Nature. They are gravitation, the electromagnetic force, the weak force, and the strong force. The Standard Model of Elementary particle physics describes the latter three forces as gauge theories [3]. For a gauge theory, the forces are determined by a symmetry group. The electromagnetic symmetry group is called  $U(1)$  and the theory is called quantum electrodynamics (QED). The charge of the electron is small and allows an expansion in powers of the charge. This expansion is called perturbation theory. The electromagnetic and weak forces are closely related and the combined theory, called the

electroweak theory, is described by the symmetry group  $SU(2) \times U(1)$ . The combined theory can also be treated by perturbation theory. Applications of perturbation theory to QED date to the 1940s.

For the strong force, the symmetry group is  $SU(3)$  and the theory is called quantum chromodynamics (QCD). Because this force is so strong, perturbation theory is not able to treat many of the interesting phenomena. The MILC Collaboration studies quantum chromodynamics (QCD) using the technique of lattice gauge theory. Lattice gauge theory was formulated by Kenneth Wilson in 1974 [4]. The lattice formulation of a quantum field theory allows a nonperturbative treatment of the theory, which is necessary for QCD and other theories with a strong coupling. According to QCD, matter consists of spin-1/2 particles that are called quarks. There are six different types of quarks and they bind together in combinations of three quarks (called baryons) or as quark-antiquark pairs (called mesons). The MILC collaboration studies the spectrum and decay properties of such bound states [5]. MILC also studies the properties of strongly interacting matter at very high temperature as existed in the early universe very shortly after the Big Bang.

### Characteristics of Lattice QCD as a Computational Problem

Lattice gauge theories are generally formulated on a regular hypercubic grid of points in space-time. Denote the grid size as  $N_s^3 \times N_t$ , where there are  $N_s$  grid points for each spatial direction and  $N_t$  grid points in the time direction. The spacing between grid points is denoted  $a$ , using units in which the speed of light  $c = 1$ . To get accurate results, the limit  $a \rightarrow 0$ , called the continuum limit, must be taken.

The variables that describe the quarks are multicomponent fields located at the grid points. There are several different ways to formulate the theory for quarks. The most compact method, called staggered or Kogut-Susskind quarks [6], has three complex components:  $\chi^i$ , where  $i = 1, 2, 3$ . The three components correspond to the symmetry group  $SU(3)$  of QCD. Another formulation, used in the original paper of Wilson [4], more closely mimics the original Dirac formulation of fermions used in QED and has a second spinor index on the quark field:  $\psi^{\alpha i}$ , where  $\alpha = 1, 2, 3, 4$  and  $i$  is as before. The MILC code supports calculations with either type of field.

The variables that describe the gauge fields are called gluons in QCD and are the analog of the photon in QED. In the continuum theory, these variables are elements of the Lie algebra of the symmetry group; however, in the lattice theory, elements of the symmetry group itself are used. In the case of the QCD, the gauge fields are  $3 \times 3$  complex, unitary matrices with unit determinant, that is, elements of  $SU(3)$ . There is one such element for each link connecting nearest neighbor grid points. If  $x$  is a grid point in space-time and  $\hat{\mu}$  is a unit vector in one of the four directions, then denote the matrix as  $U(x, x + \hat{\mu})$  or  $U_\mu(x)$ . There is a very important property of these variables that  $U(x, y) = U^\dagger(y, x)$ , where  $\dagger$  denotes the adjoint or transpose conjugate. Thus, links where  $y$  is a neighbor in a negative direction from  $x$  can be expressed in terms of a matrix based at  $y$ . That is,

$$U(x, y = x - \hat{\mu}) = U^\dagger(y, x) = U^\dagger(y, y + \hat{\mu}) = U_\mu^\dagger(y).$$

Thus, only the matrices corresponding to links oriented in the positive directions are stored.

To summarize, at each grid point, four  $3 \times 3$  complex matrices that describe the gluon or gauge fields of QCD are stored. The quarks are described by 3- or  $3 \times 4$ -component complex fields. In Nature, there are six different types of quarks labeled  $u, d, c, s, t$ , and  $b$ . This label has been given the fanciful name flavor. The lightest three quarks  $u, d$ , and  $s$  are most important in the calculations because they are light enough that they can spontaneously appear and disappear from the vacuum as quantum fluctuations. Quark flavors whose vacuum fluctuations are included in the calculation are said to be dynamical quarks. The  $t$  and  $b$  quarks are much too heavy for this effect to be significant for them. Calculations including a dynamical  $c$  quark are just starting to be explored. A quark or antiquark that appears in a bound state whose properties are studied is called a valence quark. All the quarks except for  $t$  have been treated as valence quarks. (The  $t$  quark decays too quickly to form bound states.) Special techniques are needed to treat the valence  $c$  and  $b$  quarks because they are so much heavier than the  $u, d$ , and  $s$  quarks [7].

In lattice QCD the partial differential equations of the continuous theory become finite difference equations on the grid of space-time points. The computations are very easy to vectorize or to parallelize. The MILC code is designed for parallelization via domain

decomposition [8, 9]. Contiguous blocks of grid points are assigned to each node or core of a parallel computer. The MILC code has only one level of hierarchy at present. Below, the word node is used for what is generally each MPI process or core of a job. Each node will be responsible for updating the variables that are stored at all the grid points “owned” by that node. Because of the finite difference equations, updating a variable stored at a site will require knowledge of variables stored at neighboring sites. However, there is one important feature of the gauge symmetry that is essential to QCD. In the finite differences that appear in place of derivatives, one cannot just subtract the values of fields at neighboring grid points; one must first “parallel transport” a field to a neighboring site by multiplying by the gauge matrix  $U$  corresponding to the link joining the sites. Thus,  $\chi(x) - \chi(y)$  is not valid and one would need to compute  $\chi(x) - U_\mu(x)\chi(y)$ , if  $y = x + \hat{\mu}$ , in order to maintain the gauge symmetry of the theory. In practice, this means there are many instances of multiplication of 3- or  $3 \times 4$ -component vectors by  $3 \times 3$  matrices. This allows for some data reuse in what is otherwise a sparse problem. It also encourages the programmer to develop a library of routines that operate on matrices and vectors.

The other issue of dealing with finite differences and domain decomposition is that it is necessary to take into account the possibility of a neighboring value possibly being off-node. In the MILC code, this is dealt with via messaging and setting of pointers. The programmer is shielded from the bother of distinguishing between on-node and off-node neighbors. Three routines are used when accessing values from neighboring grid points. They are start\_gather, wait\_gather, and cleanup\_gather. The initial development of the MILC code was done on the Intel IPSC/860 and Ncube 6400. These machines had long latencies compared with some of the other parallel machines available then. Thus, it was impractical to fetch a neighboring value for a single grid point. These calls are designed to fetch all of the off-node values in a particular direction for a needed field. Actually, because of red-black checkerboarding for many operations, there is also a choice of fetching only from red sites, black sites, or all sites. The code uses the notion of parity rather than checkboard color, and that notation is used below. An even site is one for which the coordinates of the grid point obey  $(x + y + z + t) \bmod 2 = 0$ .

The other sites are odd. Since the same operations are going to be carried out on each site of the grid (or each site of one parity), it is efficient to get all off-node values with a single message from any other node that “owns” (some of) the required data. The start\_gather routine checks to see which data is needed from off-node, and which data this node owns that will be required by other nodes. It allocates buffers for each of the messages that are expected from other nodes and posts the receives. It gathers up the data that will be required by each neighboring node and sends it off. The routine also sets up a pointer for each grid point that either points to the normal on-node location of an on-node neighbor value, or to a location in the message buffer that will contain a message with the data from a neighboring node. Before the neighboring values are accessed through the pointer, the programmer must wait for the wait\_gather routine to return. If possible, other useful work can be done before the call to wait\_gather in order to overlap communication and computation. The routine cleanup\_gather frees the buffers allocated for the messages. Early on it was recognized that a significant amount of time was spent setting up the pointers, so restart\_gather was added to repeat a previous gather reusing the same buffers thus eliminating the need to recalculate the pointers or allocate space for the buffers. (This call is now obsolete, and the feature is subsumed by another routine that hides this from the application programmer.)

Through the use of the routines described above, the application programmer is freed from the burden of dealing with calls to MPI or knowing which grid points have off-node neighbors or which node contains the off-node neighbor. All the information about the domain decomposition is contained in a set of layout routines used in the initial setup routine that allocates the space for the grid of sites. The number of nodes on which a job will run is determined at run time rather than being fixed at compile time. In the original code, a site structure for each grid point contained all of the needed physical variables and some extra information about the layout. The setup routine allocates an array of sites called lattice.

## Coding Style and Examples

A brief introduction to the code with only enough detail to show some snippets of code that loop over lattice sites

and gather values from neighbor sites follows. More complete documentation is available online [10] or in the doc subdirectory of the code distribution. Topics to be discussed include: global variables, data types, site structure, moving around on the lattice, macros, and gathers.

## Global Variables

A number of variables are used so often that they are declared as globals. Each application has an include file lattice.h part of which is below.

```
/* Definition of globals */

#ifndef CONTROL
#define EXTERN
#else
#define EXTERN extern
#endif

/* The following are global scalars */
EXTERN int nx,ny,nz,nt;
/* lattice dimensions */
EXTERN int volume;
/* volume of lattice = nx*ny*nz*nt */

/* Some of these global variables
 are node dependent */
/* They are set in "make_lattice()" */
EXTERN int sites_on_node;
/* number of sites on this node */
EXTERN int even_sites_on_node;
/* number of even sites on this node */
EXTERN int odd_sites_on_node;
/* number of odd sites on this node */
EXTERN int number_of_nodes;
/* number of nodes in use */
EXTERN int this_node;
/* node number of this node */
```

In practice, only the file that contains the main function, always called control.c, defines the variable CONTROL, in which case EXTERN is null and the storage for the global variables is allocated there. In all other files, EXTERN becomes extern, and it is possible to access the global variables. The comments should clarify the meaning of these variables.

## Data Types

In order to be able to conveniently compile for either single or double precision, complex variables are defined in include/complex.h as follows:

```
/* generic precision complex number
 definition */
/* specific for float complex */
typedef struct {
 float real;
 float imag;
} fcomplex;

/* specific for double complex */
typedef struct {
 double real;
 double imag;
} dcomplex;

#if (PRECISION==1)
#define complex fcomplex
#else
#define complex dcomplex
#endif
```

In include/su3.h, these definitions are used to define complex matrices and vectors.

```
typedef struct { fcomplex e[3][3]; } fsu3_matrix;
typedef struct { fcomplex c[3]; } fsu3_vector;
typedef struct { dcomplex e[3][3]; } dsu3_matrix;
typedef struct { dcomplex c[3]; } dsu3_vector;
#if (PRECISION==1)
#define su3_matrix fsu3_matrix
#define su3_vector fsu3_vector
#else
#define su3_matrix dsu3_matrix
#define su3_vector dsu3_vector
#endif
```

In this way, the application programmer can use complex, su3\_matrix, and su3\_vector, and at compile time the value of PRECISION will determine whether single or double precision is used.

There are additional datatypes to deal with Wilson (4-component) quarks. Details can be found in the documentation. The include files complex.h and su3.h also contain prototypes of many functions that use the datatypes just defined.

## Site Structure

The file lattice.h also defines a “site” structure that contains all the physical variables needed at each grid point. This is convenient in that the programmer only has to add another structure to the list, and then all variables are allocated with one call to malloc in a fairly standard setup routine. The section on “Evolution of the Code” describes a disadvantage of this approach. Here is a simple example of a site structure that only contains the gauge matrices and two other matrices and two su3 vectors.

```
typedef struct {
 /* The first part is standard to all
 programs */
 /* coordinates of this site */
 short x,y,z,t;
 /* is it even or odd? */
 char parity;
 /* my index in the array */
 int index;
 /* Now come the physical fields,
 program dependent */
 /* gauge field */
 su3_matrix link[4];
 su3_matrix tempmat1,staple;
 su3_vector phil, phi2;
} site;

/* The lattice is a single global
 variable - (actually this is the
 part of the lattice on this node) */
EXTERN site *lattice;
```

In the file generic/make\_lattice.c there is a function make\_lattice that allocates space for the lattice and for pointers that are used by the gather routines. The variables such as coordinates, parity, and index defined in the site structure are also set up there.

```
void make_lattice() {
 register int i;
 /* scratch */
 short x,y,z,t;
 /* coordinates */
 /* allocate space for lattice, fill
 in parity, coordinates and index */
 node0_printf("Mallocing %.1f MBytes
per node for lattice\n",
 (double)sites_on_node
 * sizeof(site)/1e6);
 lattice = (site *)malloc
(sites_on_node
 * sizeof(site));
 if(lattice==NULL) {
 printf("NODE %d: no room for
lattice\n",this_node);
 terminate(1);
 }

 /* Allocate address vectors */
 for(i=0;i<N_POINTERS;i++) {
 gen_pt[i] = (char **)malloc
(sites_on_node*sizeof(char *));
 if(gen_pt[i]==NULL) {
 printf("NODE %d: no room for
pointer vector\n",this_node);
 terminate(1);
 }
 }

 for(t=0;t<nt;t++) for(z=0;z<nz;z++)
 for(y=0;y<ny;y++) for(x=0;x<nx;x++) {
 if(node_number(x,y,z,t)==mynode()) {
 i=node_index(x,y,z,t);
 lattice[i].x=x; lattice[i].y=y;
 lattice[i].z=z; lattice[i].t=t;
 lattice[i].index =
x+nx*(y+ny*(z+nz*t));
 if((x+y+z+t)%2 == 0)
 lattice[i].parity=EVEN;
 else
 lattice[i].parity=ODD;
 }
 }
}
```

## Moving Around on the Lattice

In the code above, each node is performing a loop over the entire lattice volume, not just over the sites on the node. Two utility functions defined in the layout routines `node_number(x,y,z,t)` and `node_index(x,y,z,t)` return which node a grid point is assigned to and which index it has on the node to which it is assigned. The value of `lattice[i].index` is this site's position in the entire grid, not just the part of the grid assigned to this node. The code shows how to access any variable that is part of the site structure. An alternative access scheme is based on pointers.

```
site *s;
s=&(lattice[i]);
s->x /* is now a pointer to variable
lattice[i].x whose value is the
x coordinate of that grid point */
```

## Macros

Loops should not normally iterate over the whole lattice volume. They should be restricted to the sites on a node, or the sites of one parity on that node. Also, a function that operates on a vector field may sometimes need to use `phi1` as input and other times `phi2`. However, C does not allow the name of a structure member to be passed as an argument. There are macros defined in `include/macros.h` to simplify the coding.

To simplify the loop over the sites on each node, four macros are defined.

```
/* Standard red-black checkerboard */

/* macros to loop over sites of a
 given parity.
Usage:
 int i;
 site *s;
FOREVENSITES(i,s) {
 commands, where s is a
 pointer to the current site
 and i is the index of the
 site on the node
}
*/
#define FOREVENSITES(i,s) \
 for(i=0,s=lattice;
```

```
i<even_sites_on_node;i++,s++)
#define FORODDSITES(i,s) \
 for(i=even_sites_on_node,
 s = &(lattice[i]);
 i<sites_on_node;i++,s++)
#define FORSOMEPARITY(i,s,choice) \
 for(i=((choice)==ODD ?
 even_sites_on_node : 0), \
 s= &(lattice[i]); \
 i< ((choice)==EVEN ?
 even_sites_on_node :
 sites_on_node); \
 i++,s++)
#define FORALLSITES(i,s) \
 for(i=0,s=lattice;
 i<sites_on_node;i++,s++)
```

In each case, loop is restricted to the required sites, and either the integer `i` or the pointer `s` can be used to navigate as described above.

To deal with the issue of not being able to pass the identifier of a structure member, two new concepts “field offset” and “field pointer” are defined. The macros to implement them are also in `macros.h`.

```
/* "field offset" and "field pointer" */

/* used when fields are arguments
 to subroutines */
/* Usage: fo = F_OFFSET(field),
 where "field" is the name of a field
 in lattice.

 address = F_PT(&site , fo),
 where &site is the address of the
 site and fo is a field_offset.

 Usually, the result will have to be
 cast to a pointer of the
 appropriate type.

 (It is naturally a char *).

*/
typedef int field_offset;
#define F_OFFSET(a) \
 ((field_offset)((char *) \
 &(lattice[0]. a))-((char *) \
 &(lattice[0])))
#define F_PT(site , fo)
 ((char *) (site) + (fo))
```

## Gathers

The discussion above, of gathering data from a neighboring site, can now be illuminated with an example. The trace of the product of the four link matrices going around each elementary square of the lattice is a useful quantity. This must be summed over all squares. The two cases of the square being in a purely spatial plane or a plane with time and a spatial direction are treated separately in the following code. Each square is defined by two perpendicular directions and the corner with the smallest coordinates. If  $\hat{\mu}$  and  $\hat{\nu}$  are two different unit vectors, the corners of the square are  $x$ ,  $x + \hat{\mu}$ ,  $x + \hat{\nu}$ , and  $x + \hat{\mu} + \hat{\nu}$ . Traversing the edges of the square starting in the  $\mu$  direction, the expression becomes

$$\text{Tr}(U(x, x + \hat{\mu})U(x + \hat{\mu}, x + \hat{\mu} + \hat{\nu})U(x + \hat{\mu} + \hat{\nu}, x + \hat{\nu})U(x + \hat{\nu}, x)).$$

This can be reexpressed in our other notation as

$$\text{Tr}(U_\mu(x)U_\nu(x + \hat{\mu})U_\mu^\dagger(x + \hat{\nu})U_\nu^\dagger(x)),$$

or, using the cyclic property of the trace, as

$$\text{Tr}\left(U_\nu^\dagger(x)U_\mu(x)U_\nu(x + \hat{\mu})U_\mu^\dagger(x + \hat{\nu})\right).$$

To complete the calculation based at site  $x$ , link matrices based at two nearest neighbor sites are needed. However, from the last expression it is clear that the first matrix multiplication with data that is local to site  $x$  can be done. That work is done while waiting for the messages to arrive.

Below is part of the code generic/plaquette4.c to accomplish this task. A detailed explanation follows the code.

```
void plaquette(Real *ss_plaq,
Real *st_plaq) {
/* su3mat is scratch space of
size su3_matrix */
su3_matrix *su3mat;
register int i, dir1, dir2;
register site *s;
register su3_matrix *m1, *m4;
su3_matrix mttmp;
Real ss_sum, st_sum;
msg_tag *mtag0, *mtag1;
ss_sum = st_sum = 0.0;

su3mat = (su3_matrix *)malloc(sizeof
(su3_matrix)*sites_on_node);
```

```
if(su3mat == NULL)
{
 printf("plaquette: can't malloc
su3mat\n");
 fflush(stdout); terminate(1);
}

for(dir1=YUP;dir1<=TUP;dir1++) {
/* dir1 plays role of mu */
 for(dir2=XUP;dir2<dir1;dir2++) {
/* dir2 plays role of nu */

 mtag0 = start_gather_site
(F_OFFSET(link[dir2]),
sizeof(su3_matrix),
dir1, EVENANDODD,
gen_pt[0]);
 mtag1 = start_gather_site
(F_OFFSET(link[dir1]),
sizeof(su3_matrix),
dir2, EVENANDODD,
gen_pt[1]);

FORALLSITES(i,s) {
 m1 = &(s->link[dir1]);
 m4 = &(s->link[dir2]);
 mult_su3_an(m4,m1,
&su3mat[i]);
}

wait_gather(mtag0);
wait_gather(mtag1);

FORALLSITES(i,s) {
 mult_su3_nn(&su3mat[i],
(su3_matrix *)
(gen_pt[0][i]),
&mtmp);

 if(dir1==TUP)st_sum +=
realtrace_su3
((su3_matrix *)
(gen_pt[1][i]),
&mtmp);
 else ss_sum +=
realtrace_su3
((su3_matrix *)
```

```

 (gen_pt[1][i]),
 &mtmp);
 }

 cleanup_gather(mtag0);
 cleanup_gather(mtag1);
}

g_floatsum(&ss_sum);
g_floatsum(&st_sum);
*ss_plaq = ss_sum /((Real)
(3*nx*ny*nz*nt));
*st_plaq = st_sum /((Real)
(3*nx*ny*nz*nt));

free(su3mat);
} /* plaquette4 */

```

Space is allocated for a field major variable su3mat that can hold one su3 matrix for each site. Then there are nested loops over the two directions that define the plane of the plaquette. The first step is to start the gathers of the two matrices that are based at nearest neighbor points. Note that the call is to start\_gather\_site. (See discussion under “►Evolution of the Code.”) In the first gather, F\_OFFSET is used to specify that the gathered link corresponds to direction dir2, the number of bytes to gather is sizeof(su3\_matrix), and values are gathered from neighbors in the direction dir1. Also, values are gathered from sites with both parities and the pointer array gen\_pt[0] will have the address of the neighbors’ data when the gather is complete. This call will create a “message tag” that has the information required by wait\_gather and cleanup\_gather. Its return value is the address of that data structure. In the second call, the roles of dir1 and dir2 are reversed and the pointer array gen\_pt[1] is used.

In the first FORALLSITES loop, m1 (m4) is set to the address of the link in direction dir1 (dir2), and then mult\_su3\_an is used to take the product of the adjoint link in direction dir2 with the link in direction dir1, and the result is stored in the array su3mat. Note that both the pointer s and index i are used in this loop. The program then waits for the two gathers to complete. Then the intermediate result su3mat can be multiplied on the right by the link pointing in direction dir2

gathered from neighbor dir1, which can now be found using gen\_pt[0]. Since there are no adjoints required, mult\_su3\_nn is used. Note that a single su3 matrix mttmp is used because the calculation of the trace is completed by the call to realtrace\_su3 before proceeding to the next site. In the call to realtrace\_su3, the first argument is the link whose address is in gen\_pt[1]. This routine calculates just the real part of the trace of the product of the adjoint of the first argument and the second argument. Finally, g\_floatsum is called, which is an application-specific global sum, saving the programmer from having to make a call to a specific message passing API, such as MPI. Actually, this code could be improved by doing a single call to g\_vecfloatsum, which would be more efficient. (This routine is not called that often.)

## Communication Options

The MILC code was developed before the advent of MPI and PVM. The initial platforms were the Intel iPSC/860 and Ncube 6400. By having a layer of application-specific calls between the programmer and the native message-passing calls, portability is greatly enhanced. All of the communication routines are contained in a single, target-specific file. In addition to the two targets just mentioned, there was initially code for the Intel iPSC simulator and the “vanilla” version that works with a single thread. Today, only com\_vanilla.c, com\_mpi.c, and com\_qmp.c (which is with the QMP message passing library defined by the USQCD software effort, described below) survive. The vanilla version of the code is remarkably useful for code development. It allows the programmer to develop and debug code in a serial environment that has all the correct syntax for parallel execution.

## Assembly Code Options

Many of the floating point operations within a QCD code involve  $3 \times 3$  matrices and vectors with multiples of 3 components. The code includes a library of such basic operations on matrices and vectors. To improve performance, some of the routines that take the most time are written in assembly code. At various times, assembly code has been developed for Intel i860, DEC Alpha, IBM RS6000, Cray T3D, Cray T3E, and Intel SSE. The code has been ported to the QCDOC special purpose computer. For the IBM Blue Gene/L and P, assembler

support is available through the USQCD libraries discussed below. Often the performance improvement from the assembly code is notable when the data is in the cache, but somewhat limited when the data must be fetched from memory.

### **Evolution of the Code**

The MILC code had its origins nearly 20 years ago and has evolved to include new applications and algorithms. It has also had to evolve to accommodate changes to computer architecture. One important change has been the widening of processor cache lines. The original MILC code was “site-major” in that all the variables for a given grid point or site are stored together. With a narrow cache line, at each stage of the calculation the required variables can be accessed from the site structure. However, as the cache line widens, an inefficiency arises when other variables are brought into the cache when they are not needed because they are stored next to the required data. The solution is to create “field-major” data that stores only a single type of variable, with one grid point’s data following another’s. Then there is the chance that data swept into the cache will be used when the code advances to do the calculation for the next grid point. Thus, the original start\_gather has been replaced with start\_gather\_site and start\_gather\_field, so the programmer can gather from either type of variable.

Around 2000, a second level of hierarchy was accommodated by use of OpenMP [11]. This was motivated by a computer that had eight processors, but a switch that only could support four MPI processes. This was not a notable success, but multithreading is being tried again as compilers have improved, and new computers such as the Cray XE6, Blue Waters and Blue-Gene/Q have or will have many more cores (or threads) that can be used in SMP mode. A port of the code to the IBM Cell Broadband Engine was done [12, 13] and work is ongoing to use GPUs as an accelerator [14, 15].

### **USQCD SciDAC Project**

The US Department of Energy under its Scientific Discovery through Advanced Computing (SciDAC) program [16] has been funding development of QCD code through the National Infrastructure for Lattice Gauge Theory project since 2001 [17]. This project unites developers from several of the major QCD groups in the

USA with the aim of sharing code to improve reliability, performance, and portability of QCD codes, and to reduce the barriers to development of new codes. The USQCD libraries [18] include QLA for basic linear algebra, QMP for application specific message passing, QIO for lattice-specific parallel input/output, and QDP for data parallel style computing that combines shifts from neighboring grid points and computation. There is also a QOP library that is highly optimized and (possibly) architecture specific. The MILC code has gradually been evolving to take advantage of these capabilities.

### **Availability of Code: Tutorials**

The MILC collaboration has made its code available to others for many years. In the beginning, the code was distributed on the basis of personal requests. The code is now distributed via a web page [1]. A mailing list has also been established at <http://denali.physics.indiana.edu/mailman/milccode>.

The documentation for the code is available at the site from which the code is distributed. There are also tutorials on the code prepared by Carleton Detar [19]. They include information about use of the SciDAC QCD libraries with the MILC code.

### **Use of MILC Code for Benchmarking**

The MILC code has been run on many parallel machines and is used for benchmarking by a number of organizations. When the Intel Paragon was being developed, slight inconsistencies in what should have been identical runs resulted in a redesign of the motherboards. The code became part of the hardware diagnostics. A MILC application su3\_rmd is part of the NERSC benchmark suite [20] used to evaluate potential purchases. It is also part of the SPEC 2006 CPU benchmark [21] and the SPEC MPI benchmark [22]. For the NSF Track 1 competition, which was won by the NCSA Blue Waters project [23], performance on a QCD problem supplied by members of MILC had to be analyzed by each applicant. The su3\_rmd application was used for this and will be part of the system tests.

### **Public Availability of Gauge Configurations: Gauge Connection, ILDG**

The MILC collaboration has also long made its gauge configurations available to other scientists.

Configurations including the effects of dynamical quarks are expensive to create, but they can be used for many physics projects once they are archived, so it makes sense to share this resource to make the best use of the public investment in the creation of the configurations. The Gauge Connection hosted by NERSC [24] was the initial repository of the configurations. More recently, the International Lattice Data Grid (ILDG) [25] has created a new standard format and a distributed collection of repositories. There are portals for the ILDG in Australia, Europe, Japan, the UK, and the USA. Many collaborations contribute configurations to the repository that are created using a variety of lattice actions.

## Bibliographic Notes and Further Reading

The MILC code is an application suite for lattice field theory. There is a vast physics literature on the subject. There has been an annual conference in the area for 25 years. For many years the proceedings were part of the Nuclear Physics B (Proceedings Supplement) series. Recently, the proceedings have been published online through Proceedings of Science (<http://pos.sissa.it>).

Several textbooks provide an introduction to lattice field theory and the algorithms that are used. They include:

*Quantum Fields on a Lattice*, I. Montvay and G. Münster, Cambridge, 1994; *Lattice Gauge Theories, An Introduction*, Third Edition, H. J. Rothe, World

Scientific, 2005; *Introduction to Quantum Fields on a Lattice*, J. Smit, Cambridge, 2002; *Lattice Methods for Quantum Chromodynamics*, T. DeGrand and C. DeTar, World Scientific, 2006; *Quantum Chromodynamics on the Lattice, An introductory presentation*, C. Gattringer and C. B. Lang, Springer, 2010.

The literature discussing the implementation and performance of lattice field theory codes is not as extensive as the physics literature. However, there is generally a Machines and Algorithms session at the annual Lattice conference. There have been a number of plenary reviews of computers built specifically for lattice QCD as well as articles about individual computers.

At the USQCD Web site [18], there are links to three other code suites Chroma, CPS, and FermiQCD that are publicly available. They are written in C++.

<sup>2</sup>Oak Ridge National Laboratory, Oak Ridge, TN, USA

### Definition

Distributed and parallel computing systems exist in many different configurations. We group them into six categories and show that the architectural characteristics of each category determines the type of application that will run most efficiently and scalability on these systems. Drawing the line between distributed and parallel systems is not easy because the definitions overlap and large systems combine aspects of both.

### Discussion

#### Introduction

Parallel and distributed computing share many traits and distinguishing the two is not easy. Usually, a sense of larger distances is associated with distributed computing, but many topics grouped under this term are relevant for parallel computing as well. Often specific systems are considered distributed computing systems,

e.g., computers working together and connected by the Internet. Instead of trying to define the two terms precisely, we will define classes of parallel computing systems, note their distinctions, and describe what applications and usage models are best suited for each class. We will order these systems according to their characteristics and will then be able to draw a line that separates distributed from what we would consider parallel computing. Nevertheless, since there is some overlap between classes of parallel computing systems, drawing that line of distinction will still leave some room for debate about what a distributed or a parallel computing system is.

### Parallel Computing Systems

Parallel computing has become pervasive and many different platforms exist to execute parallel programs. These platforms are available in the form of a machine that executes the parallel programs of a user, or more commonly, hidden behind a web interface in the form of a parallel service such as search or database access. This section defines six types of general-purpose parallel computing systems. Specialized parallel machines designed to execute one particular application have been built as well but will not be considered as part of the taxonomy described in this paper.

There are architectural differences between these systems that determine what these machines are used for. We will first look at several different parallel computing architectures and then explore the differences between them. After that we look at how these differences dictate usage, availability, performance, and construction (hardware and software).

### Volunteer Computing

Within any large collection of computers, there are usually a few machine that are idle or underutilized. In the 1980s, projects such as Condor enabled programs to use the networked computers in an office or a class room when they were idle. This allowed users to submit programs for execution during the night when these computers were not in use. With the growth of the Internet, the number of compute resources that may be idle and can be accessed remotely is now in the millions.

SETI@Home (Search for Extraterrestrial Intelligence) began in the mid-1990s to harness idle resources on the Internet. Personal computer owners, who want to volunteer some of their compute cycles, can download a screen-saver from the project home page. Whenever a computer is idle for a while, the screen-saver activates. Instead of just showing a moving graphic or blanking the screen, the SETI@Home screen-saver also contacts a centralized server and requests tasks to execute.

The goal of the SETI@Home project is to analyze radio signals from space and detect patterns that are not likely to occur naturally. For each work request, the server sends some data to the client to be analyzed. While the screen-saver is running, it processes the data, sends results back to the server, and requests more work, if it is still idle. Because users may interrupt the screen-saver or turn the computer off, the server keeps track of which data sets have been processed. It sends the same data set to multiple computers to ensure that at least one of them will finish the work, and it compares replicated work to make sure the results are valid.

The SETI@Home project became so successful in attracting volunteers that it could not keep all their computers busy anymore. A follow-on project called the Berkeley Open Infrastructure for Network Computing (BOINC) allows other projects to use volunteer resources. Currently running examples include protein folding, genetic linkage analysis, predicting the performance of quantum computers, finding weaknesses in cryptographic hash functions, creating a three-dimensional model of the Milky Way galaxy, and testing the sensitivity of climate models.

### Grid Computing

Grid computing became popular in the late 1990s. The term grid is used because, similar to an electric power grid, there are multiple producers and consumers which share their resources under predefined agreements. While one data center has surplus compute capacity after the workers leave for the day, another user may be able to buy these compute cycles. Certain operations or applications may perform faster on one type of computer, or can be executed more cheaply on another. The goal of grid computing is to bring consumers and producers together in an organized fashion that governs accounting and responsibilities. Most grid

users are both producers and consumers. While there are some similarities to volunteer computing, and the actual machines in use may be of the same types, grid computing is much more suitable for a commercial environment. Agreements to make a certain number of compute cycles, or type of system, or storage capacity available are formal and do not depend on the goodwill of anonymous users.

Some of the tools and methods used in volunteer and grid computing are similar and can be used interchangeably. However, grid computing differs from volunteer computing in that some of the systems in the grid are used for long-term storage and some resources, such as leased communication lines or particular systems, are dedicated. In volunteer computing, CPU-scavenging or cycle stealing is the norm, without guarantees when services will be available or a task will complete. In grid computing a certain level of Quality of Service (QoS) is expected.

Starting in about 2007, the term *cloud computing* started to be used. Cloud computing shares many similarities with grid computing, may be used in a grid, but also includes some aspects of volunteer computing and peer-to-peer networks. Whether the term will survive and what its exact definition will be seem to depend on the companies and organizations currently promoting and selling cloud computing systems.

M

### Cluster Computers

Cluster computing began in the late 1990s with systems cobbled together from commercial-of-the-shelf (COTS) components. These were typically PC computers with Ethernet connections located under a desk or on a shelving unit. Demand for clusters grew and commercial companies started to sell integrated turnkey systems. The individual computers that make up a cluster are now rack-able servers. On high-end systems Ethernet is replaced by faster and more costly networks such as Infiniband or Myrinet, and some clusters have redundant power supplies. The defining characteristic is that the individual parts can be bought separately and put together by an integrator in almost any fashion a customer requests.

Clusters reside in a single administrative domain. That means all the components that are part of a cluster are owned and managed by a single entity. Decisions

about what application to run on the cluster, who pays the electricity bill, and which individual user get access are made by a single organization. This differs from volunteer and grid computing which span multiple administrative domains. Frequently, some of the nodes that make up a grid are clusters.

Another difference to volunteer and grid computing is that a cluster usually consists of homogeneous components. The type and performance characteristics of CPUs, disks, memory, and network are either identical or compatible inside a single cluster. In a grid the resources are heterogeneous and one task of the system software for grid computing is to match the appropriate resource with the requirements of a given application. For example, if an application needs 64-bit x86 CPUs with at least 2 GB of memory, the system will not schedule that application on systems that lack these features. On the other hand, users of a cluster know its hardware characteristics and select or compile applications accordingly.

## Supercomputers

The term *supercomputer* is poorly defined but usually associated with high-end parallel systems. Because of their high degree of parallelism, these systems are sometimes called Massively Parallel Processors (MPP). Some of these machines fill large rooms, cost millions of dollars, and require huge amounts of electrical power and cooling. What distinguishes them from clusters is that they are designed as a single system, not built from individual, independent components. Early supercomputers used custom-built proprietary processors. That changed with the advent of high-performance general-purpose microprocessors. Today, supercomputers use the same processors that are used in desktop workstations and servers. The network of most of these machines is still custom and much more tightly coupled to the processor and memory subsystem than the COTS network cards that attach to PCs through an I/O bus. Often, multiple networks are present to serve specific functions: high-speed message passing, collective operations, file I/O, diagnostics, and administrative services. Although the line between a cluster and a supercomputer has been blurred, supercomputers stand out due to their higher-performing networks and their higher reliability.

Reliability in larger systems is a key factor that determines the *throughput* of a system. Throughput is how

many applications a system can finish in a unit of time. Supercomputers have dedicated hardware to monitor the whole system, sometimes use a dedicated network for diagnosis and control of components, and have the ability to work around failed components until they can be repaired. This is crucial for systems that exceed tens of thousand processors. With that many components, it is highly likely that at least one of them has failed at any given time, and locating and isolating these components cannot be done efficiently without a dedicated infrastructure and the necessary system software.

## Symmetric Multi Processors

The systems described so far are *distributed-memory* systems. The processors on a node have direct access to local memory, but to access data in the memory of a remote node, the data has to travel across a network in the form of a message before it can be used. Symmetric Multi processors (SMPs) are *shared-memory* machines. Each of the CPUs in an SMP can directly access all of the memory. We will see later that this allows the programming model to change. Instead of moving data to local memory before it can be accessed, SMP programming models can assume that the data is always accessible. Access time to the data may depend on which memory module holds the data.

Smaller SMPs use a memory bus that is used by all CPUs to access any of the memory attached to it. The cost, called *latency*, of accessing any memory location is roughly the same, no matter which CPU accesses which memory block. For larger SMPs, a single bus shared among all CPUs would be a bottleneck and a more sophisticated architecture, such as a crossbar switch, becomes necessary. When memory size and number of CPUs grow large, it becomes impossible to keep memory access times uniform. Non uniform Memory Architectures (NUMA) deal with this problem by keeping some memory local to a CPU. All of the memory is still accessible to all CPUs, but access times for non local memory is higher than the latency to access local memory.

When a large number of CPUs share a single memory, cache coherence becomes an issue which limits further scaling. Hardware to keep cache contents synchronized when many CPUs read and write the same memory location grows exponentially in size and cost. At some point the cost of keeping caches coherent becomes prohibitive. The only way to add more CPUs

to the system is by abandoning cache coherence and allow for non uniform memory access. That approach is taken by the supercomputers described in the previous section.

### Multicore Processors

The last few years have seen the arrival of multicore processors which combine multiple CPU cores on a single integrated circuit. Each core consists of registers, arithmetic and floating-point units, and all the other control logic that we are used to in individual CPUs. As long as Moore's law continues to hold, each new generation of integrated circuits will contain twice as many transistors as the generation eighteen months ago. Since pipelining and superscalar designs are reaching their limits, multiplying the number of cores on an integrated circuit is a fairly simple way of making use of the ever increasing number of transistors available. Parallel programming is difficult and a single more powerful CPU would be preferable. Physical limits, however, force CPU manufacturers to provide their customers with parallel systems on a chip.

The number of cores per processor is increasing and how the cores share memory ports and caches is evolving. With two or four cores it is common to give each core an L1 cache, and share the L2 cache and the ports to memory. With larger numbers of cores, multicore processors face some of the same problems that limit scaling of SMPs. Newer multicore designs will share L2 caches among groups of cores and use a Network on Chip (NoC) to connect the groups to each other and to the available memory ports. In other words, each multicore processor can be an SMP, a distributed memory system, or a combination of the two.

It should be clear by now that multicore processors are parallel systems with many properties in common with SMPs and even distributed memory systems when the number of cores grow large enough. Processors with hundreds of cores are predicted and finding ways to efficiently program these devices is currently occupying the research community and shares many traits with programming the other parallel systems discussed in this section.

### A Spectrum of Parallel Computing Systems

In this section we briefly introduced several different parallel computing platforms. While there are many similarities between them, there are major differences

that make each platform suitable for specific applications and the way they are used. In the next section we will look at the differences in more detail. In the section after that we will investigate how these differences impact various aspects of parallel computing.

We categorized these systems by describing them at a fairly high level of abstraction. In reality, most existing systems span multiple categories and cannot always be assigned to one or another category so easily. For example, volunteer computing makes use of desktop computers, but many of those computers now contain multicore processors. Sometimes they contain two or more multicore processors which make them multicore SMPs. Similarly, the nodes in a computational grid are often clusters or supercomputers. Programming these systems is difficult and different aspects have to be taken into consideration when matching an application to a class of parallel compute system.

### Difference in Architectural Characteristics

We have identified six major classes of parallel computing systems. There are many similarities among these systems, but some architectural differences exist that are important indicators for what uses and type of applications a system is most suitable. We will see that the classes of parallel computing systems can be arranged along axes that have a crucial impact on the use of these systems. One example of such an axis is physical distance between processing elements. In volunteer computing the individual processors can be spread out across the whole world and communication delays are measured in milliseconds and seconds. Sometimes the individual computers participating in a volunteer effort are turned on only at certain hours of the day. This increases response delays to hours. At the other end of the spectrum are multicore processors where a signal from one core to another has to travel fractions of a millimeter. We will now look at several such characteristics that differentiate parallel computing systems.

### Network

Volunteer computing and most grids use the Internet to connect processors into a parallel computer. Geographical distances may be large and the speed-of-light limit for electrical signals comes into play, especially with satellite links. The high overhead of network protocols such as TCP/IP, congestion along links, and slow routers

limit the bandwidth that can be achieved and impose millisecond latencies or higher.

Moving to clusters and supercomputers, latencies drop to microseconds and bandwidth improves because data has to travel shorter distances and higher capacity links are available. The network topology connecting the processing elements also changes: from the seemingly random graph of the Internet to structured topologies such as 2-D and 3-D meshes, trees, and hypercubes. These topologies provide higher *bisection bandwidth*. It is measured by letting half of the processors in a parallel computer communicate simultaneously with the other half. Assignment to each half is done such that as few links as possible must carry all the traffic. The rich topologies of clusters and supercomputers provide a much higher bisection bandwidth than the Internet where often low-speed links have to be shared among many end points.

Moving to SMPs and multicore computers, latency, bandwidth, and bisection bandwidth further improve. Data can now be shared in memory and latencies to access that data drop to nanoseconds.

How the source and the destination of a data transfer are addressed also changes as we move along the hierarchy. For volunteer and grid computing, each processing element has its own IP address which the routers of the Internet use to direct data packet to the correct destination. Clusters sometimes use the same mechanism, but supercomputers use the location of a node within the structured topology to send data to it. Instead of an address that needs to be decoded and interpreted, supercomputers use directions such as “two up and three to the left” in a 2-D grid. This makes routers simpler and faster. SMPs and multicore which have shared memory use memory addresses to access data. Very fast hardware decodes an address and accesses the appropriate memory location.

CPUs can use memory addresses directly with their load and store instructions. Moving traffic using turn-by-turn directions or determining at what IP address a particular computer resides requires hundreds to tens of thousands of CPU cycles.

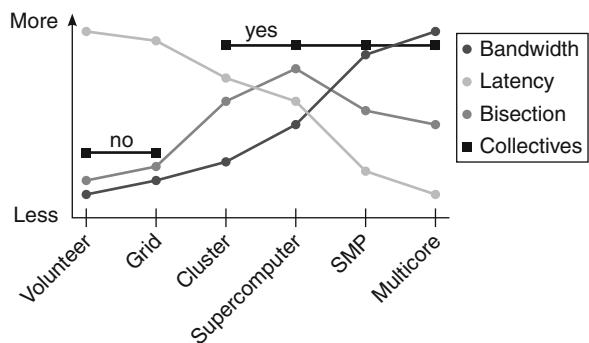

Sometimes it is necessary to distribute data from one processor to all others participating in a parallel computation. This is called a *broadcast*. In a *multicast*, data gets distributed to a select subset of the processors participating in the computation. More complex collective

operations are possible, for example, *reductions* for finding the largest value among the data each processor contributes. These operations are simple memory-to-memory copies in multicore processors and SMPs. Supercomputers sometimes have specialized hardware and a separate network for these kinds of operations. In clusters these operations become more expensive and on the Internet they require a lot of additional bandwidth and latency.

[Figure 1](#) illustrates the network characteristics of the six categories of parallel systems we are considering. We move from left, from the least integrated systems, to the right where we find the most integrated and tightly coupled systems. Doing so, data access latencies decrease, and bandwidth and bisection bandwidths increase. We will later see that the systems to the far right have fewer processors and fewer connections between them. Although the bandwidth keeps increasing, the bisection bandwidth is limited by the number of connections and therefore drops as we move from supercomputers to SMPs and multicore processors.

## Network Interface

Above we have described various network characteristics, but we have not discussed how processors are connected to the network. The network interface is a crucial component in a parallel system. In SMP and multicore systems no network interface is used to access data in memory. Instead, the role of the network interface is

**MIMD (Multiple Instruction, Multiple Data) Machines.**

[Fig. 1](#) Different parallel systems have different network characteristics. No specific values are assigned to each data point since variations in each parallel platform category are large. The data points and lines are meant to show trends

played by the memory controller. Both SMP and multicore systems may have, in addition, network interfaces if they are part of a larger parallel computer such as a cluster or a grid. However, in this section we are concerned with the functions provided by the interface between processor and the data that resides on other processors. For SMP and multicore processors, that interface is the memory controller, and for all other platforms it is the network interface.

We used bandwidth and latency to characterize the networks described in the previous section. Network interfaces are often described using the same metrics. However, it is important to see that these metrics may be different for network interfaces and the links in the network. In some cases the links in a network have a higher bandwidth capacity to accommodate multiple network interfaces.

The name interface suggests two sides: the connection to the network and the connection to the local processors. For the Ethernet cards used in volunteer and grid computing, there is a single connection from the interface to the network. (There can be multiple interfaces connecting a single machine to the network, though.) This is usually true for cluster computing as well, but supercomputers tend to integrate the network interface with a router that has multiple connections to the network. This makes it possible to build the different network topologies seen in these machines. If the interface supports it, data may move through it at multiple times the bandwidth of a single network link, if the routing algorithm makes use of more than a single link into the network. SMP and multicore interfaces, the memory controllers, connect to a memory bus or a switched network that directs data traffic to the appropriate memory bank.

The other side of the interface connects directly to the processors in the case of a memory controller for an SMP or multicore CPU. In supercomputers, the network interface is often connected to the memory bus giving it direct and low-latency access to memory. In clusters and systems that use commodity network interfaces, the interfaces are connected to an I/O bus and treated similarly to other I/O devices in the system.

In addition to bandwidth and latency, *message rate* is another important measure for network interfaces. Although latency may be low in some interfaces, it may not be possible to send another message right away. This

gap between messages limits how many messages can be sent per second. Message rate is determined by latency and the processing capabilities of the system and the network interface. Generally, moving from volunteer computing to multicore CPUs, message rate increases.

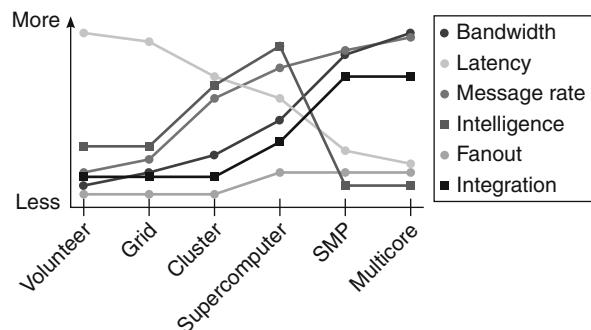

Simple Ethernet interfaces process one packet at a time and have very few additional capabilities. Sophisticated supercomputer network interfaces are small computers themselves with an embedded processor, memory, and fast data-movement hardware to connect to the network and the local memory. The network interface processor can be programmed to make decisions on where in memory to deliver a data packet, how to deal with errors in the network, and even implement collective operations. While the network processor is doing all that, the main CPU is free to continue its application processing.

**Figure 2** shows the trends for network interface characteristics for each class of parallel system we are investigating. Fanout means the number of connections between a network interface and the network. The line labeled intelligence describes the processing capabilities of the network interfaces. Integration indicates how close an interface is to local memory or the CPU.

M

## Remote Data Access

For SMP and multicore systems, accessing data associated with another processor is a simple load or store instruction that can be executed by the processor directly. For all other parallel architectures, remote data access implies sending and receiving a message

**MIMD (Multiple Instruction, Multiple Data) Machines.**

**Fig. 2** Different parallel systems have different network interface characteristics

that contains the data. These two access methods dictate which programming model is most suitable for them.

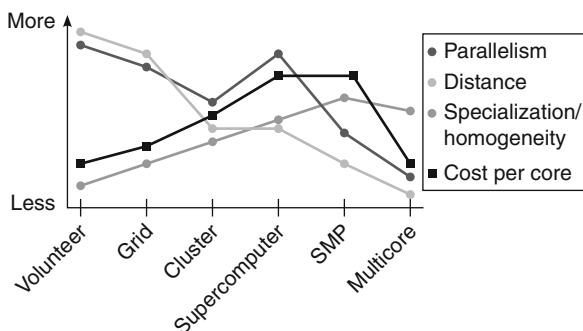

The latency and bandwidth at which remote data can be accessed depend on the access method (load/store or data transmission), and in the case of message passing, the performance and geographical distance of the network. Bulk data transfers benefit from higher bandwidths and are less affected by the latency of a network.

### Other Differences

There are several other differences between these parallel computing systems that are not directly related to their architecture. One of them is size, i.e., the number of processing elements and therefore the amount of available parallelism. In principle, volunteer computing could attract the largest number of processors to solve a particular problem. However, it is not common to gather more than a few thousand computers at a time to work on a single problem. The largest supercomputers have hundreds of thousands of processors and millions are expected in the next few years. SMPs and multicore processors configured internally as an SMP are limited to a few tens by their architecture. In larger multicore processors, the hundreds of cores will use a NoC to exchange data.

We have already mentioned geographical distance which grows smaller and allows faster data access as we move from volunteer and grid computing to multicore processors. [Figure 3](#) illustrates the trends.

Specialization and homogeneity increase moving from volunteer computing to multicore processors. Volunteer computers are of different brands and type, their

**MIMD (Multiple Instruction, Multiple Data) Machines.**

**Fig. 3** Various differences among parallel systems

peripherals differ, and their main purpose is most likely desktop computing. The compute nodes of a supercomputer are homogeneous and the only peripheral is the network interface. Additional nodes, sometimes of a different design, are responsible for I/O and user interactions. Most clusters are homogeneous, but some are built from whatever parts are available. Multicore processors today are homogeneous; all cores are of the same type. Future processors may include specialized cores mixed with general-purpose cores.

Cost per processing element varies. It is not zero for volunteer computing, since someone had to bear the purchase cost of the computer providing the “free” cycles. Since grids and clusters are purchased for a specific purpose and usually contain higher-performing computers and faster networks, their cost per CPU is higher. Supercomputer processors are expensive because of the cost of specialized network interfaces, high-performance network, and the infrastructure that integrates all the parts into a single, reliable system. Cost per processing element drops for multicore processors.

### Architecture Impact

The six major categories of parallel computing platforms differ in some crucial characteristics that determine how these systems are used and for which type of applications they are most suitable. For example, while purchasing multicore chips with a larger core count may be an economical way to increase parallelism, and allows for fast data access, the achievable level of parallelism is limited by the number of cores which technology permits on a single die. Volunteer computing can incorporate as many processors into a computation as are available, but geographical distance and network technology limits how fast remote data can be accessed. In this section we show how differences between these parallel computing platforms impact usage and available features.

### Application Type

*Master/slave* applications are well suited for volunteer computing. One process, designated the master, hands out tasks to computers that become available and ask for work to do. When a slave finishes its task, the master collects the results. It is the master’s role to coordinate tasks, for example, if one task depends on the results of another task. These types of applications are well-suited

for volunteer computing because the master can retry a task until at least one of the slaves finishes it. Note that this programming paradigm also works well on all other architectures discussed in this article. This is the case because the tasks are relatively independent and the limited communication does not tax the network. Systems with more powerful networks and faster data access can easily accommodate this style of computing, albeit at a higher cost.

Tightly coupled applications work better on tightly coupled systems such as SMPs and multicore processors. These types of applications work on a single set of data that is distributed across the memory of all participating processors. All of the tasks running on these processors perform the same operations, each on its portion of the data. Depending on the problem being solved, this may involve more or less communication with processors that are working on neighboring data elements. It is these communications, and the number and pattern of processors that need to communicate with each other, that determine how powerful the network must be for these applications to run efficiently.

## System Software

The system software controlling these systems and the services it provides depend on the type of the system. In volunteer and grid computing each computer runs a full-featured operating system (OS). The software to organize these computers into a parallel system is called *middleware* and runs on top of the OS, making use of its services.

In systems that are dedicated to running parallel applications, such as clusters and supercomputers, the OS is augmented and tailored to provide the services needed, such as message passing, and omits services that are not needed and may be disruptive e.g., email and printer servers. Some supercomputers use specialized lightweight OSs to limit administrative overhead and make resources more directly available to applications. In SMP and multicore computers a single instance of a full-featured OS controls all resources present.

## Programming Model

The programming model chosen to write an application depends on the problem to be solved as well as the platform that will execute the application. The two main

paradigms currently in use are explicit message passing and shared-memory programming. The former is well suited for applications that need to control where (in which memory) data resides and can coordinate data transfers such that the data is available locally when it is needed. Message passing maps well to the networked architectures, but also executes well on shared memory machines where the explicit mapping of data to memory regions often leads to better cache performance than when a compiler determines data layout.

Shared memory programming can only be done on SMPs and multicore processors, unless additional software layers transform memory accesses into data transmissions in distributed memory systems. Several shared-memory programming models provide higher levels of abstraction, but sometimes hide too much of the underlying architecture, such as memory layout, to reach the highest performance possible.

## Usage

The six different parallel computing platforms are used differently and for different purposes. The goal of *capacity* computing is to complete as many jobs in the shortest time possible, i.e., high throughput of jobs. This requires that enough processors are available to solve the problem and efficient scheduling such that all available resources are used.

Supercomputers and some SMPs are used for *capacity* computing. These systems were purchased to solve specific problems in the shortest amount of time possible. These *grand-challenge* problems cannot be solved on smaller or slower systems, at least not in a reasonable amount of time.

Supercomputers and most clusters are *space-shared*. Once nodes have been allocated to an application, the processors on these nodes only execute that application. In *time-sharing*, which is common on all other systems, other applications and tasks also run on the same processors. The OS accomplishes this by giving each process a small slice of time in round-robin fashion, creating the illusion that multiple processes run concurrently on the same CPU. Space-sharing lets an application progress faster since the compute resources are dedicated to that application. Time-sharing makes more efficient use of the available resources, but does not provide optimal performance for an application.

## Summary

The type of parallel platform influences what applications run well on it. In our spectrum from volunteer computing to multicore processors, applications that run efficiently on a network of volunteered compute resources run also well or better on more integrated and faster systems. Applications that run well on tightly integrated systems may not run well or scale to grid and volunteer computing. In general, cost increases as we move from volunteer computing to supercomputers. Cost for SMPs, depending on size, and multicore processors is lower than supercomputers, but the number of processing elements is limited.

In order to find the best system for a given parallel application, all factors, including architecture, performance, cost, and usage model, must be taken into consideration. Few systems are designed to run a single application or serve a single user. Therefore, compromises become necessary.

Distributed and parallel computing have many things in common. Volunteer and grid computing are usually considered distributed computing, while clusters and the other systems in the lineup are considered parallel computers. Many systems today are hybrids, such as clusters made up of SMP and multicore computers. This allows for a higher peak floating-point performance while keeping the cost reasonable. However, there are performance impacts, e.g., multiple CPUs/cores sharing a single network interface, and programming these multi-level parallel machines becomes more difficult.

## Future Directions

Parallel computing has moved from large supercomputers to the desktop. The amount of parallelism will increase with future generation processors and new programming models to make using these machines easier are being researched. Multicore processors will evolve to include specialized cores to accelerate floating-point performance and graphic processing for example. The number of processing units on these chips will continue to grow and they will begin to resemble SMPs, complete with non uniform memory access and complex networks connecting all components on the chip.

Clusters and supercomputers will continue to grow and eventually cross the exaflop barrier. Systems that

large will be plagued by component failures because of the sheer number of these components. This will require drastic measures to make the applications and the systems themselves more resilient to failures. System software will also evolve and be a crucial part to improve resiliency. Running a full-fledged OS on each of a million cores seems wasteful and may limit scalability. Research into lightweight OSs is progressing and may offer a solution to use these compute resources efficiently.

## Bibliographic Notes and Further Reading

Condor was an early software system that allowed harnessing idle cycles on a collection of workstations [7, 8]. A detailed description of Condor and its two-decade history can be found in [14]. An interesting early paper describes “worms” as a mechanism to distribute compute tasks across a set of available computers [11].

Just before the widespread use of cluster computers, a team at the University of California at Berkeley made the case for networks of workstations [3]. They built on the experience of Condor and other such projects, but felt that the larger amount of memory then available, the larger capacity, the reliability of redundant arrays of workstation disks, and the dropping cost of CPUs enabled more wide spread use of such systems.

Soon after, the first Beowulf clusters came into use [12, 13]. The late 1990s saw many cluster projects.

Several of them distinguished themselves from networks of workstations by creating system software that mimicked that of large supercomputers [4].

SETI@home is described in [2] and in more detail in [15] and [6]. The infrastructure to run SETI@home evolved into BOINC [1] which now runs many other volunteer computing projects in addition to SETI@home. The various aspects of grid computing are described by the articles in [5].

Cluster computing has been the first contact with parallel computing and system design for many people. In [9], Pfister discusses many of the issues and concepts only briefly touched on in this introductory article.

### Synonyms

Computational models; Models for algorithm design and analysis

### Definition

A model of computation is a framework for the specification and the analysis of algorithms/programs. Typically, a model of computation includes four components: an *architectural component*, described as an interconnection of modules of various functionalities; a *specification component*, determining what is a (syntactically) valid algorithm/program; an *execution component*, defining which sequences of states of the architectural modules constitute valid executions of a program/algorithms on a given input; and a *cost component*, defining one or more cost metrics for each execution. A model of computation can be evaluated with respect to three conflicting requirements: the ease of algorithm/program design and analysis (*usability*); the ability of estimating, from the cost metrics provided by the model, the actual performance of a program on a specific real platform (*effectiveness*) and on a class of platforms (*portability*). An ample variety of models of parallel computation are known in the literature, which achieve different trade-offs among the above requirements.

### Discussion

#### Overview

A major objective of Computer Science and Engineering is the development of automatic solutions to computational problems. Formally, a *computational problem*  $\Pi$  is a binary relation between a set of *problem instances* and a set of *problem solutions*. The intended meaning of  $(x,y) \in \Pi$  is that  $y$  is a solution to instance  $x$ . Both instances and solutions are strings from suitable finite alphabets, typically encoding some kind of mathematical objects, such as numbers, matrices, sets, or

graphs. Informally, an *algorithm* is a procedure that specifies how to obtain an output string from an input string by the repeated application of primitive operations (functions) from some chosen set. What constitutes an *execution* of the algorithm on a given input must be unambiguously specified, and the execution process must terminate within a finite number of steps, generally a function of the given instance. Algorithm  $\mathcal{A}$  solves problem  $\Pi$  if, for any input instance  $x$  of  $\Pi$ , it outputs a solution  $y$  such that  $(x,y) \in \Pi$ . In the outlined context, a *model of computation* is a formalism for the specification of algorithms. Such a specification can be referred to as a *program*. A program whose execution terminates on every input specifies an algorithm. In principle, an algorithm is rigorously defined only by means of a program, within a chosen model of computation. In practice, however, when an algorithm is described in the literature, the main ideas are typically presented at a high level, while several ("straightforward, yet tedious") details are left implicit. The details can be provided in different ways, within the chosen model of computation, yielding different programs for what is informally considered to be the same algorithm. Sometimes, an approach to solving a problem is described at an even higher level of abstraction, where even the model of computation is left at least in part unspecified, providing what will be referred to as an *algorithmic strategy*. For example, the quicksort algorithmic strategy to sort a set of records consists in separating the records into two subsets, to be sorted recursively, the keys of the records in the first subset being all smaller than those in the second subset. This strategy can be made specific assuming serial or parallel execution, assuming sequential or random memory access, rearranging the records *in situ* or using a proportional amount of auxiliary storage, etc. Depending on the model of computation, further elements may be specified by an algorithmic description, such as the order of execution of actions (e.g., the order of the two recursive calls in quicksort), which processor is assigned which action (when processors form an explicit component of the model), which data must be stored in which memory region (particularly relevant if memory access time is not uniform), and so on. A variety of different algorithms can then be produced, all referred to as quicksort, in recognition of the common underlying algorithmic strategy.

In the 1930s, several models of computation were proposed including the *recursive functions* of Gödel, the *Turing machines* of Turing, and the  $\lambda$ -*calculus* of Church. These models were soon recognized to be equivalent to each other, in the sense that there are automatic translations of programs from one model to another that preserve the input-output behavior: On a given input, the translated program terminates if and only if the original program terminates and, if so, it produces the same output. Turing machines can be physically realized (taking the infinitude of the storage tape with a grain of salt), for example, as interconnections of Boolean gates and flip flops (taking noise with another grain of salt). Therefore, the effectiveness of the model is not under question. The *Church–Turing thesis* states that Turing machines (as well as any equivalent model) provide a *complete* model of computation, in the sense that any procedure that is intuitively reckoned as executable admits a specification in the model. The thesis has been debated but it is generally accepted, as no counterexamples have been discovered yet. The *halting theorem* of Turing and related results show that no complete model of computation exists if all programs within the model are guaranteed to terminate. In summary, Turing machines or equivalent models determine the boundary between the problems that can be solved algorithmically and those that cannot. Parallel computing does not alter this boundary, although it can greatly enhance the performance of real machines.

An algorithm automates the solution to a problem at the *logical level*: A procedure with a finite description can be applied to solve all of the (typically) infinitely many instances of the problem. But it is also of great practical interest to automate the solution at the *physical level*, by realizing its execution as a physical process. Physical processes utilize resources, which raises the question of *efficiency*, that is, of minimizing, or at least reducing, the *cost* due to resources consumed by the execution process, such as *space*, *time*, and *energy*. Thus, in addition to enabling the specification of an algorithmic strategy, models of computation can provide a framework to specify aspects of the physical execution of that strategy, to analyze the corresponding cost, and ultimately to design efficient algorithms. In summary, a model of computation typically includes the following four components (which may be trivial in some cases):

- An *architectural component*, described as an interconnection of modules of various functionalities. The state sets of each module and the rules that determine the possible state transitions are also provided.
- A *specification component*, determining what is a (syntactically) valid program.
- An *execution component*, defining which sequences of states of the architectural modules constitute valid executions of a given program on a given input.
- A *cost component*, defining one or more cost metrics for each execution.

Several properties are desirable in a model of computation. For example, the following three have been identified in [2] as key properties for a model  $\mathcal{M}$ :

- *Usability*, which refers to the ease with which an algorithm can be specified and its cost analyzed in the model.
- *Effectiveness*, with reference to a target platform  $\mathcal{P}$ , reflects how well the actual cost of execution of programs for  $\mathcal{P}$ , obtained by suitably translating programs specified on  $\mathcal{M}$ , can be derived from the cost metrics of  $\mathcal{M}$ .
- *Portability*, with reference to a (possibly wide) class  $\mathcal{C}$  of target platforms, characterizes the effectiveness of  $\mathcal{M}$  with respect to all of the platforms of  $\mathcal{C}$ .

While usability, which is inherent to the model's definition, is a somewhat subjective property and cannot be easily captured by a quantitative metric, effectiveness and portability are related to the target physical machines and, to some extent, they are amenable to quantitative analysis [2]. Unfortunately, the above three properties are often in conflict with one another. This is perhaps the main reason behind the considerable proliferation of models proposed over the years, resulting from different trade-offs among the various requirements, as briefly discussed below.

The desirable properties of models of computation and their trade-offs have played a role even for sequential computing, a paradigm broadly characterized by the constraint that operations are executed one at the time. Usability considerations have led to the success of the Random Access Machine (RAM) model. As commercial platforms have evolved deep memory hierarchies with half a dozen levels, the uniform memory-access

time of the RAM has made the model less and less effective with respect to these platforms. Several variants to the cost component of the model have been proposed [22], to capture the variability of access time, block transfer, pipelined transfer, and other features of current memory organizations. The scenario has become only more complex with the advent of parallel computers.

With a given execution of a given algorithm one can associate a *functional trace*, an acyclic directed graph whose nodes correspond to the primitive operations specified by the algorithm on input  $x$ , and where an arc from node  $u$  to node  $v$  indicates that the result of operation  $u$  is an operand for operation  $v$ . The functional traces of an algorithm represent what may be called the *logical* aspect of the computation. All models must provide means to specify the functional traces (as a function of the problem input). However, several other aspects arise when the computation is to be realized as a *physical process*, the evolution of the state of a computer. There is ample freedom in how the logical structure of an algorithm can be physically realized and there is ample freedom in choosing which aspects of the physical realization to capture explicitly within the model of computation. Some reflection on these degrees of freedom can provide some orientation when navigating among the multitude of models.

The physical execution of a computation requires various types of unit: *control units*, which coordinate the construction of the trace from the program and the input; *operation units*, which perform the primitive operations defined by the trace; *memory units*, (cells), which store values from the time they are generated to the time(s) they are used; and *communication units*, (channels), which connect different units. Parallel computers have several units of each type whose role in the computation has to be specified. The management of these *resources* is of central importance for parallel computing, and models of computation differ widely in the mechanisms they provide for specifying the use of machine resources.

A general question to be addressed is whether a given resource is better handled automatically or better left under the control of the algorithm designer and programmer. Unfortunately, this question has no simple, universal answer. Automatic resource management typically leads to better usability, and some time even

to greater effectiveness (e.g., when management decisions can benefit from dynamic information available only at execution time). However, there are cases where understanding the mathematical structure of the target computation is crucial to the efficient use of resources. In these cases, the algorithm designer can potentially provide a better resource management. However, the required level of competence may be high and, therefore, the amount of programming effort should be budgeted. Moreover, the performance attained through a poor resource management explicitly coded in the algorithm could turn out worse than the one ensured by a suboptimal automatic management.

The amount of resource control left to the algorithm designer is an interesting criterion for comparing the relative effectiveness of models of computation and can be used to organize some of them in a hierarchy where, proceeding from top to bottom, an increasing number of resource-management aspects is explicitly represented.

## Representative Models

At the top level of the hierarchy of models one can place those at the heart of *functional* [1] and *dataflow languages* [9], in which programs specify only the functional traces of an algorithm. Important cost metrics identifiable at this level are the *number of operations*, often referred to as *work* and denoted  $W$ , and the *length of a critical path*  $L$ , that is the length of a longest path in the functional trace graph. The ratio  $W/L$  provides an indication of the amount of parallelism *implicit* in the algorithm. In fact, an insightful result due to Brent [6] shows that, off-line, the operations of a trace can be scheduled in at most  $2L$  stages each including at most  $W/L$  operations. However, to actually make this parallelism *explicit* when dynamically executing a program is not necessarily trivial.

In physical systems, data have to be stored from the time they are produced to the time they are used, leading to the notion of *storage*, a set of cells that can represent different values at different times. Most models of computation explicitly introduce the notion of storage and let the computation be defined directly in terms of transformations to be applied to the storage content. The Turing machine, the RAM, imperative programming languages such as FORTRAN or C, and most parallel models

reviewed below are examples of storage-based models. In *shared-memory models*, a computation is specified as a sequence of transformations applied to a global *shared memory*. Parallelism can be expressed by parallel loop constructs, whose iterations can be executed simultaneously, or by parallel function calls. *Synchronization* mechanisms are also provided, to constrain the time sequence of the updates, since different sequences will generally produce different results. The work metric of a shared-memory program is the same as that of a functional program encoding the same algorithmic strategy. However, while for a functional program any topological ordering of the trace is legal, for a shared-memory program synchronization instructions may introduce further constraints.

The *Work-Depth model* introduced in [23] is an example of shared-memory model which has been widely used in the literature for the design and analysis of parallel algorithms. An algorithm in the Work-Depth model is described as a standard RAM algorithm enriched with parallel instructions, for example, a parallel loop, which make it possible to specify sets of parallel tasks (single elementary operations as well as complex procedures). Operands and results of the operations reside in a shared memory. The relative order of execution of instructions that belong to different parallel tasks is unconstrained. However, all tasks generated by a given instruction must complete before the next instruction can be executed. This constraint can be modeled by adding arcs to the trace graph. The length of the critical path in this augmented graph is called the *depth* of the shared-memory computation and denoted by  $D$ . Clearly,  $D \geq L$ . In general, implementing the same algorithm within less space may result in a greater depth, hence in a smaller amount of parallelism.

Formulating an algorithm within a shared-memory model, as opposed to a functional language, enables the algorithm designer and programmer to take control of a simple, but important aspect of resource management: the reuse of memory. In a system that executes a functional program, memory is automatically allocated to hold intermediate values, with no burden for the programmer. However, since determining when values will be no longer reused is computationally hard (being in general an undecidable property), an automatic system will often be unable to reuse memory space, in situations where a programmer would know

(by an analysis of the algorithm at hand) that the space could be safely reused. On the other hand, poor programmer's choices regarding memory reuse may inhibit precious parallelism ( $D \gg L$ ), as the proponents of functional programming have often pointed out.

In the hierarchy of models, one level below parallel shared-memory models one can place the *Parallel Random Access Machines* (PRAMs) [10, 12]. A PRAM comprises a set of  $P$  RAM processors; each processor has a unique identification number (id), is equipped with a local memory, and has also direct access to a shared memory. Whereas algorithms developed on shared-memory models specify only which variables are involved in each operation, PRAM algorithms also specify which processor is to carry out the operation. In fact, a PRAM program is syntactically very similar to a RAM program where instructions can make reference to the processor's id, thus enabling the same program to result in different executions on different processors. Instruction mechanisms to dynamically activate and deactivate processors are also provided. Under plausible scenarios, a PRAM could automatically execute a shared-memory algorithm incurring a slowdown logarithmic in the number of processors, to systematically handle the assignment of operations to processors. In a nutshell, a parallel data structure could be employed where operations to be executed are inserted and then deleted when an available processor takes them up for execution. For most algorithms of practical interests, however, this overhead can be avoided by a direct specification of the algorithm within the PRAM model. Since such a specification is often rather straightforward, the distinction between shared-memory and PRAM algorithms is often blurred in the literature, although the distinction ought to be retained, for conceptual clarity.

Shared-memory and PRAM models assume that memory cells form a uniform and global address space, where any subset of addresses can be simultaneously accessed at a cost independent of the subset. Physical machines depart significantly from this idealized assumption. First, memory is partitioned into banks, and while accesses to cells in different banks can be concurrent, accesses to cells in the same bank are serialized. Second, processing elements and memory banks are organized into a network, the topology of which can be a degree of freedom. The result is that the cost of accessing

a subset of memory locations is highly dependent upon the distribution of such subset across the physical memory. To investigate the impact of these physical constraints, a class of *network-of-processors* models has been widely studied. Typically, one such model consists of a network of  $P$  RAM processors where each processor is directly connected to one memory bank. The network specifies point-to-point connections among the processors according to a certain topology. Each processor can execute standard RAM instructions, accessing data in its local memory bank, as well as specific instructions to send and receive messages from the immediate neighbors determined by the network's topology. In terms of cost, it is assumed that a word can be exchanged between direct neighbors in constant time. A variety of interconnection topologies have been considered, such as the complete graph, arrays of various dimensions, hypercubes and hypercubic networks, trees and fat-trees, and expander-based networks. A model based on the complete graph, referred to as *Module Parallel Computer*, was introduced in [18] to investigate the impact of memory granularity decoupled from the further constraint imposed by a limited connectivity. However, due to physical and technological constraints, a small degree, preferably independent of the number of processors, is more realistic.

Particularly suitable for writing algorithms for networks of processors is the *message passing programming paradigm*, in which parallel computation results from the cooperation of a number of sequential processes that exchange messages. A message passing language can be obtained by augmenting a sequential language with send and receive instructions. At execution time, a set of processes is activated, each executing the given program. Processes have a unique identification number, which serves as an address for send and receive instructions and provides a mechanism to differentiate the actions of different processes. Each process has its own memory space, accessible only to that process. A distinct copy of a statically defined variable is available to each process; thus, an instruction involving that variable has different effects for different processes. Message passing has become the main programming paradigm in parallel high performance computing, particularly in the form provided by the *Message Passing Interface* (MPI) library [19]. An MPI program can be

written assuming a specific mapping of processes to the nodes of a given topology and constraining message exchange to immediate neighbors. Strictly adhering to the network-of-processors model presents the unwelcome consequence that the transfer of messages between arbitrary nodes has to be managed in software, a solution that is typically neither convenient nor efficient. To circumvent this obstacle, the design of efficient routing algorithms for various topologies has been widely studied. Today, virtually all commercial systems provide a hardware router that can automatically deliver messages from any node to any other node. The design and programming of algorithms is then relieved of the burden of managing the details of message transport. However, as discussed in the following paragraphs, careful data mapping and operation scheduling remain crucial to performance, resulting in communication patterns that the router can deliver faster.

In the outlined context, it is natural to wonder to what extent should algorithm design be aware of memory granularity and network topology. This question has been investigated, in part, by considering automatic ways of emulating a PRAM computation on a network [14]. Roughly speaking, a rather sophisticated analysis has shown that one PRAM step can be reduced to a constant number of arbitrary data permutations, on an amortized average, or to logarithmically many permutations, in the worst case. The average and the worst-case approaches are substantially different, but share an unwelcome property: In order to limit contention at individual memory banks, the PRAM memory is distributed among the available banks through hash functions or sophisticated schemes based on expander graphs, so that the physical layout of data turns out to be a highly scrambled version of the original PRAM layout, thus forfeiting any *locality structure* captured by the latter. For most networks of practical interest, an arbitrary permutation is rather costly. In contrast, many computations of interest can be mapped into such networks in a way that most memory accesses by a given processor involve its own memory bank or that of nearby processors. Hence, at least asymptotically, there is much to be gained in explicitly optimizing an algorithm for a given topology, by understanding the locality structure and exploiting it by suitable scheduling and mapping of data and operations. For most past and current machines,

this conclusion has been tempered by the fact that the actual data-transfer time is often negligible when compared to the high local latency associated with initiating an interprocessor communication (currently, in the order of microseconds). In the future, however, one can expect that local overheads will decrease (being mostly of a technological and economical nature) while transfer time is destined to increase as machines become larger (being rooted in the more fundamental constraint arising from the finiteness of the speed of light).

Substantial effort has been devoted to the development of efficient network algorithms together with lower-bound techniques to assess their performance [16]. The variety of possible interconnections opens a fertile field for theoretical investigations, but at the same time brings formidable challenges. The prospect of rethinking and reprogramming each algorithm for a number of different topologies is not very attractive in practice. A few avenues have been explored to mitigate this *portability* issue.

One approach is based on efficient simulations of a *guest* network by a *host* network, to enable the automatic porting to the host of algorithms optimized for the guest. A wealth of useful and often nontrivial simulation results have been obtained. Unfortunately, even a (worst-case) optimal general-purpose simulation does not guarantee that an optimal guest algorithm is transformed into an optimal host algorithm, although weaker performance guarantees can often be made, in the presence of some structural similarity between the host and the guest. A second approach is based on the introduction of computational models whose cost component includes parameters aimed at capturing some key performance-related properties of networks. Algorithms on these models can be *parameter aware*. The hope is that networks of interest can be well approximated by the model, with a suitable choice of the parameter values. The *Bulk Synchronous Parallel* (BSP) model [24] and the *LoGP* model [8] are the most popular representatives of this class, but numerous variants and refinements have been also proposed in the literature.

In the BSP model, the architectural component consists of a set of RAM processors that can exchange messages via a communication infrastructure. The execution of an algorithm consists of a sequence of rounds,

called *supersteps*: In each superstep a processor can execute operations on local data and send messages to other processors, which are received only at the beginning of the next supertep. The cost of a superstep is expressed as  $w + gh + \ell$ , where  $g$  and  $\ell$  are model parameters (respectively a measure of inverse bandwidth and of global synchronization time),  $w$  is the maximum number of operations executed by any processor, and  $h$  is the maximum number of messages sent or received by any given node. A shared-memory variant of BSP, called *Queuing Shared-Memory* (QSM) model, was introduced in [11], where in the cost of a superstep the maximum number of reads/writes issued by a processor takes the place of the quantity  $h$ , the latency parameter is dropped and the maximum contention for an individual shared-memory location is explicitly accounted for.

A significant generalization of BSP is the *Decomposable BSP* (D-BSP) model [21, Chap. 2], whose architectural component is based on a binary-tree conceptual structure where each leaf corresponds to a RAM processor and each internal node identifies a cluster of processors residing at the leaves of its subtree. By letting the computation proceed independently within clusters of a given level and charging bandwidth and synchronization costs increasing with the cluster size, the model encourages the algorithm designer to expose a form of data locality called *submachine locality*. The availability of different parameters at different tree levels affords a better approximation of specific processor networks.

As is well known, *data locality* is all important in sequential computing, owing to the hierarchical structure of storage. A strong relation between submachine locality and temporal locality of reference was revealed by efficiently simulating D-BSP algorithms on standard sequential memory hierarchies [21, Chap. 2]. An integration of the memory and network hierarchies arises when accounting for communication delays due to the finite speed of messages, both in the network and within the memory [5]. In recent years, parametric models that capture hierarchical features of both memory and network have been motivated by the increasing popularity and widespread adoption of platforms based on multicore architectures. These models typically feature a hierarchical memory system comprising one large shared memory connected to the processors through several levels of nested smaller memory modules (or

caches) which are shared by progressively smaller subsets of processors. Examples of these models are the *Hierarchical Multi-level caching* (HM) model by [7] and the *Multi-BSP* model by [25].

Models of computation which account for the memory and network hierarchies typically provide parameters that capture salient features of each level of these hierarchies (e.g., bandwidth and latency characteristics, memory or cluster sizes, etc.). Algorithms developed on these models are typically *parameter aware*, in the sense that they adapt their strategies based on the model's parameters in order to maximize data locality. An ambitious goal is the design of algorithms which exhibit (near-)optimal performance for a large range of the model's parameters without using these parameters to influence the course of their computation. The development of algorithms of this kind has been explored for the D-BSP model [3] and for the HM model [7], and the terms *network oblivious* and *multicore oblivious* algorithms have been respectively employed (in analogy with cache-oblivious algorithms which pursue a similar goal in the context of sequential memory hierarchies). It is remarkable that some problems (although not all) do admit oblivious algorithms.

A somewhat radical avenue to solve the challenge of portability, or rather to avoid it altogether, would be enabled by the convergence to just one type of machine architecture and organization for parallel computers. Can such a convergence be reasonably expected? One reason to build different machines is that they may better suited to different computational tasks. Therefore, an interesting theoretical question with important practical ramifications concerns the existence of *universal machines*. More specifically, the question of universality can be cast as follows. Consider the class of all machines with a given value of a cost metric, chosen as a mathematical abstraction of the actual cost of realizing the machine. A machine  $U$  is universal for this class if it can simulate any of its members. The quality of  $U$  can be characterized by two metrics: (a) the machine cost *blowup*, that is, the ratio between the cost of  $U$  and the cost of the machines in the class, and (b) the *slowdown*, that is, the worst-case ratio between the time taken by  $U$  and the time taken by some machine in the class to perform some computation. The existence of universal machines with blowup

and slowdown both very close to one would imply that little performance would be given up by building only machines of the universal type.

For the class of *Bounded Degree Networks* (BDNs), that is processor networks whose degree is constant with respect to the number  $P$  of nodes, if  $P$  is taken as the cost, then it is known that there are universal BDNs with blowup equal to one and with slowdown  $O(\log P)$ . Examples are the *shuffle-exchange* and the *cube-connected-cycles* BDNs, both of degree 3. More generally, a slowdown  $S \leq \log P$ , can be achieved by BDNs with a blowup  $P^{\Theta(1/S)}$  [20]. An alternate measure of cost, which better reflects the scenario of VLSI technology, is the *layout area*. The area of BDNs has been investigated in the *VLSI* model of computation [22], which enables the study of the space layout. A number of area-universal architectures have been proposed, for example, with polylogarithmic blowup and slowdown. These networks exhibit what has been dubbed the *fat-tree* structure, with processors at the leaves and switching subnetworks at the internal nodes. It is instructive to wonder why universal BDNs are not area universal networks. Mathematical analysis shows that the bisection bandwidth of universal BDNs grows proportionally to  $P/\log P$  with the number of processors, which in turn forces the area to grow proportionally to  $P^2/\log^2 P$ . Therefore, the layout of a BDN is scarcely populated with processors, hence it is not effective on algorithms that are more limited by computation than by communication requirements. An example is the multiplication of two square matrices, for which a two-dimensional mesh is a more effective architecture than a shuffle-exchange or a cube-connected-cycles network of the same area. (Technically, the bisection bandwidth of a network is the minimum bandwidth across any cut that splits the network into two subnetworks of (nearly) the same number of nodes.)

The universality results mentioned above, both for the processor and for the area measures of cost, are valid assuming constant delays for communications between direct neighbors in the BDN. It is provable that, in any layout of a network that is universal in this model, the average geometric distance between direct neighbors grows as some function of  $P$ . Therefore, the assumption of constant delays becomes physically unrealistic, for large enough machines. A VLSI-like model where

communication delays are assumed to be proportional to the distance between source and destination has been considered in [4]. In this type of model, a mesh topology of the same number of dimensions as the hosting physical space achieves universality with constant blowup and slowdown. Thus, the mesh topology, already adopted in several supercomputers, appears as a promising candidate to which computer architecture could converge, at least on a large scale.

In balance, it is safe to assume that in the short and in the middle term, a strong convergence among commercial platforms is not to be expected. The design of effective algorithms for such platforms will therefore require different models of computation or at least models that are suitably parametrized. However, even if the objective were to develop efficient algorithms for just one type of machine, a multiplicity of models would likely prove quite useful. Developing an algorithmic strategy at the functional or the shared-memory level, without being concerned at first with too many resource optimization issues, and subsequently refining the algorithm and adapting it to more constraining models may prove a more manageable task than designing directly for the target machine. Of course, as in most design processes that proceed in stages, decisions made in the early stages, based on partial cost metrics, may lead to an overall suboptimal design. However, such a design can often provide a valuable starting point for further efforts. Furthermore, a retrospective on parallel algorithm design would show that, when pursued with a grain of salt, the stage-by-stage approach is generally quite effective.

## Bibliographic Notes and Further Reading

In [13, 17], many relevant models for parallel computation are surveyed and critically discussed. The PRAM and network-of-processors models are the topics of two excellent reference books, respectively by J. Jájá [15] and F.T. Leighton [16], which illustrate these models through an ample spectrum of algorithms and theoretical results. The book by J. Savage [22] proposes a comprehensive survey of models of computation, for both sequential and parallel processing, discussing their relative power and several related complexity issues. Finally, the first section of the recent Handbook of Parallel Computing [21], edited by S. Rajasekaran and J. Reif, comprises 16 chapters devoted to models of computation.

## Modulo Scheduling and Loop Pipelining

ARUN KEJARIWAL<sup>1</sup>, ALEXANDRU NICOLAU<sup>2</sup>

<sup>1</sup>Yahoo! Inc., Sunnyvale, CA, USA

<sup>2</sup>University of California Irvine, Irvine, CA, USA

Loop parallelization is the most critical aspect of any parallelizing compiler, since most of the time spent in

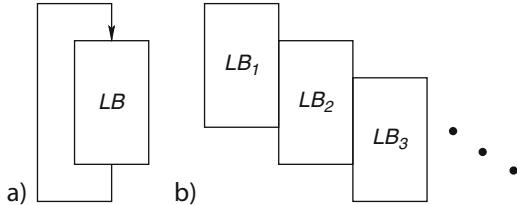

executing a given program is spent in executing loops. In particular, the innermost loops of a program (i.e., the loops most deeply nested in the structure of the program) are typically the most heavily executed. It is therefore critical for any parallelizing (Instruction Level Parallelism (ILP)) compiler to try to expose and exploit as much parallelism as possible from these loops.

Historically, loop unrolling, a standard non-local transformation, is used to expose parallelism beyond iteration boundaries. When a loop is unrolled, the loop body is replicated to create a new loop. Compaction of the unrolled loop body helps exploit parallelism across iterations as the operations in the unrolled loop body come from previously separate iterations. However, in general, loops cannot be fully unrolled, both because of space considerations, and because of the fact that loop bounds are often unknown at compile-time. Furthermore, the extent of parallelism exposed by loop unrolling is restricted by the amount of unrolling.

In order to extract higher levels of parallelism (i.e., beyond unrolling) in software, the various iterations of a loop are pipelined (akin to pipelining of operations in hardware [1, 2]) subject to dependences and resource constraints. This technique is known as *loop pipelining*. An example of loop pipelining is shown in Fig. 1. Figure 1b shows the pipelined execution of the different iterations of the loop shown in Fig. 1a, where  $LB_i$  represents the loop body of the  $i$ -th iteration.

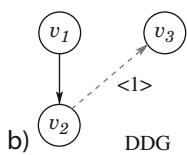

Loop pipelining has its roots in the hand-coding practices for microcode compaction [3, 4]. *Modulo scheduling* [5, 6] pipelines (or overlaps) the execution of successive iterations of a loop such that successive iterations are initiated at regular intervals. The interval between successive iterations is determined based on data dependences and resource constraints. This constant interval between the start of successive iterations is called the *initiation interval (II)*.

Modulo Scheduling was the first method proposed for *loop pipelining* or *software pipelining* (the term “software pipelining”, originally coined to describe a specific transformation [7], is nowadays commonly used interchangeably with loop pipelining to describe any and all transformations that deal with extracting parallelism along the lines discussed in this entry). The objective of loop pipelining is to find a recurring pattern (kernel) across iterations, whether themselves compacted or

**Modulo Scheduling and Loop Pipelining.** Fig. 1 Loop pipelining

not previously, as they get pipelined and replacing the original loop with this pattern, plus a prologue and epilogue code. The problem of loop pipelining then reduces to how to determine the (best) kernel of this transformed loop.

## Preliminaries

In general, an operation in a loop body is dependent on one or more operations. These dependences may either be data dependences (flow, anti or output) [8] or control dependences [9, 10]. Data dependence between operations of the same iteration is termed *intra-iteration dependence*; data dependence between operations from different iterations is termed *inter-iteration* or *loop-carried dependence*. Subsequently, a dependence refers to a data dependence unless stated otherwise explicitly.

For example, in Fig. 2, the dependence between operation  $v_2$  and operation  $v_1$  is an intra-iteration dependence, whereas the dependence between  $v_2$  and  $v_3$ , shown by a dashed arrow in the data dependence graph (DDG) shown in Fig. 2b, is a loop carried dependence. The dependence distance (in number of iterations) between  $v_2$  and  $v_3$  is shown in angled brackets. Next, some terms used in the rest of the entry are defined.

```
do i = 1, N
 1: B[i] = A[i-1] + r
 2: A[i] = B[i] + 1
end do
```

**Modulo Scheduling and Loop Pipelining.** Fig. 3 Loop recurrences

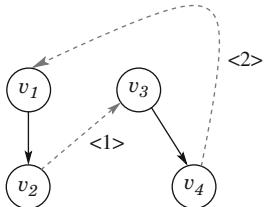

**Definition 1** Given a dependence graph  $G(V, E)$ , a path from an operation  $v_1$  to an operation  $v_k$  is a sequence of operations  $\langle v_1, \dots, v_k \rangle$ , such that  $(v_{i-1}, v_i) \in E$  for  $i = 1, 2, \dots, k$ .

**Definition 2** A cycle in a dependence graph is a path  $\langle v_1, \dots, v_k \rangle$  such that  $v_1 = v_k$  and the path contains at least one edge. A cycle is simple if, in addition,  $v_1, \dots, v_{k-1}$  are distinct.

A loop carried dependence in conjunction with intra-iteration dependences may form a simple cycle in the dependence graph. For example, in Fig. 3, the intra-iteration dependence and the loop carried dependence between the operations  $v_1$  and  $v_2$  form a simple cycle. A loop has a *recurrence* if an operation in one iteration of the loop has a direct or indirect dependence upon the same operation from a previous iteration, e.g., in Fig. 3 operations  $v_i^k$  and  $v_i^{k-1}$  constitute a recurrence, where  $v_i^k$  represents the  $i$ -th operation of the  $k$ -th iteration. In general, a recurrence may span several iterations, i.e., an operation  $v_i^k$  may depend on an operation  $v_i^{k-j}$ , where  $j > 1$ . The existence of a recurrence manifests itself as a simple cycle in the dependence graph. Subsequently, a cycle refers to a simple cycle in a dependence graph.

The *length* of a cycle  $c$ , denoted by  $len(c)$ , is defined as the sum of the latencies of operations in  $c$ . The *delay* of a cycle  $c$ , denoted by  $del(c)$ , is defined as the time interval between the start of operation  $v_1$  and the start of operation  $v_{k-1}$  in a given schedule plus one, where operations  $v_1, v_{k-1} \in c$ , see Definition 1. Let  $dist(c)$  denote the sum of the distances (corresponding to all the loop carried dependences) along  $c$ . For example, in Fig. 4 the path  $\langle v_1, v_2, v_3, v_4, v_1 \rangle$  constitutes a simple cycle. The length of the cycle is 4 and  $dist(c) = 1 + 2 = 3$ .

Note that the delay of a cycle  $c$  may not be equal to its length as the delay of a cycle is dependent on

**Modulo Scheduling and Loop Pipelining.** Fig. 4 A simple cycle

the actual scheduling of operations constituting the cycle. In general, for any cycle  $c$  in a dependence graph,  $\text{len}(c) \leq \text{del}(c)$ .

## Modulo Scheduling Algorithm

The objective of modulo scheduling is to optimize performance (execution time) of a loop over the execution of the entire loop, i.e., beyond the iteration boundaries (unlike basic block scheduling techniques which optimize the performance of a single iteration of the loop). Intuitively, modulo scheduling finds an initiation interval that is larger than what would be required by either resource availability or data dependences. Specifically, modulo scheduling takes a loop without conditionals as an input, looks at the loop body, and computes an initiation interval based on resource utilization, termed *resource-constrained initiation interval (ResII)*. Then, it looks at the recurrences in the dependence graph and evaluates the length of each recurrence. Subsequently, it computes an initiation interval based on recurrences, termed *recurrence-constrained initiation interval (RecII)* (RecII can be computed in polynomial time via, for instance, the Bellman-Ford algorithm [11, 12]). A *minimum initiation interval (MII)* is defined as follows:

$$\text{MII} = \max(\text{ResII}, \text{RecII}) \quad (1)$$

The minimum initiation interval is the smallest initiation interval for which a correct modulo schedule exists. Finally, it generates a schedule, termed a *modulo schedule*, by pipelining (or overlapping) successive iterations of the loop at intervals of MII control steps. The computation of MII based on resource utilization and recurrences ensures that no intra- or inter-iteration dependence is violated, and no resource usage conflict arises between operations of either the same or

distinct iterations. An illustration of modulo scheduling is shown in Fig. 5. Consider the loop and its data dependence graph shown in Figs. 5a and b respectively. Assuming a resource availability as shown in Fig. 5d and a single cycle latency for each resource, the corresponding modulo schedule is shown in Fig. 5c. The reader is advised to verify the schedule with respect to the dependences and resource usage. A detailed description of the modulo scheduling algorithm is presented later in this section.

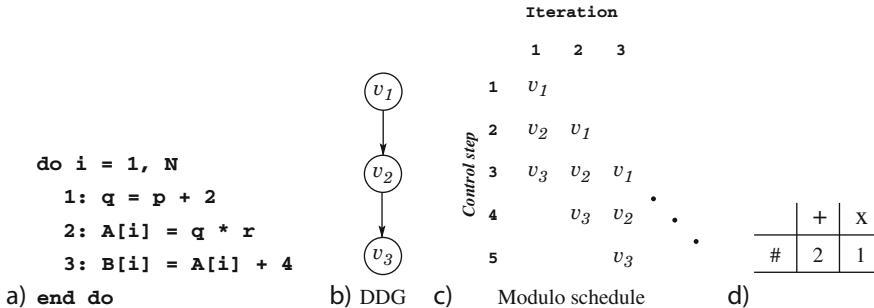

Let  $\mathcal{R}$  represent the library of resources available for scheduling loop  $\mathcal{L}$ . Resources are grouped into classes, each of which consists of identical resources. Let  $\mathcal{R}(i)$  denote the  $i$ -th resource class. Let the number of resources in the  $i$ -th class be denoted by  $\text{num}(i)$ . For example, in Fig. 5d,  $\mathcal{R}(1)$  represents the set of adders, where  $\text{num}(1) = 2$ . Similarly,  $\mathcal{R}(2)$  represents the set of multipliers, where  $\text{num}(2) = 1$ . For simplicity of exposition, each resource is assumed to have single cycle latency. The techniques discussed in this entry can be easily extended to deal with multi-cycle resources [13]. Let  $V$  denote the set of operations in the given loop body. Given a function  $r : V \rightarrow \{1, 2, \dots\}$  such that for each operation  $v \in V$ ,  $r(v)$  gives the number of the resource class used by  $v$ . For example, in Fig. 5d,  $r(v_1) = 1$  and  $r(v_2) = 2$ .

Modulo scheduling, as originally described in [5], makes the following assumptions: (1) The iteration count is known a priori (this, in practice, is not really necessary for the functioning of the algorithm), and (2) The loop body does not contain conditionals or unconditional jumps. It constrains each iteration to have an identical schedule. Modulo scheduling of an innermost loop consists of a number of pre-processing steps as described below.

1. [Generation of conditional free loop body]

In general, a loop body contains multiple control flow paths of which some control paths are executed more frequently than others. In such cases, the most frequently executed control path is selected based on either profiling information or heuristics [14, 15]. This defines the region to be modulo scheduled.

Alternatively, a control dependence can be converted to data dependence via predication [16, 17]. As a result, the resulting loop body looks like a single

**Modulo Scheduling and Loop Pipelining.** Fig. 5 An overview of modulo scheduling

basic block which is amenable to modulo scheduling. In presence of multi-level branches, hierarchical predication [18–20] or predicate matrices [21] may be used to convert multi-level control dependences to data dependences. Early exit branches and multiple branches back to the loop header are handled in a similar fashion.

2. [Minimization of Anti- and Output dependences] Anti- and output dependences can set up recurrence(s) in the data dependence graph which can potentially increase the minimum initiation interval (MII). The *dynamic single assignment form* [22–24] may be used to minimize the anti- and output dependences, which enhances performance by reducing the minimum initiation interval.

Let an integer-valued function PCOUNT and a set-valued function SUCC be defined such that, for each  $v \in V$ ,  $\text{PCOUNT}(v)$  is the number of immediate predecessors of  $v$  not yet scheduled and  $\text{SUCC}(v)$  is the set of all immediate successors of  $v$ . The algorithm for modulo scheduling is presented next.

**Algorithm 1** first computes the lower bound on MII. For this, the algorithm computes ResII and RecII. Since the loop body is yet to be scheduled, hence,  $\text{del}(c)$  cannot be computed. Therefore, as a first approximation RecII is computed based on the length of a cycle. Step 4(a) of the algorithm schedules a single iteration of a loop such that the data dependences are preserved and  $\text{usage}(i)$  of a given resource  $i$  across control steps separated by an interval which is a multiple of MII is less than or equal to  $\text{num}(i)$ . Step 4(b) of the algorithm checks whether MII is greater than RecII for the schedule obtained in Step 4(a). If the check fails then MII

---

**Algorithm 1** (Modulo Scheduling). The input to this algorithm is a dependence graph  $G(V, E)$  of the body a loop  $\mathcal{L}$ . The output is a modulo schedule.

---

1. [Compute resource usage]

Examine the loop body to determine the usage,  $\text{usage}(i)$ , of each resource class  $\mathcal{R}(i)$  by the loop body.

**for** each resource class  $\mathcal{R}(i)$  **do**

$\text{usage}(\mathcal{R}(i)) \leftarrow 0$

**endfor**

**for** each  $v \in V$  **do**

$\text{usage}(r(v)) \leftarrow \text{usage}(r(v)) + 1$

**endfor**

2. [Determine recurrences]

Enumerate all the recurrences in the dependence graph using, for example, any of the algorithms in [25, 26]. Let  $C$  be the set of all recurrences in the dependence graph. Compute  $\text{len}(c) \forall c \in C$ .

3. [Compute the lower bound of minimum initiation interval]

a) [Compute the resource-constrained initiation interval]

$$\text{ResII} = \max_{\forall \mathcal{R}(i) \in \mathcal{R}} \left( \left\lceil \frac{\text{usage}(\mathcal{R}(i))}{\text{num}(\mathcal{R}(i))} \right\rceil \right) \quad (2)$$

b) [Compute the recurrence-constrained initiation interval]

$$\text{RecII} = \max_{\forall c \in C} \left( \left\lceil \frac{\text{len}(c)}{\text{dist}(c)} \right\rceil \right) \quad (3)$$

c) [Compute the minimum initiation interval]

$$\text{MII} = \max(\text{ResII}, \text{RecII}) \quad (4)$$

4. [Modulo schedule the loop]

- a) [Schedule operations in  $G(V, E)$  taking only intra-iteration dependences into account]

Let  $U(i, j)$  denote the usage of the  $i$ -th resource class in control step  $j$

```

for each $v \in V$ do
 compute PCOUNT(v) and SUCC(v)
 /* Assign a control step number to v */
 $\ell(v) \leftarrow 1$
endfor
while $V \neq \emptyset$ do
 for each node $v \in V$ do
 /* Check whether data dependences are
 satisfied */
 if PCOUNT(v) = 0 then
 /* Check that no more than num($r(v)$)
 operations are scheduled on the
 resources corresponding to
 * $\mathcal{R}(r(v))$ at the same time modulo
 MII */
 Let $U \leftarrow \sum_{i=0}^{\lfloor \ell(v)/MII \rfloor} U(r(v),$
 $(\ell(v) - i * MII))$
 while $U > \text{num}(r(v))$ do
 $\ell(v) \leftarrow \ell(v) + 1$
 Update U
 endwhile
 for each $w \in \text{SUCC}(v)$ do
 PCOUNT($w \leftarrow \text{PCOUNT}(w) - 1$
 $\ell(w) \leftarrow \max(\ell(w), \ell(v) + 1)$
 endfor
 /* Schedule the operation */
 $V \leftarrow V - \{v\}$
 endif
 endfor
endwhile

```

- b) [Check the schedule obtained in Step 4(a) w.r.t. recurrences ]

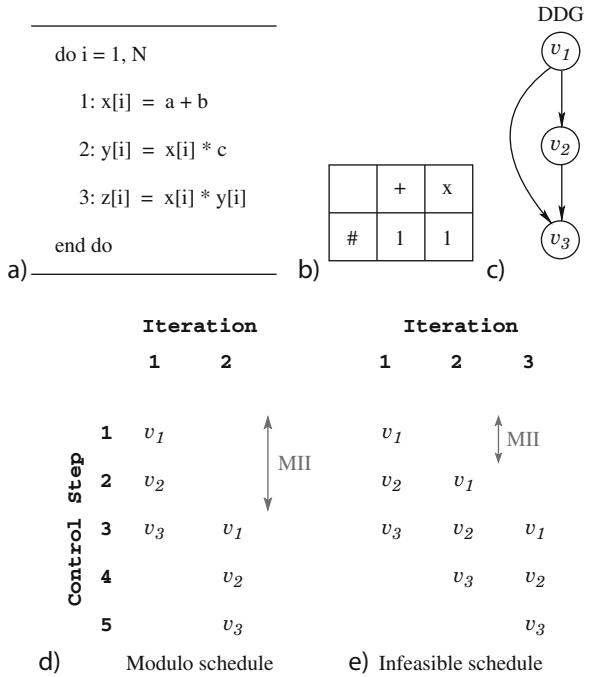

$$II' \leftarrow \max_{\forall c \in C} \frac{\text{del}(c)}{\text{dist}(c)}$$

```

if $MII < II'$ then
 $MII \leftarrow MII + 1$
 Goto step 4 (a)
endif

```

- c) [Pipeline the iterations ]
- Schedule the successive iterations MII control steps apart with each iteration having the same schedule (obtained in Step 4(a)).

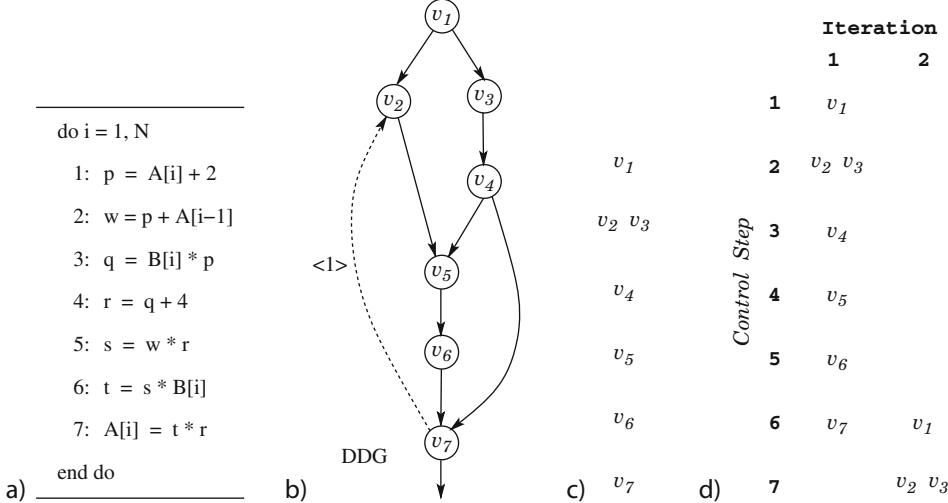

**Modulo Scheduling and Loop Pipelining. Fig. 6** Modulo scheduling in the absence of recurrences

is incremented by 1 and the algorithm iterates through Steps 4(a) and 4(b) until the check is satisfied. Subsequently, successive iterations of the loop are scheduled at an interval of MII. The following example illustrates modulo scheduling in the absence of recurrences.

*Example 1* Consider the loop shown in Fig. 6a and its DDG as shown in Fig. 6c. From the dependence graph one observes that there are no loop carried dependences in the given loop. Therefore, in this case  $MII = \text{ResII}$ .

The number of available resources (adder etc.) per control step is given in Fig. 6b. From Eq. 2,  $\text{ResII}$  for the given resource constraints is 2. The modulo scheduled loop is shown in Fig. 6d, with MII as the initiation interval. In Fig. 6d, control steps 1 and 2 correspond to the prologue of the transformed loop and control steps 3 and 4 constitute the kernel of the transformed loop. From the schedule one observes that 1 cycle is saved per iteration (except the first iteration) in the modulo schedule as compared to the sequential execution of the entire loop. Further overlap of iterations is not feasible as it would violate the resource constraints, e.g., in Fig. 6e, operation  $v_3$  of the first iteration and

**Modulo Scheduling and Loop Pipelining.** Fig. 7 Modulo scheduling in the presence of recurrences

operation  $v_2$  of the second iteration cannot be scheduled in the same control step as there is only one multiplier available.

A subtlety of Step 4(a) of [Algorithm 1](#) bears further discussion. The termination of the inner **while** loop stems from the fact that MII is greater than or equal to ResII. The constraint ( $MII \geq ResII$ ) guarantees that there exists an  $\ell(v)$  for which  $U$  is less than  $num(r(v))$ . In Step 4(a) of [Algorithm 1](#), at any control step, let *ready set* be a set of operations such that for any operation  $v$  in the ready set  $PCOUNT(v) = 0$ . Modulo scheduling involves selection of an operation among the operations in the ready set. Thus, alike list scheduling, [Algorithm 1](#) represents a family of algorithms since the method of selection of an operation from the ready set is not specified. In the presence of multi-function resources, (A multi-function resource can execute more than one type of operations.) determining ResII becomes non-trivial. In such cases, exact ResII can be computed by performing an optimal bin-packing of the reservation tables for all the operations. However, the drawback of such an approach is its exponential complexity.

A cycle  $c$  in the dependence graph imposes the constraint that the time interval between an operation in the current iteration and the same operation  $dist(c)$  iterations later must be at least  $del(c)$ . Consequently, one has the following recurrence constraint:

$$del(c) - RecII \cdot dist(c) < 0 \quad (5)$$

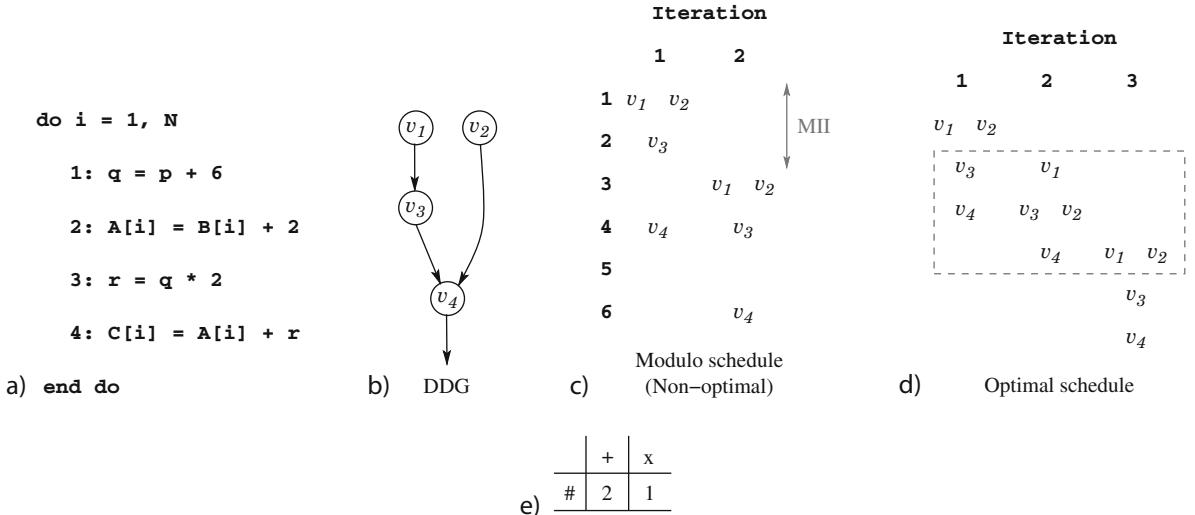

In the presence of multiple recurrences,  $RecII$  is given by [Eq. 3](#). Next, an example of modulo scheduling in the presence of recurrences is presented.

**Example 2** Consider the loop shown in [Fig. 7a](#) and its DDG as shown in [Fig. 7b](#). From [Fig. 7b](#) one observes that the dependence graph contains one cycle,  $c = \{v_2, v_5, v_6, v_7, v_2\}$ .

The length of the cycle ( $len(c)$ ) is 4 and its distance ( $dist(c)$ ) is 1. First, one computes the lower bound on the minimum initiation interval. Assuming the number of resources given in [Fig. 6b](#),  $ResII$  for the DDG given in [Fig. 7b](#) is 3. Since the loop body is yet to be scheduled, hence,  $del(c)$  cannot be computed. Therefore, as a first approximation [Algorithm 1](#) computes  $RecII$  based on the length of a cycle. In this case,  $RecII$  is 4. From [Eq. 1](#), one gets  $MII = 4$ . The corresponding schedule of the loop body is shown in [Fig. 7c](#). From [Fig. 7c](#) one notes that delay of the cycle  $c$  is 5 (=  $del(c)$ ). Since  $del(c) > len(c)$ , an MII of four will lead to a recurrence violation. Therefore, the value of MII is incremented by one and the loop is rescheduled. The final modulo schedule is shown in [Fig. 7d](#). As an exercise, the reader can verify that  $MII = 5$  does not lead to any recurrence violation.

### Remarks: Infeasibility of MII

Modulo scheduling a loop requires computing the recurrence constrained initiation interval ( $RecII$ ) which

**Modulo Scheduling and Loop Pipelining.** Fig. 8 Limitations of modulo scheduling

in itself requires computing the delay of each cycle in the dependence graph of the loop. However, the delay of a cycle is dependent on the schedule for which RecII is known. Several approaches have been proposed to resolve the circular dependence. Rau et al. [5] used linear search to find MII where MII is increased by one iteratively. The FPS compiler [27] used binary search to determine MII where the lower bound is computed using Step 3 of Algorithm 1, and the upper bound is the length of the locally compacted loop body. One could employ an enumerative branch-and-bound search of all possible schedules or use a trial-and-error approach guided by some heuristics. However, the former is computationally very expensive, while the latter does not always guarantee compact schedules. Huff [28] modeled the problem as a minimal cost-to-time ratio problem [29]. Feautrier [30], Govindarajan et al. [31], Eichenberger et al. [32], Altman et al. [33] model modulo scheduling as an integer linear programming [34] problem. However, the exponential complexity of integer linear programming algorithms render such techniques impractical for large loops. Similarly, techniques such as *simulated annealing*, *Boltzmann machine algorithm*, and *genetic algorithms* [35] have been proposed but can become very time expensive for large loops.

## Limitations

Modulo scheduling constrains each iteration to have an identical schedule and schedules successive iterations

at a fixed minimum initiation interval (MII). However, in general, optimal schedule for many loops cannot be achieved by duplicating the schedule of the first iteration at fixed intervals. The constraint that each iteration has the same schedule is ultimately an arbitrary choice, but a fundamental component of modulo scheduling, necessary to ensure convergence in the sense of finding a fixed MII.

For example, consider the loop and its data dependence graph shown in Fig. 8a and b respectively. Let  $v_i^k$  denote the  $i$ -th operation of the  $k$ -th iteration. The modulo schedule of the data dependence graph in Fig. 8b is shown in Fig. 8c. Given a resource library shown in Fig. 8e, ResII for the dependence graph is 2. Since there are no loop carried dependences, therefore,  $MII = ResII$ . Note that operation  $v_4^1$  cannot be scheduled in control step 3 as it would lead to a resource conflict with operations  $v_1^2, v_2^2$  scheduled in control step 3. Thus, a fixed initiation interval in conjunction with the modulo constraint can potentially create “gaps” in the schedule.

In order to extract higher levels of parallelism, one must forgo the constraints imposed by modulo scheduling, i.e., one has to

- Allow successive iterations to be scheduled at different initiation intervals.
- Allow iterations to have different schedules.

An optimal schedule is shown in Fig. 8d. Observe that the first two iterations have different schedules.

Subsequently, iteration 3 is scheduled like iteration 1, iteration 4 is scheduled like iteration 2, and so on. Further, the second and the third iterations are initiated with different initiation intervals. The schedule of the second iteration in Fig. 8d helps close the gap in the first iteration in Fig. 8c, as  $v_4^1$  can now be scheduled in control step 3 without any resource conflicts. Thus, relaxing the constraints (of modulo scheduling) facilitates compaction which yields better performance.

As scheduling of iterations progresses, the execution of operations tend to form a repeating pattern (also known as a *kernel*), as shown in Fig. 8d by the ‘boxed’ set of operations. While such kernels cannot be detected by modulo scheduling, the technique discussed in section “OPT: Optimal Loop Pipelining of Innermost Loops” can detect such kernels.

## Modulo Scheduling with Conditionals

In the previous section modulo scheduling of loops without conditionals was discussed. We now describe how to modulo schedule loops with conditionals.

### Hierarchical Reduction

*Hierarchical reduction* [7] was proposed to make loops with conditionals amenable for modulo scheduling. The hierarchical reduction technique, derived from G. Wood [36], reduces a conditional to a pseudo-operation whose scheduling constraints (both inter-iteration and loop carried dependences) represent the union of the scheduling constraints of the two branches. The significance of hierarchical reduction is:

- Conditionals do not limit the overlapping of different iterations.
- It enables migration of operations outside a conditional around the conditional. Branches of different conditionals can be overlapped via hierarchical percolation scheduling, a technique known as *trailblazing* [37].

The algorithm for hierarchical reduction can be summarized as follows: First, the THEN and ELSE branches of a conditional statement are scheduled independently. Next, the entire conditional is reduced to a pseudo-operation whose scheduling constraints represent the union of the scheduling constraints of the two branches. The latency of the pseudo-operation is the maximum of the length of the two branches; the

resource usage of the pseudo-operation is the maximum of the resource usage of the two branches. Dependences between operations inside the branches and those outside are replaced by dependences between the pseudo-operation representing the conditional and those outside. In the presence of nested control flow, each conditional is scheduled hierarchically, starting with the innermost conditional.

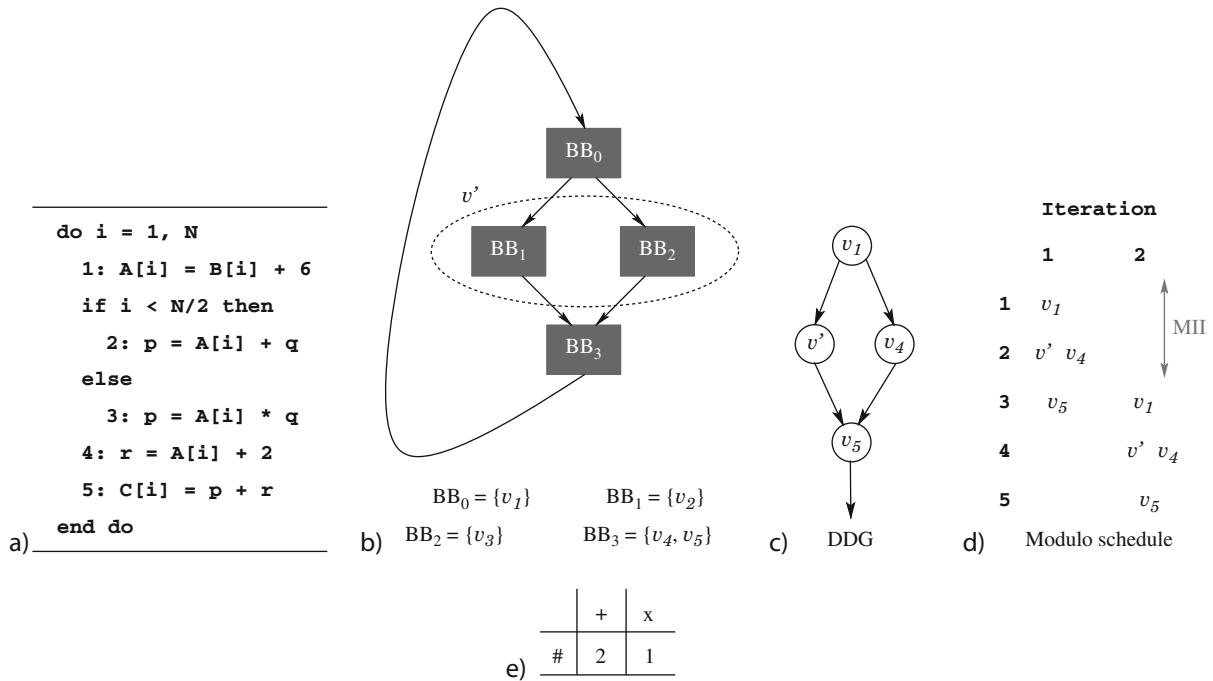

The dependence graph thus obtained is free of conditionals, hence, amenable for modulo scheduling. The dependence graph is then modulo scheduled using Algorithm 1. During code generation two sets of code, corresponding to the two branches, are generated. Any code scheduled in parallel with the conditional is duplicated in both branches.

*Example 3* Consider the loop shown in Fig. 9a. The corresponding control flow graph is shown in Fig. 9b, where  $BB_i$  denotes the  $i$ -th basic block. From Fig. 9a, one notes that the operations  $v_2$ ,  $v_3$ , and  $v_4$  are dependent on operation  $v_1$ . Further, even though  $v_4$  is in basic block  $BB_3$ , it can be scheduled in parallel with the conditional. As discussed above, the conditional, i.e. basic blocks  $BB_1$  and  $BB_2$  are replaced with the pseudo-operation  $v'$ . The dependence graph of the transformed loop is shown in Fig. 9c.

The set of resources used by  $v'$  consists of an adder and a multiplier. Assuming the number of resources given in Fig. 9e, the dependence graph is then modulo scheduled using Algorithm 1 and is shown in Fig. 9d.

### Enhanced Modulo Scheduling

Predication (also known as *if-conversion*) [16] is another technique to convert loops with conditionals into straight line code. Predication removes conditionals by computing a condition for the execution of each operation. Predicated execution assumes architectural support for predicate registers which hold the condition for execution of the operations. A predicate register is specified for each operation and predicate define operations are used to set the predicate registers based on the appropriate condition. Predication-based modulo scheduling techniques [38, 39] schedule operations along all execution paths together. Thus, the MII for predicated execution is constrained by the resource usage of all the loop operations rather than those along

**Modulo Scheduling and Loop Pipelining.** Fig. 9 Modulo scheduling with conditionals

the execution path with maximum resource usage of all paths.

*Enhanced Modulo Scheduling (EMS)* [40] integrates hierarchical reduction and predicated execution to alleviate their limitations. Predication eliminates the need for pre-scheduling the conditional constructs (required in hierarchical reduction); regeneration of conditionals eliminates the need for additional hardware (required by predicated execution), thus EMS can be used on processors without support for predicated execution. An overview of the algorithm is now presented. First, the loop body (with conditionals) is converted into a straight line predicated code using the RK algorithm [17]. The predicated loop body is then modulo scheduled using [Algorithm 1](#) in conjunction with modulo variable expansion [7] to rename registers with overlapping lifetimes. Finally, the predicate define operations are replaced with conditionals.

### Modulo Scheduling with Multiple Initiation Intervals

Hierarchical reduction transforms a loop with conditionals such that the basic algorithm can be used for modulo scheduling the transformed loop. However, in

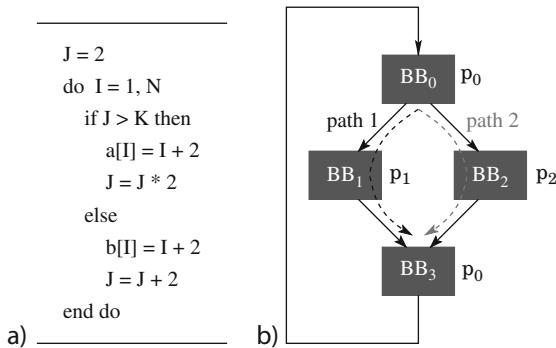

general, two paths of a conditional may imply two different dependences (both intra-iteration and loop carried dependences) and thus, may have different initiation intervals. The initiation interval of the transformed loop is thus constrained by the worst path i.e.,

$$MII = \max_{\forall i} II_{path(i)} \quad (6)$$

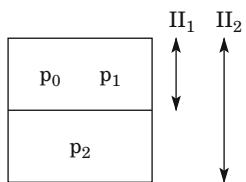

where  $II_{path(i)}$  is the initiation interval of path  $i$ . From [Eq. 6](#) one observes that a path with a shorter MII is penalized due to other paths. Similarly, in the case of predicated execution MII is determined by the sum of operations from all paths. Thus, all paths are penalized due to the fixed MII. As an illustration, consider the example in [Fig. 10a](#).

Assuming an availability of one adder and one multiplier, MII of basic block  $BB_1$  is 1 whereas the MII of basic block  $BB_2$  is 2. A fixed MII-based modulo scheduling would have assigned an MII of 2 to both the paths, which slows down the execution of path 1.

In [41], modulo scheduling with multiple initiation intervals was proposed for architectures with support for predicated execution. In [Fig. 10b](#), the predicate for each basic block is shown next to each basic block. Predicate  $p_0$  is the true predicate. After if-conversion, path 1

**Modulo Scheduling and Loop Pipelining.** Fig. 10 A loop with control flow

**Modulo Scheduling and Loop Pipelining.** Fig. 11 Multiple initiation intervals

corresponds to the operations predicated on  $p_0$  and  $p_1$ , and path 2 to the operations predicated on  $p_0$  and  $p_2$ . The initiation intervals for the two paths are shown in Fig. 11.

From Fig. 11 one notes that during execution of path 1, only operations from path 1 are fetched and executed. However, during the execution of path 2, operations from both the paths are fetched, and operations predicated on  $p_1$  are squashed. Path 2 corresponds to a longer initiation interval  $II_2$  due to larger number of operations. Notice that path 1 is never penalized. The execution paths of a loop body often have different execution frequencies. In order to minimize penalty during the scheduling process, the algorithm assigns higher priorities to the more frequently executed paths, i.e., smaller initiation intervals are assigned to the more frequently executed paths. A detailed description of the algorithm can be found in [41].

## Discussion

Several techniques [35, 42, 43] have been proposed in the past to find the global minimum of the search

space of feasible schedules. However, the high complexity of such approaches makes them computationally very expensive for practical purposes. *Iterative modulo scheduling* [13] algorithm provides a heuristic to control both the search for a valid schedule and the choice of a next state in the search space when the search arrives at a dead end, i.e., when the current schedule is found infeasible. The algorithm is iterative in the sense that it schedules and re-schedules operations to find a “fixed-point” solution which simultaneously satisfies all the scheduling constraints. When the scheduler finds that there is no slot available for scheduling the current operation, it displaces one or more previously scheduled, conflicting operations. These are in turn re-scheduled as the search continues. If the search fails to yield a valid schedule even after a large number of steps, then the initiation interval is increased by a small amount and the entire process is repeated. From Eq. 5, a larger MII delays the execution of a recurrence operation. In the worst case, an MII equal to the schedule length transforms into a list schedule (non-modulo) which is always feasible.

A large number of techniques have been proposed over the last three decades for loop pipelining. In [44], Gasperoni and Schwiegelshohn proposed an algorithm for scheduling loops on parallel processors. In [45], Wang and Eisenbeis proposed a technique called *Decomposed Software Pipelining* wherein software pipelining is considered as an instruction level transformation from a vector of one dimension to a matrix of two dimensions. In particular, the software pipelining problem is decomposed into two subproblems – one is to determine the row numbers of operations in the matrix and another is to determine the column numbers. In [46], Ruttenberg et al. compared optimal and heuristic methods for modulo scheduling. Allan et al. surveyed various techniques for software pipelining in [47].

## Kernel Recognition

All techniques described in this entry can be perceived as kernel recognition techniques. The basic idea behind kernel recognition is to unroll the loop and compact operations from different iterations “as much as possible” (In the presence of vectorizable operations in the loop body the compaction of operations must be constrained in some way to force the emergence of a

repeating pattern.) while looking for a repeating block of instructions. Once a repeating pattern is found in the unrolled, compacted, overlapping bodies of the iterations, the repeating pattern (also referred to as *kernel*) constitutes the loop body of the new loop with a prologue and an epilogue. URPR (Unrolling, Pipelining and Rerolling) algorithm [48] (an extension of the microcode loop compaction algorithm URCR [49]) was one of the early algorithms proposed for loop pipelining based on kernel recognition. URPR assumes that the iteration count is known a priori, the loop body has no conditionals, no subroutine calls, no I/O statements. Some of the other early works include [6, 7, 50]. The techniques differ in type of their underlying assumptions. Broadly speaking, resource constraints (functional units, registers) and conditionals have been the basic distinguishing features. In [51], a loop pipelining technique called *OPT* was proposed to achieve the effect of unbounded unrolling and compaction of a loop. The schedule obtained using *OPT* is *time optimal*, i.e., no transformation of the loop based on the given data dependences can yield a shorter running time for innermost loops without conditionals. Additional hardware assists, such as predicate matrices, specific to loop pipelining were proposed in [21]. In [52], *perfect pipelining* was proposed for loop pipelining of loop with conditionals. Akin to *OPT*, the kernel recognized by perfect pipelining corresponds to unbounded unrolling and compaction; furthermore, perfect pipelining finds a kernel for all paths despite arbitrary flow of control within the loop body. Next the *OPT* algorithm geared toward optimal loop pipelining of innermost loops is discussed.

### OPT: Optimal Loop Pipelining of Innermost Loops

Techniques such as URPR exploit parallelism across the iterations of a loop by unrolling the loop before compaction. If the loop is unrolled (say)  $k$  times then parallelism can be exploited in this unrolled loop body by compacting the  $k$  iterations, but the new loop still imposes sequentiality between every group of  $k$  iterations. Although additional unrolling and compaction can be done to expose higher levels of parallelism, this becomes expensive very rapidly. *OPT* [51] overcomes this problem by achieving the effect of unbounded unrolling and compaction of a loop. The

schedule obtained using *OPT* is *time optimal*, i.e., no transformation of the loop based on the given data dependences can yield a shorter running time for the loop.

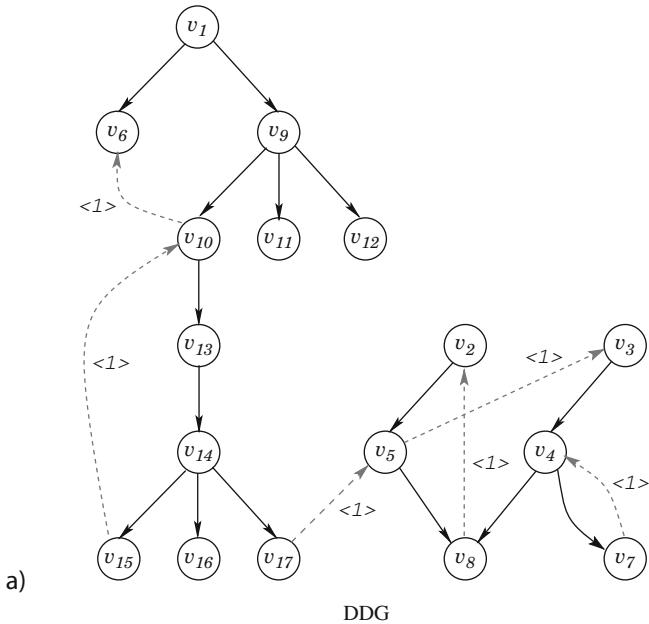

The basic technique examines a partially unrolled loop, say the first  $i$  iterations, and schedules the operations of those iterations as soon as possible. However, the greedy approach may introduce “gaps” – control steps with no operations – between the operations of an iteration due to loop carried dependences; the presence of gaps may in turn forbid the formation of a kernel. In such cases, the gaps are shrunk, i.e., the operations are rescheduled such that there is no effect on the critical path length, in order to force the occurrence of a kernel. A kernel emerges naturally after scheduling a large enough portion of an unrolled loop; the kernel arises as a result of combination of (fixed) dependences and finite number of operations in the loop body. A kernel can be inferred from a greedy schedule and where gaps, if any, are bound by a constant, in at most  $O(n^2)$  iterations [51]. Next, some terms are defined and the algorithm for optimal parallelization of innermost loops is presented. Let  $v_i^k$  denote the  $i$ -th operation of the  $k$ -th iteration.

**Definition 3** Let  $\text{num}(c)$  denote the number of loop carried dependences in a cycle  $c$ . The **slope** of cycle  $c$  is defined as the ratio  $\text{len}(c)/\text{num}(c)$  [53].

The slope of a cycle establishes a bound on the rate that operations in the cycle can be executed. Let  $\text{slope}(v)$  be the maximum slope of any cycle on which  $v$  depends. If  $v$  is not dependent on any cycle, then  $\text{slope}(v) = 0/1$ . When an iteration is scheduled, it is spread across some interval of control steps  $t_1, \dots, t_k$ . Operations from an iteration tend to cluster into groups of mutually dependent operations (referred to as a *region*) with gaps between the regions. For example, in Fig. 12b there are two maximal regions.

**Definition 4** Let  $A_1, \dots, A_j$  be the maximal regions of an iteration, where  $A_i = t_i, \dots, t_{i'}$  and  $t_{i'} < t_{i+1}$  for all  $i$ . Then  $\text{gap}(A_i, A_{i+1}) = t_{i+1} - t_{i'}$ .

In Fig. 12b, iterations 4 and 5 have the same maximal regions; the only difference between the iterations is the size of the gap. Two iterations  $i$  and  $i + c$  are said to be *alike* if they have the same maximal regions and the gaps in iteration  $i + c$  are as large or larger than in

Iteration

| 1                                      | 2                          | 3                                | 4                          | 5                          |
|----------------------------------------|----------------------------|----------------------------------|----------------------------|----------------------------|
| $v_1 \ v_2 \ v_3$                      | $v_1$                      | $v_1$                            | $v_1$                      | $v_1$                      |
| $v_4 \ v_5 \ v_6 \ v_9$                | $v_9$                      | $v_9$                            | $v_9$                      | $v_9$                      |
| $v_7 \ v_8 \ v_{10} \ v_{11} \ v_{12}$ | $v_3 \ v_{11} \ v_{12}$    | $v_{11} \ v_{12}$                | $v_{11} \ v_{12}$          | $v_{11} \ v_{12}$          |

| $v_{14}$                               | $v_5 \ v_6 \ v_7 \ v_{14}$ | $v_6 \ v_{14}$                   | $v_6 \ v_{14}$             | $v_6 \ v_{14}$             |
| $v_{15} \ v_{16} \ v_{17}$             | $v_{15} \ v_{16} \ v_{17}$ | $v_3 \ v_{15} \ v_{16} \ v_{17}$ | $v_{15} \ v_{16} \ v_{17}$ | $v_{15} \ v_{16} \ v_{17}$ |
|                                        | $v_8 \ v_{10}$             | $v_4 \ v_{10}$                   | $v_{10}$                   | $v_{10}$                   |
|                                        |                            | $v_2 \ v_7$                      |                            |                            |
|                                        |                            | $v_5$                            |                            |                            |
|                                        |                            | $v_8$                            | $v_3$                      |                            |
|                                        |                            |                                  | $v_2 \ v_4$                |                            |
|                                        |                            |                                  | $v_5 \ v_7$                |                            |
|                                        |                            |                                  | $v_8$                      | $v_3$                      |
|                                        |                            |                                  | $v_2 \ v_4$                |                            |
|                                        |                            |                                  | $v_5 \ v_7$                |                            |
|                                        |                            |                                  | $v_8$                      |                            |

b)

M

Modulo Scheduling and Loop Pipelining. Fig. 12 A greedy schedule

iteration  $i$ . The gaps in iteration  $i + c$  can be shrunk to the size of the gaps in iteration  $i$  if there is no dependence path from an operation in  $A_k$  of iteration  $i$  to an operation in  $A_j$  ( $k < j$ ) of iteration  $i + c$ , where iterations  $i$  and  $i + c$  are alike with  $j$  maximal regions. For example, in Fig. 12b iterations 4 and 5 are alike and there is no dependence path from the first region of iteration 4 to second region of iteration 5. Thus, it is safe to shrink the gap in iteration 5 to the size of the gap in iteration 4. Though in Fig. 12b the gaps are completely closed, it is not always safe to completely close the gaps. Gaps in an iteration may be completely closed subject to the following condition [54]:

**Condition 1** Let iteration  $i$  and  $i + c$  be alike. Assume that all iterations  $i$  through  $i + c$  have the same number of maximal regions. Let  $A_j^k$  be the  $j$ -th maximal region on the  $k$ -th iteration, where  $i \leq k \leq i + c$ . If

$$\text{gap}(A_j^k, A_{j+1}^k) \leq \text{gap}(A_j^{k+1}, A_{j+1}^{k+1})$$

then the gaps in iteration  $i + c$  and  $i$  may be completely closed.

Next, the OPT algorithm is presented.

The function  $\text{ShrinkGaps}(\mathcal{L}_k, \mathcal{L}_i)$  shrinks the gaps in iteration  $\mathcal{L}_i$  as discussed earlier. In theory, there are loops for which the strategy of making iterations look alike cannot succeed in polynomial time. Let the denominator of  $\text{slope}(v)$  be the period of  $v$ . The length of a kernel based on this approach is at least the least common multiple of the operation periods. If many operations in a loop body have large and relatively prime periods, then the complexity of the algorithm is potentially exponential in  $n$ . The efficiency of the algorithm is dependent on the cost of computing a greedy schedule. This can be easily done using a modified topological sort of the dependence graph. The cost is proportional to the number of operations scheduled.

*Example 4* Consider the data dependence graph shown in Fig. 12a originally proposed as an example in [55]. The corresponding greedy schedule (i.e., operations are scheduled as early as possible subject to data dependences) is shown in Fig. 12b. Even though the greedy schedule corresponds to maximum parallelization, however, from Fig. 12b one observes that a kernel does not emerge as successive iterations are scheduled.

---

**Algorithm 2** The input to this algorithm is a singly nested loop  $\mathcal{L}$  with a dependence graph  $G(V, E)$ . The output is an optimal schedule of  $\mathcal{L}$ . Let  $\mathcal{L}_k$  represent the  $k$ -th iteration of  $\mathcal{L}$ .

**Modulo Scheduling and Loop Pipelining.** Fig. 13 Optimal schedule corresponding to the dependence graph in Fig. 12a

In Fig. 12a, the cycle containing the operations  $v_2, v_5, v_8$  has the greatest slope (three). Operations  $v_3, v_4$ , and  $v_7$  are dependent on this cycle and thus have the same slope. All other operations have a slope of zero (0/1). From Fig. 12b one notes that the schedule is eventually split into two groups that repeat every iteration, one with a slope of three, the other with a slope of

zero. In an attempt to generate a kernel, the algorithm reschedules the operations not on the critical path so that they have the same slope as the operations on the critical path. In Fig. 12b, operations with a slope of zero (0/1) in iterations 4 and 5 could be delayed without affecting the length of the schedule. Eliminating the “gaps” in the iterations produces the (optimal) schedule

shown in Fig. 13. The boxed area is the kernel for the loop; scheduling additional iterations (without gaps) reproduces these three control steps. Note that no operation on the critical path has been delayed as a result of re-scheduling.

## Monitors, Axiomatic Verification of

CHRISTIAN LENGAUER  
University of Passau, Passau, Germany

### Definition

A monitor is a shared abstract data structure that can be used by several processes in parallel. To keep its data in a consistent state, calls to its operations (or *methods*) are executed under mutual exclusion, and there is the possibility of suspending and resuming the caller, depending on the state of the monitor data.

## Discussion

### Overview

For a brief introduction to axiomatic verification with Hoare logic, see the related entry, ►Owicki-Gries Method of Axiomatic Verification. Here, the first issue is the verification of sequentially accessed abstract data structures (frequently called *classes*), and the second the measures that have to be taken to synchronize concurrent calls to monitor operations and make them mutually exclusive.

### Hoare Rules for Classes

The Hoare rules for classes are simple. The main requirement is that the data satisfy an invariant  $I$ .  $I$  must hold after initialization of the data (e.g., in Java, after each constructor call), possibly, under some assumptions; and it must hold at the end of each class method  $op$  provided it holds at its start:

Constructor methods:  $\{pre\} op \{I\}$

Other methods:  $\{pre(op) \wedge I\} op \{post(op) \wedge I\}$

$pre(op)$  and  $post(op)$  are the pre- and postcondition for method  $op$ .

### Hoare Rules for Monitors

To protect concurrent calls properly, two levels of synchronization are added.

### Short-Term Scheduling

Short-term scheduling ensures the mutual exclusion of the execution of concurrent method calls. It is a problem-independent requirement and can be installed by the compiler, that is, the programmer need not worry about it. This is so, for example, in Concurrent Pascal and Modula-2 but not in Java, where the programmer has to add the modifier **synchronized**.

No additional Hoare axioms are necessary. Under the assumption of mutual exclusion, it can be assumed that the monitor data are not being corrupted in parallel while a monitor method is being executed.

### Mid-Term Scheduling

Mid-term scheduling ensures that the monitor data are in the state expected and required by the method being executed. For example, when removing an item from a shared buffer, the buffer must not be empty. If it is empty, the method must be suspended and resumed after an item has been inserted.

Mid-term scheduling is a problem-dependent issue, that is, the programmer must be able to specify it. The usual device is a built-in abstract data structure that holds a FIFO queue (named *cond*) of identifiers of processes that have entered the monitor and have been suspended. The queue is initially empty and comes with two methods:

*wait* suspends the process which calls it, and appends it to the queue; the next process waiting for monitor entry, if any, is granted access

*signal* removes a process from the queue and resumes it after suspending the calling process

There are several signaling strategies which differ in how the process that calls *signal* is treated and when the resumed process is given access to the monitor; these are sketched later in this entry.

Hoare axioms are needed for calls to *wait* and *signal*. Let  $B(cond)$  be the condition to be enforced. The rules proposed originally by Hoare [9] are:

Suspension:  $\{I\} cond.wait \{I \wedge B(cond)\}$

Resumption:  $\{I \wedge B(cond)\} cond.signal \{I\}$

That is, one can presume the validity of condition  $B(cond)$  at the point of resumption if one proves it to hold at the point of suspension. The invariant must be part of both pre- and postconditions because the monitor changes hands.

The waiting condition can be tuned a little bit to avoid unnecessary waiting [10]. Let  $E$  be such that  $I \wedge E \Rightarrow \neg B(cond)$ :

Suspension:  $\{I \wedge E\} cond.wait \{I \wedge B(cond)\}$

Resumption:  $\{I \wedge B(cond)\} cond.signal \{I \wedge E\}$

### Auxiliary and Private Variables

The verification of monitors is akin to the restricted setting of Owicky and Gries (►Owicki-Gries Method of Axiomatic Verification): the conditional critical region of Owicky and Gries [16] corresponds to the body of a monitor operation. That is, auxiliary variables are necessary for the relative completeness of the proof method.

For monitors and other shared abstract data structures, there exists a special kind of auxiliary variable, called a *private variable*. Of a private variable, one instance exists for each process that accesses the monitor [13] and, in a proof, it is indexed by the identifier of the process (see the example below).

The auxiliary variable axiom of Owicky and Gries ensures that auxiliary variables need not be implemented.

### Example

Consider the implementation of an integer semaphore as a monitor, using a syntax close to Concurrent Pascal [2]. Say the semaphore is employed to govern the use of  $m$  instances of a resource by  $n$  parallel processes (assuming  $n \geq m$ ) in an infinite loop. The claim to be proved is that the resources are managed correctly and efficiently [13].

In Concurrent Pascal, a monitor is defined by giving it a name and stating its parameters, then declaring the monitor data and operations, and finally providing an initializing statement.

*Semaphore implementation:*

```
type semaphore = monitor (m : integer);

var s : integer,
 q : condition;

proc P;
begin
 if s = 0 then q.wait fi;
 s := s-1
end;

proc V;
begin
 s := s+1;
 q.signal
end;

begin s := m end
```

*Main program:*

```
resource r(sem : semaphore(m)) ::

cobegin S1 // ... // Sn coend

Si :: while true do
 noncritical section;
 sem.P;
 critical section;
 sem.V;
 noncritical section
od
```

Note that the critical section is not mutually exclusive but can be entered in parallel – by up to  $m$  processes.

### Auxiliary variables:

Inside the monitor, a two-valued private variable is declared:

```
var INC : 0..1
```

which is indexed implicitly with the identifier *caller* of the process currently accessing the monitor. Thus, in the proof, *INC* is an array of  $n$  elements; each element is private to one of the processes accessing the monitor. In the initialization, all elements of the array are set to 0.

### Monitor invariant:

The invariant states that the number of current decrements of the semaphore corresponds to the number of elements of array *INC* currently set to 1:

$$I : 0 \leq s = m - \sum_{caller=1}^n INC[caller]$$

### Proof outline for the main program:

The main program iterates indefinitely, which is specified by the false postcondition. The program manipulates array *INC* such that the number of elements currently set to 1 corresponds to the number of processes currently executing the critical section:

```
{m ≥ 0}
resource r(sem : semaphore(m)) ::

cobegin S1 // ... // Sn coend
{false}

Si :: {I ∧ INC[i] = 0}
while true do
 {I ∧ INC[i] = 0}
 noncritical section;
 {I ∧ INC[i] = 0}
 sem.P;
 {I ∧ INC[i] = 1}
 critical section;
 {I ∧ INC[i] = 1}
 sem.V;
 {I ∧ INC[i] = 0}
 noncritical section
 {I ∧ INC[i] = 0}
od
{false}
```

The proofs for *P* and *V* have to certify their respective manipulations of *INC* as well as the establishment of the invariant, provided it holds before their calls.

### Proof outline for *P*:

```
proc P;
```

```

begin
 $\{I \wedge INC[caller] = 0\}$
 if $s = 0$ then
 $\{I \wedge INC[caller] = 0 \wedge s = 0\}$
 $q.wait$
 $\{I \wedge INC[caller] = 0 \wedge s \neq 0\}$
 fi;
 $\{I \wedge INC[caller] = 0 \wedge s > 0\}$
 $s := s - 1;$
 $\{INC[caller] = 0 \wedge s \geq 0\}$
 $INC := 1$
 $\{I \wedge INC[caller] = 1\}$
end

```

*Proof outline for V:*

```

proc V ;
begin
 $\{I \wedge INC[caller] = 1\}$
 $s := s + 1;$
 $\{INC[caller] = 1 \wedge s > 0\}$
 $INC := 0;$
 $\{I \wedge INC[caller] = 0 \wedge s \neq 0\}$
 $q.signal$
 $\{I \wedge INC[caller] = 0\}$
end

```

*Proof outline for the monitor initialization:*

```

 $\{m \geq 0\}$
 $s := m;$
for $i := 1$ to n do $INC[i] := 0$ od
 $\{I \wedge s = m \wedge (\bigwedge_{i=1}^n INC[i] = 0)\}$

```

*Claim:*

A process is suspended if and only if  $m$  other processes are executing the critical section.

*Proof sketch:*

Note that the invariant holds at all points at which the monitor can change hands, that is, where processes may enter or leave the critical section or are suspended or resumed. The only points at which the invariant does not hold is in the postconditions of the semaphore decrement (in  $P$ ) and increment (in  $V$ ) but, at both these points, it is reestablished immediately under the mutual exclusion provided by the monitor's short-term scheduling.

In the following arguments, note that  $B(q) = s > 0$ :

$\Rightarrow$ : That processes are being suspended when  $m$  processes are executing the critical section follows

directly from the invariant, which guarantees that, in this case,  $s = 0$ . Note that  $s = 0 \Rightarrow \neg B(q)$ .

$\Leftarrow$ : Processes are suspended only when necessary, since  $pre(q.wait) \Rightarrow \neg B(q)$ .

### Other Signaling Strategies

The problem of signaling received further attention almost immediately. The question is when exactly the signaler should leave the monitor and when the signee should be resumed. The different signaling strategies make use of, in all, three waiting queues:

The *condition queue*: the monitor's FIFO queue for mid-term scheduling.

The *entry queue*: the monitor's FIFO queue for short-term scheduling.

The *urgent queue*: an additional FIFO queue for short-term scheduling that takes priority over the entry queue (only used in strategy SU).

Five signaling strategies have been proposed [1]:

signal + continue (SC): Java

Signaler continues.

Signalee moves from the condition queue to the entry queue.

signal + exit (SX): Concurrent Pascal

Signaler leaves the monitor for good.

Signalee is removed from the condition queue and resumed.

signal + wait (SW): Howard [10], Modula, Euclid

Signaler is added to the entry queue.

Signalee is removed from the condition queue and resumed.

signal + urgent wait (SU): Hoare [9], Pascal-Plus

Signaler is added to the urgent queue.

Signalee is removed from the condition queue and resumed.

automatic (AS): Owicky-Gries general setting [15] (the **await** statement).

Implicit SC.

Hoare axioms, which are by nature more complicated than the ones mentioned previously in this entry, were proposed early on [11].

A drawback of the SC strategy is that a process, upon resumption, may encounter the monitor data not in the expected state – some other process may have interfered! Andrews [1] states that the advantages of the SC

strategy are that it is simpler – it suffices to provide only a single condition queue per monitor object, not one queue per condition to be waited on – and that the proofs of *wait* and *signal* are less context-dependent and thus easier to do in isolation. He also conjectures that the SX strategy fosters operation fragmentation.

## Bibliographic Notes and Further Reading

The verification rules for abstract data structures were first proposed by Tony Hoare [8] soon after his seminal paper on axiomatic program verification [7].

The monitor concept was invented in the early 1970s by Tony Hoare [9] and Per Brinch-Hansen [2], and it was quickly included in several programming languages of the time. Some problems with monitors were quickly discovered and discussed [12]. One consequence is to avoid call hierarchies, that is, calling one monitor operation while executing an operation of another monitor [14].

Over the years, the monitor concept has been reviewed repeatedly and its variants have been classified [1, 3]. An extended monitor concept for Java with the option of several signaling schemes and with prioritized resumption has been proposed [4].

Ole-Johan Dahl reviewed the axiomatic verification of monitors at the honorary symposium for Tony Hoare in 1999 on the occasion of his retirement from Oxford University [6] and, 5 years earlier, at a similar function for Tony Hoare's 60th birthday [5]. Dahl seemed unaware of Howard's early work [11]. In 1999, when electricity failed in the middle of the talk due to the flooding of a transformer in bad weather, Dahl completed his presentation with clarity and composure without visual aids in the windowless room, which was illuminated only by the exit signs – and took questions afterward!

## Moore's Law

JOHN L. GUSTAFSON  
Intel Corporation, Santa Clara, CA, USA

## Synonyms

There are no exact synonyms for Moore's law with respect to chip technology. Kryder's law for hard disk storage, Butter's law for fiber optic transmission speeds, and Nielsen's law for consumer home network speeds are examples of very similar formulations for other technologies. These may be regarded as derivatives of Moore's law, and they are often described as "A Moore's law for mass storage" etc. Technologists often

cite Moore's law very broadly to refer to any technology that changes as an exponential function of time.

## Definition

Moore's law states that the number of transistors on a chip doubles every 24 months.

More precisely, the law is an empirical observation that the density of semiconductor integrated circuits one can *most economically manufacture* doubles about every 2 years. Thus, the cost of manufacturing a transistor drops by half about every 2 years. Some definitions use 18 months as the doubling period instead of 2 years; see the Discussion section below for clarification.

Caltech professor and chip pioneer Carver Mead coined the term "Moore's law" in 1970.

## Discussion

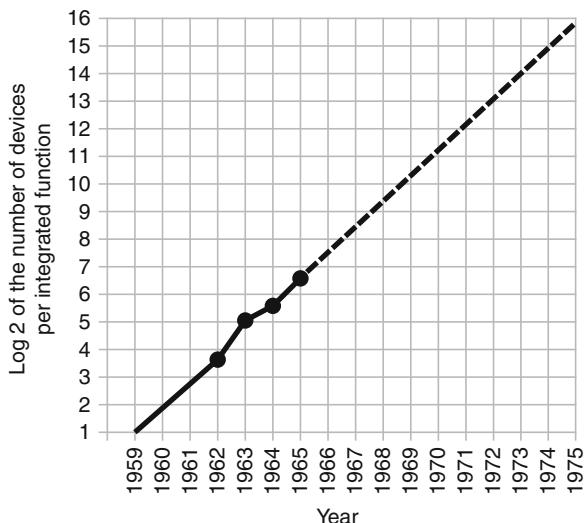

### History

The idea of putting complete circuits on a monolithic block of semiconductor material originated with Jack Kilby (Texas Instruments, 1958) and, independently, Robert Noyce (Fairchild Semiconductor, 1959). Gordon E. Moore's 1965 paper on the progress in integrated electronics [1] noted the rapid rate of density improvements in just those 6 years. He made the bold prediction that "with unit cost falling as the number of components per circuit rises, by 1975 economics may dictate squeezing as many as 65,000 components on a single silicon chip."

Figure 1 shows Moore's original graph [1].

Only four data points were used to create the original graph, and Moore's original estimate was twice as optimistic as the rate of improvement given in later revisions: "The complexity for minimum component costs has increased at a rate of roughly a factor of two per year." Notice that these are the transistor counts for individual functions, not for processors, since the first complete microprocessors on a chip would not be possible until several years later.

At the time, the driving motivation for integrated circuitry was to satisfy the needs of the military and the US space program, both of which had a high tolerance for the cost of parts needed to do a particular job. Moore observed, even in 1965, that the decrease in cost would eventually usher in an era of personal computing and "personal portable communications equipment," that is,

**Moore's Law. Fig. 1** Moore's original graph estimating the trend of device density

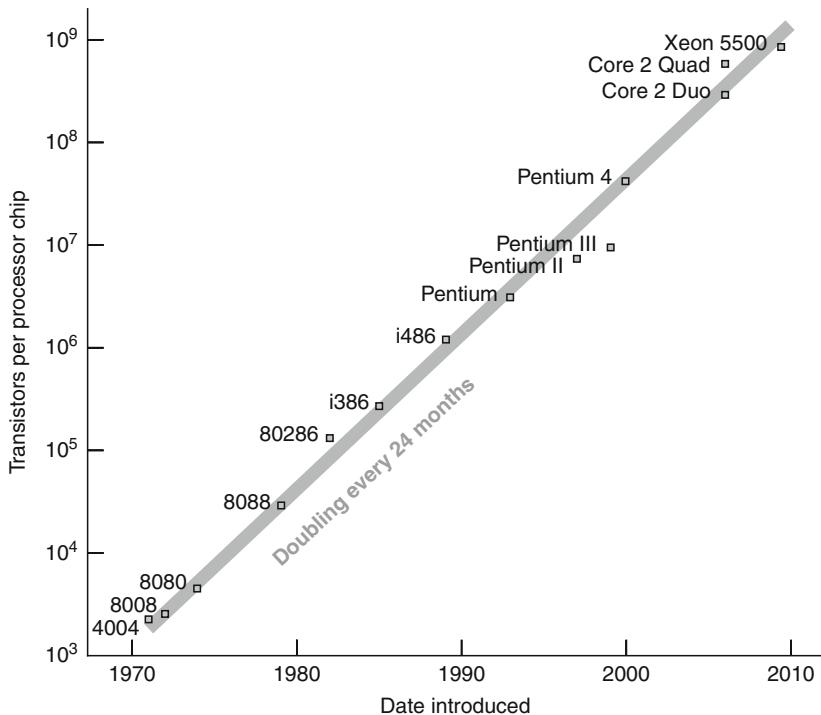

cellular phones. A cartoon accompanying Moore's article showed a set of store kiosks for cosmetics, notions, and "handy home computers," intended as a joke to overstate Moore's prediction. The humor and intended exaggeration of the cartoon is almost completely lost on the modern reader, since it depicts a scene not unlike that found in current shopping malls.

Around 1970, Caltech Professor Carver Mead, a pioneer of very large-scale integration (VLSI) technology, coined the term "Moore's law" for the density doubling rule of thumb. Moore updated his paper in 1975 [2]. That paper used a more complete set of data to revise the rate of improvement to a density doubling every 24 months.

The more recent graph in Fig. 2 begins where Moore's original graph left off, and encompasses four decades of Intel family processors. It makes clear that for processor chips, a doubling every 2 years is an excellent match to the empirical data.

### A Self-fulfilling Prophecy

What started as an empirical observation about the integrated circuit business became a *self-fulfilling prophecy* that pervades computing. Moore himself was perhaps the first to apply that phrase to his law, in a 2005 interview. The law is as much an economic guideline as a technical one [3]. Moore's paper began as a forecast but became an industry guideline. As a well-known trend

Moore's Law. Fig. 2 Moore's law for CPU device density

M

believed by an entire industry, there are risks to introducing products that are either above or below the trend line, since the entire supply chain from the suppliers to chip fabrication facilities to the consumers of the electronic systems built from those chips is calibrated to the expectations of the forecast.

If a commercial entity aims below Moore's trend line, the result will be a product that has insufficient performance to compete in the marketplace. If it aims above Moore's trend line, it will find the infrastructure unavailable to produce the parts except at extremely high costs, and they will not be in balance with the performance of chips available from other vendors. Thus, the entire semiconductor industry marches to the same beat as the safest business practice.

### Moore's Law and Software

Niklaus Wirth observed that software demands for hardware speed and memory capacity grow faster than Moore's law, resulting in a net decrease in system performance [4]. He quotes M. Reiser's remark "Software is getting slower more rapidly than hardware becomes faster," and a variant on C. Northcote Parkinson's

cynical observation (Parkinson's law) that work expands to fill the time available for its completion:

"Software expands to fill the available memory."

Bill Gates made a similar observation, but said that the net result is to keep system speed about the same, not to get worse. Gates speculates that this is for more than one reason: programmers add more and more features but also code less and less efficiently as hardware grows in capability. Worrying less about the efficiency of software makes the software less costly to produce. This is an example of how Moore's law can enable trade-offs that save costs in areas of computing other than chip technology. Many applications and operating systems now contain tens of millions of lines of software as a side effect of Moore's law.

The cost of software was trivial relative to the cost of hardware in the early days of electronic computing. The operation cost of a 1960s mainframe computer was over a hundred times as much as the cost of a programmer on a per-hour basis. Thus, it was common for programmers to program at the lowest level of machine language to achieve sufficiently high performance. Moore's law

has dropped the price of hardware so dramatically that when one seeks a new application, programming the application is often the most expensive aspect of using the computing system. Therefore, there is considerable incentive to use the cost savings of Moore's law improvements to reduce programming cost by putting more of the performance burden on the hardware and less on the programmer.

### Misconceptions About Moore's Law

Perhaps the most common misconception about Moore's law is that it predicts *performance* will double periodically, as measured by clock speed or any other performance metric. This is partially supported by device-level physics, since decreasing the size of a transistor allows it to switch faster. However, because not all performance features scale with the transistor performance (such as the speed of signals on the chip), performance improvements generally require redesign as well as the shrinking of features. Moore did not make any predictions about performance nor did he ever cite a doubling interval of 18 months. The "18 month" period of doubling is the result of an attempt by former Intel executive David House to estimate and publicize a growth rate for the performance improvement in microprocessors. While transistor counts are easy to quantify, it is much more difficult to find a rigorous definition of absolute computer performance.

### Implications for Parallel Computing

In recent years, Moore's law has become a major reason that interest in parallel computing methods has become prominent and intense. The most recent and obvious consequence of the increased density of VLSI is that a single processing chip usually contains more than one processor. This has brought the issues of parallel computing to developers of even very small and inexpensive devices.

A more profound effect of Moore's law that drives parallel computing has been in operation for decades: *not all technology features and requirements scale at the same rate as Moore's law*, forcing designers to make architectural changes. For example, whereas processor capability and memory capacity have improved about a million-fold with Moore's law in the last 35 years, the time latency between the processor and the (off-chip) memory has improved only very slightly over

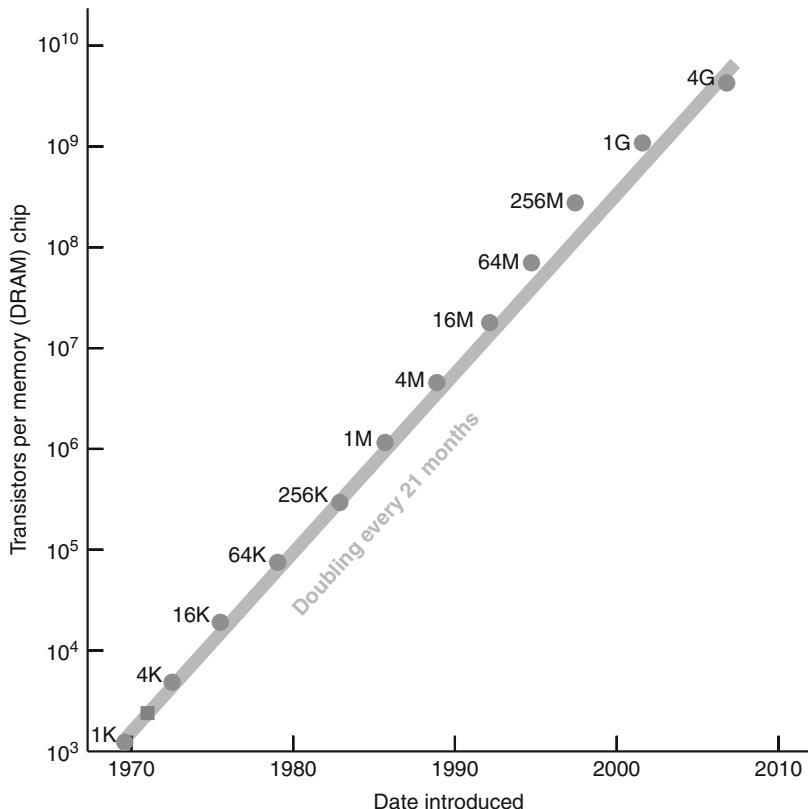

that same period. The simple "von Neumann architecture," in which a single monolithic memory supplies data and instructions to a single monolithic processor, is now impractical because of this disparate scaling. Yet, programmers have created a vast body of serial software to fit that increasingly untenable model. Modifications to the von Neumann architecture (such as automatic caching of memory or the automatic overlapping of operations and memory transfers) have helped to convert Moore's law device density improvements into higher performance without changes to that traditional serial software, but only up to a point. Beyond that point, the programmer faces the need for parallel computing techniques to exploit the higher device density of VLSI for continued improvements in performance.

A simple way to understand this is to consider cost. Imagine that to double performance of a computer system while maintaining the illusion of a single memory space and a single thread of execution will increase the cost by a factor of four. The alternative is to buy two computers without changing the design, which nominally doubles the cost of the processing hardware. Added to this is the cost of connecting them and the cost of reprogramming so they can operate in parallel. Depending on the application, the connection and reprogramming costs might be quite a bit less than another factor of two, so the parallel approach has lower total cost.

Moore's law predicts a steady state in the drop of the cost of a megabyte of memory. The data for the first introduction of each new generation of dynamic random-access memory (DRAM) chip actually shows a doubling approximately every 21 months, not every 24, as shown in Fig. 3.

While memory parts became cheaper for computer makers, the price per megabyte of memory charged by vendors diverged sharply in the 1990s between makers of distributed memory parallel computers and those making monolithic designs [5], as shown in the Table 1 below, compiled in 1992.

The first four entries reflect the commodity pricing of DRAM for personal computers and workstations. The last three entries reflect the price of proprietary memory designs from vector supercomputer makers of the same period, and are higher by almost two orders of magnitude. The nCUBE 2 and Intel Paragon, being distributed memory parallel systems, were able to

Moore's Law. Fig. 3 Device density for dynamic-access memory

Moore's Law. Table 1 Price for distributed memory versus monolithic memory, ca. 1992

| Computer           | List price to add 1 megabyte of memory |
|--------------------|----------------------------------------|
| Apple Mac IIxi     | \$124                                  |
| 386 PC             | \$112                                  |
| Sun SPARCstation 2 | \$81                                   |
| SGI Indigo         | \$172                                  |
| nCUBE 2            | \$350                                  |
| Intel Paragon      | \$344                                  |
| NEC SX-3           | \$2,740                                |
| Hitachi EX Series  | \$4,000                                |
| CRAY Y-MP          | \$7,800                                |

price memory much closer to what was being offered for individual workstations since they did not attempt to preserve the programming view of a serial (von Neumann) architecture. By the late 1990s, "Beowulf"

clusters for supercomputing were built, literally out of consumer-grade personal computers and so had the same cost per megabyte of DRAM. This illustrates how Moore's law creates upheavals in prevailing computer architectures, and in particular led to the now-ubiquitous use of distributed memory and parallel processing to create the fastest computing systems.

### The ASCI Program and Other "Above Trend" Efforts

The Accelerated Strategic Computing Initiative was a late 1990s US Department of Energy program intended to replace nuclear weapon testing with computer simulation. In recognizing the vast improvement in computing power required to achieve this, the proponents included "accelerated" in the name to indicate the desire to *exceed Moore's law* [6]. While hundreds of millions of dollars were spent on the very large parallel supercomputing systems developed for the program and placed

at the national weapons laboratories, this was still such a small fraction of the overall computing market that there was no impact to accelerate Moore's law. The density and price of the systems did not deviate from the predicted trend. The systems were somewhat more powerful than the trend of supercomputer speed versus year, simply because they were more expensive per system on an inflation-adjusted basis.

The 2002 Japanese Earth Simulator was another striking national effort at stretching beyond the performance trend that succeeded through more massive expenditure. The cost for the Earth Simulator was an estimated \$350 million [7]. Since parallel supercomputer developers do not have sufficient influence in the total computing market to bend Moore's law, they simply spend more money to build larger facilities. The largest computing facilities such as those built by Google and Microsoft contain several acres of computing equipment with attendant power, cooling, and interconnect.

## The Future of Moore's Law

### Early Pessimism

In 1973, Carver Mead stated in a classroom lecture at the California Institute of Technology that Moore's law would come to a physics-based "day of reckoning" around 1984, when transistors would be so small that a single electron would determine its on-off state. Part of the inaccuracy of his prediction may have been the result of using a 1-year period of doubling instead of the 2-year period Moore cited in his revision in 1975. Another error may have been to assume that transistor geometries would scale down uniformly in all three dimensions; current devices are tall and thin on the chip relative to their horizontal dimensions, like a very high hedge maze, which has delayed some of the impending limits of scaling semiconductor physics.

### Optical Limits

Similar pessimistic predictions have appeared, often based more on engineering limitations than on fundamental physical laws. For example, the primary manufacturing method has been photolithography, in which light passing through a mask creates chemical changes in a polymer (photoresist) causing it to harden in precise patterns. Optical theory says one cannot create images

more accurate than about one wavelength of light, because of diffraction effects. This predicts that Moore's law must end when device features became smaller than a single wavelength of visible light. That limitation would have meant that device features could not be smaller than about 0.5 μm. Yet, mass-manufactured chips, at the time of this writing, have features as small as 0.045 μm. Engineers overcame the barrier using much smaller wavelength light in the ultraviolet, in combination with sophisticated mathematical corrections to the diffraction effects so that features smaller than a single wavelength could image reliably. What appeared to be an absolute physical limit was actually simply an engineering problem to overcome.

### Heat and Power Limits

At present, heat and power dissipation are engineering challenges for the future of Moore's law. Chips that use more than about 140 W are difficult to cool economically, so designers are using changes to device parameters as well as changes to the architecture. Lowering the operating voltage is one technique, but equally helpful is to *reduce the clock speed*. While reducing the clock speed slows serial processing, it can allow designers to pack more processors onto a single chip because multiple processors still fit into the power budget. This is one reason the chip industry embraced "multicore" parallel architectures. Efforts to raise clock speed were at the point of diminishing returns, but the use of parallel computing allowed the performance per chip to stay on the Moore's law trend line.

### Design Effort Limits

Chip designers laid out the earliest chips manually. They made masks with black tape, by hand, hence the term "taping out" a chip. As the number of devices grew to the hundreds, computers and automated equipment displaced that part of the design effort. However, even as the ability of computer software tracked the need to manage millions and then billions of individual devices, some speculated that the process would become prohibitively arduous and hence human-limited. While some devices (such as memory chips) involve many repetitions of a single small design "cell," the more complex chips (such as processors used in servers) involve the custom design and management of many different cell types. Placing the devices and routing the connections

between them in an optimal way is an NP-hard problem that taxes both human designers and the software tools. The production of a new state-of-the-art processor involves thousands of engineers and about 200 different software applications for various stages of the design and manufacture. While this level of investment has tended to reduce the number of industrial companies that are able to create competitive semiconductor devices, it has not resulted in a slowing of Moore's law.

### Reliability at the Atomic Scale

If the feature sizes of chips continue to shrink as predicted by Moore's law, chips will soon contain features that are only a few atoms across. This limit occurs around 2015–2020. At such sizes, quantum effects and temperature noise will force us to fundamentally rethink the way circuits accomplish computation. Note that an individual atom has multiple quantum states that can store information, so Moore's law does not necessarily end when device features are at the individual atom level of detail.

### Lack of Market Need

Some have even speculated that Moore's law will end not for technological reasons but because all of our electronics will be "good enough," and thus manufacturers will not seek further improvements to size and cost. While this argument might hold for any given device type, like a four-function calculator, many areas of human endeavor (such as high-performance computing to simulate physical behavior) have seemingly boundless appetites for improvements and have no ceiling on what they demand for speed and storage.

### Manufacturing Facility Cost

Another economic argument against continued progress is the exponentially increasing cost of the manufacturing facilities for semiconductor chips. According to Dan Hutcheson, CEO of VLSI Research, the cost of building a fabrication facility doubles every 4 years. This forecast is one he called "Rock's law," after early Intel venture capitalist Arthur Rock [8]. While larger facilities create economies of scale, Rock's law seemingly collides with the cost-reduction part of Moore's law. However, the cost *per transistor* may continue to drop even as the plants that produce them become increasingly expensive to build. A closely related metric is the cost *per unit*

area of building a chip. Like the facility cost, this metric is increasing, even though the cost per transistor is decreasing.

### Perspective

The rate of technology advance in chip technology is a rate of improvement without precedent in human history. Some have observed that if automobile technology followed Moore's law, a car would now cost less than a penny, would use drops of gasoline instead of gallons, and would safely go hundreds of thousands of miles per hour. The rate of change has been so staggering, and so different from that of other industries, that many computing businesses fail if their management tries to apply the kind of product marketing used for non-technology companies. A recurring situation is that the parts cost to a computer maker drops by a factor of two, and the company's executives face the choice of passing this savings to their customers (which they fear will cause their revenue to drop with Moore's law) or maintaining their prices with the aim of increasing their profits. The consequence of the latter choice is often that another company with little to lose and everything to gain by introducing a competitive product undercuts them by passing on the savings of Moore's law to customers. Even in an economy that has moderate inflation, consumers of technology have come to expect inexorable improvement in the price and capabilities of any electronic device.

For many years, Moore's law served as a *damper* on parallel computing efforts. Why rewrite software when in less than 2 years you can simply buy a serial computer that is twice as fast? Now, in contrast, the shrinking of transistor size and cost means the issues of parallel computing are everywhere.

## Bibliographic Entries and Further Reading

Ray Kurzweil has extended Moore's law to many other areas of technological change that seem to be advancing exponentially. *The Singularity is Near: When Humans Transcend Biology* (Viking 2005; Penguin 2006) [9]. In his "The Law of Accelerating Returns," <http://www.kurzweilai.net/articles/art0134.html?printable=1>, Kurzweil points out that each apparent limit to the feasibility of progress for some technology is overcome by innovations that jump to a slightly different technology that avoids the limit, and Moore's law is an example of this phenomenon.

Niklaus Wirth lectured and wrote often about how software "bloat" seemed to negate and even overwhelm the advances provided by Moore's law. A representative example is "A Plea for Lean Software" [4].

The September 2006 issue of *IEEE Solid State Circuits* is a special issue on Moore's law. It includes the article by David E. Liddle referenced below that points out many of the subtle and economic implications of Moore's law. See [http://www.ieee.org/portal/site/sscs/menuitem.656c9fab99af5fb8699305765bac26c8/index.jsp?&pName=sscs\\_enews\\_home&month=09&year=2006](http://www.ieee.org/portal/site/sscs/menuitem.656c9fab99af5fb8699305765bac26c8/index.jsp?&pName=sscs_enews_home&month=09&year=2006).

One of the best in-depth articles on the chip manufacturing technology underlying Moore's law is by Jon Stokes, in Ars Technica (last updated September 2008). <http://arstechnica.com/hardware/news/2008/09/moore.ars>.

## MPI (Message Passing Interface)

WILLIAM GROPP

University of Illinois at Urbana-Champaign, Urbana, IL, USA

### Synonyms

Message passing

### Definition

MPI is an ad hoc standard for writing parallel programs that defines an application programmer interface (API) implementing the message-passing programming model. MPI is very successful and is the dominant programming model for highly scalable programs in computational science. The fastest parallel computers in the world, with more than 200,000 cores, run programs written in MPI, and the fastest applications (achieving over 1 PetaFLOPs in 2010) use MPI.

MPI was created in two stages. The original MPI standard [7], developed between 1992 and 1994, specified a library interface for point-to-point and collective communication, along with various support routines and other features. The second stage, from 1995 to 1997, extended MPI to include parallel I/O, remote memory access, and creation of additional processes, among other features.

## Discussion

### MPI-1

The MPI standard provides a way to make use of the Communicating Sequential Processes (CSP) programming model. In MPI, conventional processes make explicit calls to library routines defined by the MPI standard to communicate data between two or more processes.

In the message-passing model, processes communicate by sending messages. This is a two-sided operation: the sending process describes the data to be sent

and the receiving process describes how to receive the message. More specifically, the sender and the receiver each must describe the following: What data is sent? To whom is it sent? Where (in memory) is it received at the destination process? In addition, the receiver may need to know: who sent the data and how much data was sent. In addition, it is common to provide one additional nonnegative integer of information to be communicated from the sender to the receiver. This is called the *message tag*. It can be thought of as a way to identify a specific kind or type of message to the receiving process, and the receiving process can specify that a particular receive operation will only accept a message with a specific tag (in earlier message-passing systems, this tag was sometimes called the *message type*).

MPI generalizes the notion of what data is send and to whom the data is sent. The most common specification for data is a pointer to data and a length (e.g., in bytes). For example, the Unix write routine describes the data to write this way. In MPI, this is generalized in two ways. First, the type of data is described in terms of an *MPI\_Datatype*. The basic MPI Datatypes match the basic datatypes in the programming language being used with MPI. Thus for an “int” in C, there is an MPI\_INT datatype; for an “INTEGER” in Fortran, there is an MPI\_INTEGER datatype. This allows users to describe the amount of data to be sent in natural terms (10 ints) rather than as a specific number of bytes, which may depend on the particular platform (e.g., is an int 4 or 8 bytes). In addition, this allows an MPI implementation to convert the data being sent to match the receiving process. For example, if the sender uses 4 byte ints in big-endian format and the receiver used 8 byte ints in little-endian format, the MPI implementation can ensure that the data is correctly received. Thus, to specify the data that is to be sent (or the location into which data is to be received), MPI specifies a 3-tuple: pointer, count, and MPI Datatype.

The MPI Datatype parameter allows an additional generalization. In MPI, there are routines to define new, user-defined datatypes in terms of the any defined (basic predefined or user-defined) datatype. These datatypes may describe multiple data items and need not be contiguous. For example, MPI provides a routine to define a “vector” datatype that describes blocks of a datatype, separated by a stride in memory. By using such a datatype (or one of the other MPI datatype

constructors) in the 3-tuple describing the data to send (or to receive), the programmer can describe an arbitrary set of data to send or receive.

MPI also generalizes how the source and destination processes are described. Perhaps the simplest way to identify the source and destination is to number all of the processes, starting from zero (this works to identify MPI processes belonging to the same executing MPI program; it does not and is not intended to identify the MPI processes outside of the MPI program as a hostname and process id (pid) pair would on typical cluster). The number between zero and the number of processes minus 1 is called the *rank* of the process. In early message-passing systems, this rank was all that was necessary to identify the source and destination of a process.

In MPI, the rank of a process is relative to a collection of processes. These collections are called *MPI\_Groups*, and the programmer may construct new groups from any existing *MPI\_Group*. When an MPI program starts, there is a group that contains all processes in the MPI program. This group is combined with a *communication context* (more on that below) in an MPI object, called a *Communicator*. In MPI-1, all communication is relative to a communicator. When an MPI program starts, the communicator MPI\_COMM\_WORLD is defined, and each process can determine which rank it is relative to this communicator and how many processes are part of this communicator. Allowing the creation of new communicators containing different numbers of processes makes it much easier to build applications and libraries that can work with subsets of processes. Thus, in MPI, the destination process for a send (or the source process in a receive) is specified with the 2-tuple of rank and communicator.

In addition to sending and receiving data, MPI provides routines to initialize and end an MPI program; these are the routines MPI\_Init and MPI\_Finalize, and routines to determine the number of processes in a communicator (and in the MPI program if the communicator is MPI\_COMM\_WORLD) and the rank of a process in a communicator. These routines are MPI\_Comm\_size and MPI\_Comm\_rank, respectively. With these routines, and with MPI\_Send to send a message and MPI\_Recv to receive a message, we can show a simple MPI program.

The following example of an MPI program illustrates these basic MPI routines. In this complete C program, the process with rank 0 in MPI\_COMM\_WORLD sends two integer values to the process with rank 1, which then prints out the values received.

```
#include "mpi.h"
#include <stdio.h>
int main(int argc, char *argv[])
{
 int rank, size, sbuf[2], rbuf[2];
 int dest, source, tag;
 MPI_Status mystat;
 MPI_Init(&argc, &argv);/* Initialize MPI */
 MPI_Comm_rank(MPI_COMM_WORLD,
 &rank);
 MPI_Comm_size(MPI_COMM_WORLD, &size);
 if (rank == 0) {
 sbuf[0] = 1; /* Any data process zero wants to
 send */;
 sbuf[1] = size;
 dest = 1; /* destination rank */
 tag = 0; /* message tag */
 MPI_Send(sbuf, 2, MPI_INT, dest, tag,
 MPI_COMM_WORLD);
 }
 else if (rank == 1) {
 source = 0; /* Source rank */
 tag = MPI_ANY_TAG; /* receive the next
 message from source, independent of the tag */
 MPI_Recv(rbuf, 2, MPI_INT, source, tag,
 MPI_COMM_WORLD, &mystat);
 printf("Received %d %d from sender\n", rbuf[0],
 rbuf[1]);
 /* mystat.MPI_SOURCE contains the source
 rank;
 mystat.MPI_TAG contains the tag of the message
 */
 }
 printf("Process %d is exiting\n", rank);
 MPI_Finalize(); /* No MPI calls after MPI_Finalize
 executes */
 return 0;
}
```

Most of these features have already been discussed; the one MPI item that is new here is the *MPI\_Status* object. This is used to contain information about the

source, tag, and size of the message. It is also important to understand how this parallel program executes. When receiving, a specific source and tag may be specified, or MPI\_ANY\_SOURCE or MPI\_ANY\_TAG used, respectively. In that case, the *MPI\_Status* object may be used to determine the source and tag, respectively. These also allow the specification of nondeterministic programs.

In MPI, each process executes with its own address space. There are no shared variables or direct access to memory in another process (in MPI-1). If the above program is started with two processes (which may be on two processors, two cores of the same processor chip, or even two processes executing on the same core), each process has a full copy of all of the variables. For example, in the above example, there is an “int sbuf[2]” in each process. In addition, MPI programs execute independently; it is only when an MPI routine is called that two or more processes may communicate. In particular, language features or routines that are not part of MPI will execute independently in each process. In this example, the printf right before the call to MPI\_Finalize is executed by each process and in whatever order occurs as the program executes.

## Major Features of MPI-1

MPI provides a rich set of routines. They are described in separate chapters in the MPI standard, and include both point-to-point (two party) and collective (many party) communication.

The core of MPI-1 is the point-to-point communication routines. We have already seen the two most basic routines – MPI\_Send and MPI\_Recv. MPI provides a number of variations on each of these. One of the most important is the nonblocking versions of these routines. In this case, the corresponding MPI routine only initiates the communication – a separate MPI routine is required to ensure that the communication has completed. This permits the MPI implementation to overlap the execution of these operations with other computation or communication. Another variation is different send modes. In addition to the basic send mode, there is a *synchronous* send mode, where the send operation completes only when the matching receive begins, and the *ready* send mode, which requires that the matching receive has already been initiated on the destination

process (permitting optimization of the message delivery). MPI also provides for *persistent* communication for operations that are repeated, such as communication within a loop. MPI also provides routines to test for the presence of a message and to cancel nonblocking communication.

MPI Datatypes have already been mentioned; MPI provides routines to create datatypes that represent regularly strided data (vector), blocks of different size (similar to the Unix IOV structure), and (in MPI-2) blocks of the same size. By specifying a data layout with an MPI datatype, rather than by having the user first gather the data into a contiguous buffer and then send it, the MPI library can eliminate a memory copy and, in some cases, exploit special instructions to more efficiently move data.

In addition to point-to-point communication, MPI provides a rich set of collective communication and computation routines. For example, the routine MPI\_Bcast allows one process to broadcast the same data to every other process in an MPI communicator. Other routines provide one-to-many (MPI\_Scatter), many-to-one (MPI\_Gather), and many-to-many (MPI\_Alltoall) communication. These routines are provided because efficient, scalable implementations require great care and depend upon the specifics of the underlying network hardware. Collective computation is also very important, and MPI provides routines to perform parallel prefix (MPI\_Scan), reduction (MPI\_Reduce), reduction to all (MPI\_Allreduce), and a distributed reduction (MPI\_Reduce\_scatter). Like the point-to-point communication routines, data is described by the 3-tuple of pointer, count, and datatype.

An innovative feature of the MPI API is the profiling interface. Each MPI routine is available in two versions: one with the MPI prefix and one with a PMPI prefix. The PMPI version performs exactly the same operations as the MPI version. The user is permitted to override the MPI versions. Thus, to count the number of times that MPI\_Send is used in a program, all an MPI programmer needs to do is to compile the following code and link it with their application:

```
#include "mpi.h"
static int sendCount = 0;
int MPI_Send(void *buf, int count, MPI_Datatype
 dtype, int rank, int tag, MPI_Comm comm)
```

```
{
 sendCount++;
 return PMPI_Send(buf, count, dtype, rank, tag,
 comm);
}
int MPI_Finalize(void)
{
 int rank;
 MPI_Comm_rank(MPI_COMM_WORLD,
 &rank);
 printf("Process %d called MPI_Send %d times\n",
 rank, sendCount);
 return PMPI_Finalize();
}
```

This works on any system and does not rely on operating system-specific features. A number of tools take advantage of this feature to provide performance and correctness debugging information about an MPI program.

As mentioned above, communication in MPI is relative to communicators that contain a group of processes and a communication context. This communication context is not accessible to the user but is a hidden property of the communicator. The reason for this is to support modular programming, where different suppliers provide software libraries that use MPI. These libraries must be certain that their communication cannot be intercepted by other routines in the application. Without private communication contexts, it isn't possible to make this guarantee. Thus, each communicator in MPI contains a group of processes and a private communication context. A new communication context is created every time a new communicator is created. The routine MPI\_Comm\_dup creates a new communicator with the same group of processes but a new communication context; it is recommended that libraries using MPI call this routine to get a private communicator and use that communicator for all communication.

While the communication context is not directly accessible to the user, the group of process is and may be manipulated by the user. However, for many users, the best way to create a new communicator is by “splitting” an existing communicator into new ones with MPI\_Comm\_split.

MPI also provides a set of routines to create and use virtual process topologies; these are arrangements of

processes so that each process has a natural set of neighbors. MPI\_Cart\_create, for example, takes as input an MPI communicator and the description of a Cartesian mesh and returns a new communicator, where the neighbors of each process in the mesh of processes can be determined and where the processes may be mapped onto the physical network in such a way that communication with neighbor processes is especially efficient.

Other features in MPI-1 allow the definition of data to be cached on a communicator and routines to define the behavior when a recoverable error is encountered. The rich set of features of MPI, along with the focus on performance and completeness, helped MPI rapidly become the preferred way to use the message-passing programming model on parallel computers. But within two years of the release of MPI, users were asking for additional features. To respond to that need, the MPI Forum reconvened and began defining a set of extensions to MPI.

## MPI-2

MPI-2 [6] defines a set of *extensions* to MPI-1: any valid MPI-1 program is a valid MPI-2 program. While MPI-2 roughly doubled the number of routines in MPI, most of the additions were in four areas: remote memory access, dynamic processes, parallel I/O, and C ++ and Fortran 90 language bindings.

## Major Features of MPI-2

Remote memory access (RMA) provides a “one-sided” model of communication, where one process specifies both the source and the destination of the communication. Sometimes called “put/get” programming, MPI provides routines to put data into a remote process (MPI\_Put), get data from a remote process (MPI\_Get), and update data in a remote process (MPI\_Accumulate). This resembles more conventional shared memory programming, however, with several important differences. First, all data transfers still happen as a result of a call to an MPI routine. The process performing the transfer is called the origin; the process that is the target of the transfer is called the target. Second, the local and remote completion of that transfer may require additional MPI calls. While the details are

quite lengthy and subtle, there are two modes in MPI. The first, called active target, requires each process to call a routine to begin and end both use of RMA routine (the access epoch) and access by other processes (the exposure epoch). The *Bulk Synchronous Programming* model has a very similar form.

The second mode is call passive target. In this mode, the origin process makes initiates and completes the RMA operation without requiring that any MPI routine be called on the target process. This provides something similar to a conventional shared memory model. The reason for these two modes is that there are implementation issues and opportunities for optimization with each; the programmer can pick the one that is most appropriate for their needs.

The following code fragment is an example of the MPI one-sided interface. It implements the same communication of data and the point-to-point example above. This example uses the active target synchronization with the routine MPI\_Win\_fence. MPI also provides routines to specify the region of memory that is exposed to access or updates from remote processes. The *MPI\_Win* object contains this information and can be considered as the one-sided version of the MPI Communicator.

```

MPI_Win_create(rbuf, 2, MPI_INT, sizeof(int), ...,
 &win);
MPI_Win_fence(0, win);
if (rank == 0) {
 MPI_Put(sbuf, 2, MPI_INT, 1, 0, 2, MPI_INT,
 win);
}
MPI_Win_fence(0, win);
If (rank == 1) {
 printf("Received %d %d from sender\n", rbuf[0],
 rbuf[1]);
}
MPI_Win_free(&win);

```

In the MPI-1 model, the number of processes is fixed when the program begins. In MPI-2, routines are provided to create new MPI processes as part of the same running MPI program (e.g., MPI\_Comm\_spawn) and to connect two MPI programs that are already running (e.g., MPI\_Comm\_connect and MPI\_Comm\_accept). These routines return a special kind of

communicator (called an intercommunicator) that contains two groups of processes. In the case of MPI\_Comm\_spawn, the two groups are the group of processes that called MPI\_Comm\_spawn and the group of processes created by MPI\_Comm\_spawn. Intercommunicators are part of MPI-1, but until MPI-2, they were rarely used.

MPI-2 also provides a rich set of parallel I/O routines. The viewpoint taken is that writing to a file is like sending a message and reading from a file is like receiving a message. Following that model, MPI provides routines to read and write data, using the same 3-tuple to describe the data in the MPI program. By using user-defined MPI datatypes to set a “file view” (describing which parts of a file each of the MPI processes can access), very general I/O patterns can be described in a single MPI call. And in addition to independent I/O routines, MPI provides *collective* I/O routines, where all processes (in the communicator use to open the file with MPI\_File\_open) perform coordinated I/O operations. These collective I/O routines can provide far more scalable performance than the independent I/O routines.

MPI-1 specified bindings to C and Fortran 77, and MPI-2 added a binding to C++ and defined Fortran 90 bindings. These bindings are relatively simple; there was little attempt, for example, to provide a high-level C++ binding.

In the original MPI model, a collection of processes is created (by some mechanism not defined by the MPI standard) to begin the execution of an MPI program. However, many implementations provided a program, mpirun, to start an MPI program. To provide a more standard interface, the MPI-2 standard recommends (but does not require) a program mpiexec to start MPI programs.

MPI-2 has been a mixed success. The MPI I/O routines are widely available and used by software libraries such as HDF5 and parallel netCDF. The one-sided (RMA) routines are available but with uneven implementation quality; in addition, while the MPI RMA model permits an interesting class of applications (including client-server), it is a poor match to other one-sided applications. The absense of a read-modify-write operation makes operations such as fetch-and-increment very difficult. Despite these problems, MPI

remains the dominant parallel programming model in computational science.

## The Future of MPI

MPI continues to evolve. The MPI Forum has begun discussions on the next version of MPI, which will be called MPI-3, and will most likely be a further extension of the current MPI-2 API. Among discussion for MPI-3 are the following features.

Blocking collectives communication operations can limit the scalability of algorithms. During the development of MPI-2, the MPI Forum felt that users could implement nonblocking versions of the collectives simply by creating a thread and calling a blocking MPI collective routine from within the thread. In practice, this was not sufficient. In some cases, the overhead of thread support was too costly, particularly for collectives involving small amounts of data. In addition, some systems, such as the IBM Blue Gene/L (one of the most powerful parallel computers) allowed only one thread per core, making this approach inefficient. MPI-3 is likely to offer nonblocking collectives, similar to the nonblocking point-to-point and nonblocking parallel I/O routines in MPI.

The remote-memory access interface defined in MPI-2 was designed to support certain types of operations, such as halo exchanges used in numerical simulations, and it works well for those. But it is ill suited to more dynamic uses of RMA, and it is not an effective API for the operations needed by implementations of Partitioned Global Address Space (PGAS) languages. Other APIs, such as ARMCI and GASNET, offer a more flexible interface (while requiring either more hardware support or less precise semantics than MPI). The MPI Forum is exploring ways to extend the MPI RMA model to make it a more general purpose.

One strength of MPI has been its support for components and multilingual programming. The MPI Forum is looking at ways to ensure that MPI works well with a variety of programming models, from SMP parallelism to coexistence with PGAS languages such as UPC and CAF.

Large scale system with millions of processor cores, on which MPI is likely to be used, are likely to suffer frequent faults. MPI (starting with the original MPI-1) does provide a flexible error-handling model. But after

an error, the behavior of MPI is undefined. The MPI Forum is attempting to define what faults and situations the MPI implementation should continue through (while indicating an error) to enable the development of portable, fault-tolerant programs.

The above show that MPI will evolve to address new capabilities and requirements in large-scale parallel computing systems. See [www mpi-forum.org](http://www mpi-forum.org) for information on the current status of MPI and the MPI standardization efforts.

## More on History of MPI

MPI really began at the Workshop on Standards for Message Passing in a Distributed Memory Environment in Williamsburg, Virginia, held in April, 1992. The meeting was called by Ken Kennedy, who had the foresight to see both the need and opportunity for a specification of a standard library for message passing. A preliminary proposal, developed by Dongarra, Hempel, Hey, and Walker, led the community to come together to develop a standard. An organizational meeting held at Supercomputing in Minneapolis in November, 1992, laid out the goals, along with a commitment by the author of this entry to maintain an implementation of the current draft of the standard. This draft and reference implementation helped to both refine the standard and provide initial implementations on a variety of platforms, aiding in the adoption of the new standard. Today, there are many high-quality implementations, both open source (such as MPICH2 and Open MPI) and proprietary implementations from the major parallel computer vendors.

MPI was developed by a group of researchers, application specialists, and vendor representatives. An open process was used with regular (every 6–8 weeks) meetings. Email (and later wiki) discussions were used to engage the broader community. Votes, apportioned as one per participating institution, were used to choose the standard; voting at two consecutive meetings was required, allowing for “buyer’s remorse.” More details on the process are in [4].

## Conclusion

MPI is possibly the most successful parallel programming model ever, having reached age 17 (as of 2011) and

continuing to go strong. Built upon the sound basis of communicating sequential processes and using a truly open process to define the interface, MPI, particularly for the highly scalable systems, has become the parallel programming model to beat.

## Bibliographic Notes and Further Reading

An annotated version of the MPI standards are available in [1, 8]. Official versions of the documents are available at [www mpi-forum.org](http://www mpi-forum.org). A tutorial introduction to MPI-1 and MPI-2 is available in [2, 3]. There are many other tutorial and research publications on MPI; there is one annual conference devoted to MPI: the EuroMPI (formerly Euro PVMMPI) meetings produce a proceeding every year in Springer’s Lecture Notes in Computer Science (e.g., see [5]).

## MPI-2 I/O

► MPI-IO

## MPI-IO

JEAN-PIERRE PROST  
Morteau, France

### Synonyms

MPI-2 I/O

### Definition

MPI-IO is a portable interface defined by the Message Passing Interface (MPI) Forum in order to perform parallel I/O operations within distributed memory programs, leveraging MPI key concepts such as communicators, datatypes, and collective operations. It was first introduced as the I/O chapter of the second specification of the Message Passing Interface, referred to as MPI-2.

### Discussion

#### Introduction

In June 1994, the MPI Forum released their first draft MPI 1.0, defining point-to-point and collective communication operations between tasks (i.e., virtual processes) within a given context, called a communicator. Point-to-point communication operations could be either blocking or nonblocking. This draft also introduced the concept of a datatype describing a virtual data layout in the memory of the sending or the receiving process(es). In March 1995, a second draft MPI 1.1 was released to correct errors and make clarifications from the first draft.

Until July 1997, implementations of the MPI 1.1 draft were released by major computer companies and by open source initiatives, and practical experiences with the “standard” were gathered by numerous distributed memory application developers.

Among the shortcomings of the draft specification that this experimentation helped identify was the lack

of support for parallel I/O in a portable way across existing and emerging distributed and parallel file systems, limiting the scope of distributed memory applications to in-memory processing or to coding using either proprietary I/O interfaces or the Posix interface that these file systems supported.

Therefore, in July 1997, the MPI Forum published the second version of MPI, referred to as MPI 2.0, that contained an I/O chapter, specifying a portable interface for parallel I/O aimed at MPI applications. MPI-IO was born.

The MPI key concepts are leveraged by the MPI-IO specification. The basic idea behind MPI-IO is to consider reading a file like receiving data from the file into virtual memory and writing a file like sending data from virtual memory into the file. The file can therefore be assimilated to either a sending task in read operations or a receiving task in write operations.

With this analogy in mind, independent I/O read and write operations are like point-to-point receive and send operations, respectively, and collective I/O operations are like collective communication operations between the group of initiating tasks in the context of a communicator and the file. These read and write operations, just like communication operations, can be blocking or nonblocking. And describing from where to read data within the file or where to write data into the file is only a matter of defining a file datatype, referred to as a file view, after opening the file.

In order to gain better advantage of parallel file system specifics and reach optimal performance, without sacrificing application portability across parallel systems, file hints are introduced. Each target run time environment is free to support a given file hint, and setting an unsupported file hint to an open file simply has no (positive or negative) effect.

#### Access Pattern Expression

In order to specify the access pattern associated with an open file, a file view must be defined by each task accessing the file, unless the default view is to be used and each task sees the file as a linear byte stream.

A file view essentially specifies:

- An absolute displacement into the file (in bytes), specifying where the file pointer ought to be placed

in the file before the next access takes place by the calling task;

- An elementary datatype (etype), representing the MPI datatype of each element within the file to be accessed by the calling task;
- A file datatype (filetype), representing the layout of the elements to be accessed by the calling task; this layout must be an MPI datatype derived from the etype.

Typically, all tasks participating to the collaborative access of a given file set complementary views of the file, in order to partition the file data among themselves. [Figure 1](#) shows how a file can be partitioned in a cyclic manner across three tasks by chunks of two elements each.

A file view is associated with an open file by modifying the file handle returned when the file was opened. At any given time, only one file view can be set by a given task on a given open file. Setting a new file view changes the current file view.

*Note:* The default file view corresponds to a displacement of zero bytes, and to the etype and the filetype set to MPI\_BYTE.

## Data Access Functions

File data can be accessed either independently by each task, which has opened the file, or collectively by all tasks having opened the file.

The area of the task's virtual memory involved in the data access is specified by a memory buffer's address, an MPI datatype, and a count.

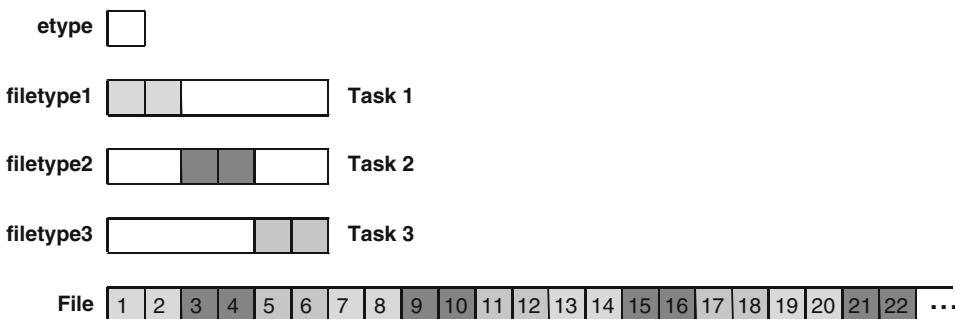

The region of the file to be accessed is specified by the file view associated with the open file and a file

position, which represents the location within the file where the access is to begin.

The file position is expressed either as an explicit offset within the file view, i.e., as a number of etype elements to be skipped within the file view before reading or writing file elements, or as the current position of the task's file pointer.

Each open file has two types of file pointers maintained by the MPI environment, an individual file pointer for each task and a shared file pointer shared by all tasks having opened the file. The file pointer to be used for a given data access is determined by the name of the data access function called. After opening a file, each task's file pointer and the shared file pointer are set to zero and point to the byte within the file associated to the displacement specified in the file view or to the beginning of the file if the active file view is the default view. Note that the same file view must be set by all tasks having opened the file when the shared file pointer is to be used.

All data access can be either blocking or nonblocking. In the case of blocking calls, the call returns to the task when the data has been read from (or written to) the file. In the case of nonblocking calls, the call returns immediately to the task, which may choose later on to either test whether (call to the MPI\_Test or MPI\_Testall functions) or wait until (call to the MPI\_Wait or MPI\_Waitall functions) the data has been read from (or written to) the file. Note however that nonblocking collective data access functions are called split collective since they are made of two suboperations, a (nonblocking) begin operation that initiates the access and a (blocking) end operation that completes the access for all tasks synchronously.

**MPI-IO. Fig. 1** Partitioning an open file across three tasks

MPI-IO. Table 1 Data access function characteristics

| Data access function name    | Independent/collective | Blocking/nonblocking | File position   |
|------------------------------|------------------------|----------------------|-----------------|
| MPI_File_read_at             | Independent            | Blocking             | Explicit offset |
| MPI_File_write_at            | Independent            | Blocking             | Explicit offset |
| MPI_File_iread_at            | Independent            | Nonblocking          | Explicit offset |
| MPI_File_iwrite_at           | Independent            | Nonblocking          | Explicit offset |
| MPI_File_read_at_all         | Collective             | Blocking             | Explicit offset |
| MPI_File_write_at_all        | Collective             | Blocking             | Explicit offset |
| MPI_File_read_at_all_begin   | Collective             | Split collective     | Explicit offset |
| MPI_File_read_at_all_end     |                        |                      |                 |
| MPI_File_write_at_all_begin  | Collective             | Split collective     | Explicit offset |
| MPI_File_write_at_all_end    |                        |                      |                 |
| MPI_File_read                | Independent            | Blocking             | Individual fp   |
| MPI_File_write               | Independent            | Blocking             | Individual fp   |
| MPI_File_iread               | Independent            | Nonblocking          | Individual fp   |
| MPI_File_iwrite              | Independent            | Nonblocking          | Individual fp   |
| MPI_File_read_all            | Collective             | Blocking             | Individual fp   |
| MPI_File_write_all           | Collective             | Blocking             | Individual fp   |
| MPI_File_read_all_begin      | Collective             | Split collective     | Individual fp   |
| MPI_File_read_all_end        |                        |                      |                 |
| MPI_File_write_all_begin     | Collective             | Split collective     | Individual fp   |
| MPI_File_write_all_end       |                        |                      |                 |
| MPI_File_read_shared         | Independent            | Blocking             | Shared fp       |
| MPI_File_write_shared        | Independent            | Blocking             | Shared fp       |
| MPI_File_iread_shared        | Independent            | Nonblocking          | Shared fp       |
| MPI_File_iwrite_shared       | Independent            | Nonblocking          | Shared fp       |
| MPI_File_read_ordered        | Collective             | Blocking             | Shared fp       |
| MPI_File_write_ordered       | Collective             | Blocking             | Shared fp       |
| MPI_File_read_ordered_begin  | Collective             | Split collective     | Shared fp       |
| MPI_File_read_ordered_end    |                        |                      |                 |
| MPI_File_write_ordered_begin | Collective             | Split collective     | Shared fp       |
| MPI_File_write_ordered_end   |                        |                      |                 |

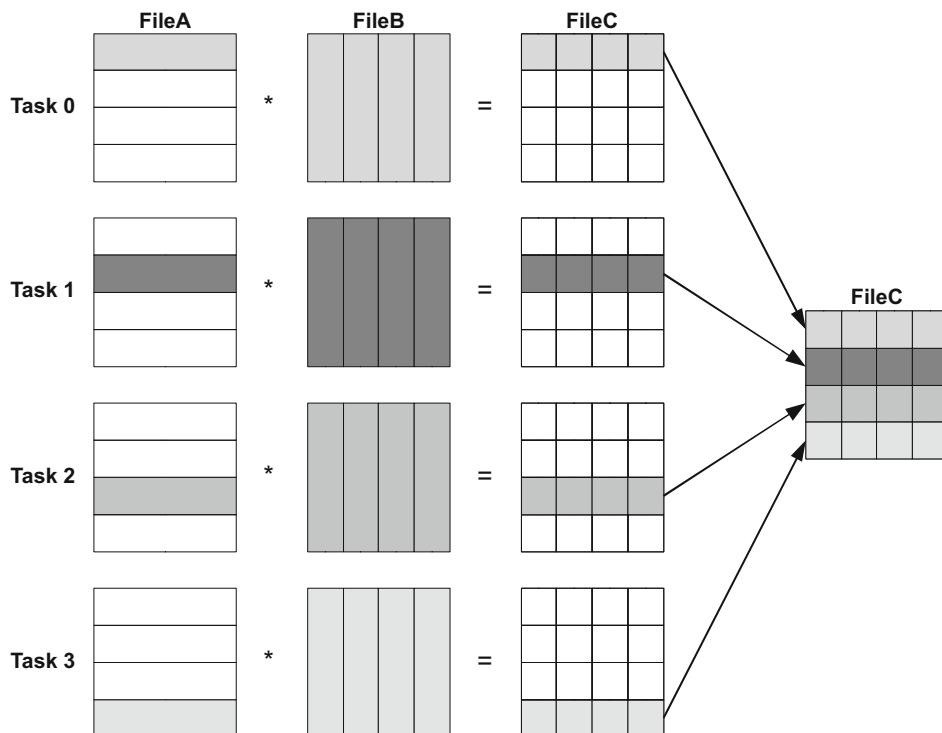

Table 1 specifies for each data access function whether the access is independent or collective, whether it is blocking or nonblocking, and whether it uses an explicit offset or the individual (or shared) file pointer (fp) to express the file position.

Assuming *fh* refers to an open file, whose file view has just been set to the view described in Fig. 1,

Table 2 above identifies the calling task and the *etype* elements read or written by each data access function call stipulated. It is assumed that *buf* points to a valid task memory area that contains the appropriate number of *etype* elements being read or can contain the appropriate number of *etype* elements being written.

**MPI-IO. Table 2** Examples of data access function calls

| Data access function call and calling task(s)                                                                                                                                                                                                                                                                                                                                                            | Etype elements read or written                                  |

**MPI-IO. Fig. 2** Matrix partitioning across four computing tasks

### File Consistency

File consistency determines the outcome of concurrent and conflicting accesses to the same file by multiple tasks. Two accesses are concurrent if the respective data spans associated with the accesses overlap. They conflict

if they are concurrent and at least one access is a write operation.

Sequential consistency of concurrent and conflicting accesses to the same file guarantees each access is atomic and the outcome of the accesses is the same as

```

#include "sys/types.h"
#include "stdlib.h"
#include "stdio.h"
#include "string.h"
#include "mpi.h"

#define P 4 /* number of tasks */
#define Nb 64 /* slice size */
#define Ng (Nb * P) /* global size of matrix */

static char fileA[] = "fileA";
static char fileB[] = "fileB";
static char fileC[] = "fileC";

void
main(int argc, char *argv[])
{
 int i, j, k;
 int iv;
 int myrank, commsize;
 int extent;
 int colext;
 int slicelen;
 int sliceext;
 int length[3];
 MPI_Aint disp[3];
 MPI_Datatype type[3];
 MPI_Datatype ftypeA;
 MPI_Datatype ftypeB;
 MPI_Datatype ftypeC;
 MPI_Datatype slice_typeB;
 MPI_Datatype block_typeC;
 MPI_Datatype slice_typeC;
 int mode;
 MPI_File fh_A, fh_B, fh_C;
 MPI_Offset offsetA;
 MPI_Offset offsetB;
 MPI_Offset offsetC;
 MPI_Status status;
 int val_A[Nb][Ng], val_B[Ng][Nb], val_C[Nb][Nb];

 /* initialize MPI */
 MPI_Init(&argc, &argv);
 MPI_Comm_rank(MPI_COMM_WORLD, &myrank);
 MPI_Comm_size(MPI_COMM_WORLD, &commsize);
}

```

**MPI-IO. Fig. 3** Sample code for an out-of-core 2D matrix multiplication

that, which would have been achieved if the accesses were performed in a serial order, although that order is unspecified.

By default, sequential consistency is only ensured by MPI-IO for concurrent accesses to the same file by the tasks, which opened it in the same collective operation.

Sequential consistency for conflicting accesses can only be ensured across a set of tasks, if they enabled the atomic mode when they collectively opened the file.

For all other concurrent and conflicting accesses, sequential consistency cannot be ensured unless the

```

MPI_Type_extent(MPI_INT, &extent);
coext = Nb * extent;
slicelen = Ng * Nb;
sliceext = slicelen * extent;

/* create filetype for matrix A */
length[0] = 1;
length[1] = slicelen;
length[2] = 1;
disp[0] = 0;
disp[1] = sliceext * myrank;
disp[2] = sliceext * P;
type[0] = MPI_LB;
type[1] = MPI_INT;
type[2] = MPI_UB;
MPI_Type_struct(3, length, disp, type, &ftypeA);
MPI_Type_commit(&ftypeA);

/* create filetype for matrix B */

mode = MPI_MODE_RDONLY;
MPI_File_open(MPI_COMM_WORLD, fileB, mode, MPI_INFO_NULL, &fh_B);
mode = MPI_MODE_CREATE | MPI_MODE_WRONLY;
MPI_File_open(MPI_COMM_WORLD, fileC, mode, MPI_INFO_NULL, &fh_C);

```

**MPI-IO. Fig. 3** (Continued)

tasks accessing the same file explicitly perform appropriate file sync operations collectively among themselves.

### File Hints for Performance

File hints can be specified when a task opens a file in order to take advantage of parallel file system specifics or minimize the use of system resources,

leading to optimized parallel I/O when accessing that file.

Reserved hints are defined by MPI-IO to set the access style to the open file (random, sequential, reverse sequential, read mostly, write mostly, read once, write once), to enable collective buffering (allowing the same buffer to be shared across accessing tasks), to specify an

```

/* set file error-handlers to MPI_ERRORS_ARE_FATAL in order to shorten sample code
 (default file error handler is MPI_ERRORS_RETURN) */
MPI_File_set_errhandler(fh_A, MPI_ERRORS_ARE_FATAL);
MPI_File_set_errhandler(fh_B, MPI_ERRORS_ARE_FATAL);
MPI_File_set_errhandler(fh_C, MPI_ERRORS_ARE_FATAL);

/* set views */
MPI_File_set_view (fh_A, MPI_OFFSET_ZERO, MPI_INT, ftypeA, "native", MPI_INFO_NULL);
MPI_File_set_view(fh_B, MPI_OFFSET_ZERO, MPI_INT, ftypeB, "native", MPI_INFO_NULL);
MPI_File_set_view(fh_C, MPI_OFFSET_ZERO, MPI_INT, ftypeC, "native", MPI_INFO_NULL);

offsetA = MPI_OFFSET_ZERO;
offsetB = MPI_OFFSET_ZERO;
offsetC = MPI_OFFSET_ZERO;

/* read horizontal slice of A */
MPI_File_read_at_all(fh_A, offsetA, val_A, slicelen, MPI_INT, &status);

/* loop on vertical slices */
for (iv = 0; iv < P; iv++) {

 /* read next vertical slice of B */
 MPI_File_read_at_all(fh_B, offsetB, val_B, slicelen, MPI_INT, &status);
 offsetB += slicelen;

 /* compute block product */
 for (i = 0; i < Nb; i++) {
 for (j = 0; j < Nb; j++) {
 val_C[i][j] = 0;
 for (k = 0; k < Ng; k++) {
 val_C[i][j] += val_A[i][k] * val_B[k][j];
 }
 }
 }

 /* write block of C */
 MPI_File_write_at_all(fh_C, offsetC, val_C, Nb * Nb, MPI_INT, &status);
 offsetC += Nb * Nb;
}

/* close files */
MPI_File_close(&fh_A);
MPI_File_close(&fh_B);
MPI_File_close(&fh_C);

/* free filetypes */
MPI_Type_free(&ftypeA);
MPI_Type_free(&slice_typeB);
MPI_Type_free(&ftypeB);
MPI_Type_free(&block_typeC);
MPI_Type_free(&slice_typeC);
MPI_Type_free(&ftypeC);

/* finalize MPI */
MPI_Finalize();
}

```

**MPI-IO. Fig. 3** (Continued)

I/O node list and a striping pattern across these nodes. Each implementation is free to support or not these reserved hints. If they are not supported, they are simply ignored. If they are supported, the implementation

should comply with the semantics defined for them in the MPI-IO specification.

Additional implementation specific hints can be supported by an implementation. The naming of these

hints should be chosen in such a way that conflicting names across implementations be prevented. For instance, IBM defined additional hints in their MPI-IO implementation on top of the IBM General Parallel File System (GPFS) in order to specify a sparse access style to the file, to control GPFS data prefetching, or to benefit from GPFS data shipping feature. This feature partitions a file across a specific number of I/O agents and ships all data accesses from the MPI tasks to these I/O agents over the interconnecting network, hence limiting the number of concurrent tasks accessing the file and grouping several small accesses into fewer larger data blocks to be accessed.

It is clear that file hints are to be used cautiously and only when relevant to the I/O patterns exhibited by the application on a per file basis. Applying inappropriate file hints, when supported by a given implementation, may lead to decreased performance.

### Sample Code: Out-of-Core Matrix Multiplication

In order to illustrate the main MPI-IO concepts, Fig. 2 above depicts the matrix partitioning scheme that is used in order to perform the out-of-core multiplication of two square matrices A and B. Each task is computing a slice of the resulting matrix C.

Figure 3 presents the corresponding code. Matrix A is initially stored in file “fileA,” matrix B in file “fileB,” and the result of the multiplication, matrix C, is stored in file “fileC.” All matrices are 256\*256 square matrices containing integer numbers, stored in row major order.

### Bibliographic Notes and Further Reading

The MPI-IO interface [2] was defined in the late 1990s by the Message Passing Interface Forum [5] in an attempt to provide an interface for portable and efficient parallel I/O operations in distributed memory programming environments.

Implementations have been developed over the years on top of various parallel file systems, such as the General Parallel File System on IBM Scalable Power systems [7] and on the Blue Gene/L supercomputer [12], the Lustre file system [3], the Parallel Virtual File System Version 2 [4], or the NEC SX Global File System [11].

An open source implementation of MPI-IO, referred to as ROMIO [10], is available. It provides portability onto various back-end parallel file systems through an abstract-device I/O interface [9].

Performance studies [1, 6] and benchmarks [8] have been carried out to demonstrate the efficiency that can be achieved for read and write operations through specific I/O strategies [1, 6] and the use of MPI-IO’s file hints [8].

## Multiflow Computer

GEOFF LOWNEY

Intel Corporation, Hudson, MA, USA

### Definition

The Multiflow Trace was a VLIW computer system, designed and manufactured by Multiflow Computer, Inc. of Branford, CT, USA. The Multiflow Trace was distinguished by its ability to issue as many as 7, 14, or 28 operations in each instruction, whose width could be up to 1,024 bits, depending upon the model. Designed as a target for a *trace scheduling* compiler, users were not required to divide the code into parallel routines. The compiler, sometimes with guidance from the programmer, found instruction-level parallelism in ordinary code, and constructed the very long instructions prior to the running of the program. Design of the Multiflow Trace began in 1984, with the first systems delivered in 1987. The last of the approximately 120 systems sold was delivered in 1990.

### Discussion

#### Introduction

In the late 1970s, instruction-level parallelism (ILP) was a research topic. In fact, Joseph (Josh) Fisher coined the term in 1980, while a professor at Yale University. Dynamic ILP, where the parallelism is discovered by the hardware as the program runs, had been explored in supercomputing. Static ILP, where the microcoder, assembly language programmer, or compiler scheduled multiple operations into a single instruction, existed in microcoded machines and in some specialized accelerators. Several researchers had demonstrated that only limited amounts of instruction-level parallelism could be discovered in a basic block, which seemed a natural boundary for compile-time scheduling.

In his dissertation research at New York University, Fisher demonstrated that extensive instruction-level parallelism could be discovered by scheduling across multiple basic blocks. His compiler technique, called *trace scheduling*, identified paths, or traces, through a program at compile-time, unrolling loops if needed. Operations on the trace were scheduled across basic block boundaries and packed into long instruction words.

Fisher's ideas made it practical to build general-purpose computers designed to exploit instruction-level parallelism. No expensive dynamic hardware would be required. Fisher called these machines VLIW (Very Long Instruction Word) computers, and his research team at Yale developed the concepts behind the VLIW architecture and trace scheduling compilers.

Fisher and two of his colleagues from Yale (John Ruttenberg and John O'Donnell) founded Multiflow in 1984. Compiler and hardware design started immediately, with the compiler written at Yale serving as an initial guide to the hardware design. Three years later, Multiflow delivered the Trace 7/200, followed quickly by the 14/200, and the 7/300, 14/300, and 28/300, all running the Unix operating system, with code compiled by Multiflow's Trace Scheduling Compiler. During the 3 years of their delivery, the Trace systems were consistently at or near the top of the performance/price ratio of scientific computers, despite their relatively modest 65ns cycle time.

## Design Principles

The Trace machines were designed as a target of a trace scheduling compiler. As much as possible, all scheduling decisions and resource allocation checks were made by the compiler, not the hardware. At compile-time, the compiler modeled how the program would behave on a cycle-by-cycle basis, created a schedule of its execution, and then at run-time, the hardware executed the schedule. For events that were not modeled by the compiler, such as an instruction cache miss, the entire execution pipeline was stalled until execution resumes.

Compile-time modeling of program behavior was the essence of the trace scheduling design. This idea is also applicable to modern processors that support more dynamic behavior in hardware, and it has been used successfully in many compilers derived from the Multiflow compiler.

## The Trace Machines

*Implementation.* There were two generations of Multiflow computers. The 200 series, first shipped in January, 1987 with a 65 ns cycle time, was implemented in CMOS gate arrays and TTL logic, using Weitek CMOS floating point chips. The 300 series followed in July, 1988, using the Bipolar Integrated Technologies (BIT) ECL

floating point parts. The cycle time remained at 65ns. A third generation of Multiflow machines was under design when the company closed in March 1990. It was an ECL semi-custom implementation targeting a 15 ns cycle time.

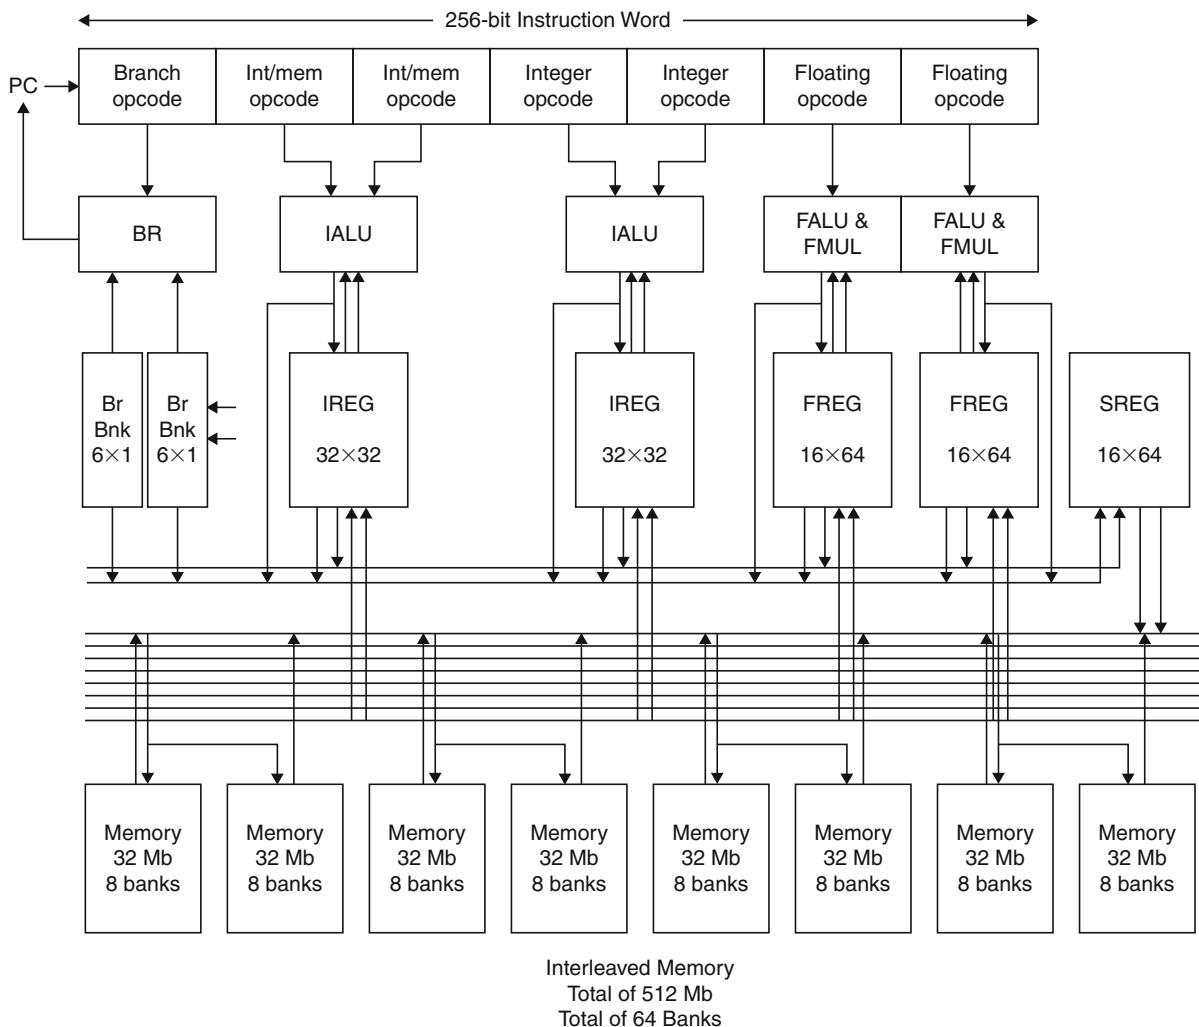

*Basic architecture.* An instruction on the Multiflow Trace machine consisted of several RISC-level operations packed together into a single wide instruction. The wide instructions directly controlled multiple register files, pipelined memory units, branch units, integer ALUs, and pipelined floating point units. Execution was fully synchronous, with a single program counter directing instruction fetch. All operations took a statically predictable number of machine cycles to complete. Pipelining was exposed at the instruction level. The processor was not scoreboarded, and machine resources could be oversubscribed. The memory system was interleaved. The compiler needed to avoid register conflicts, schedule the machine resources, and manage the memory system.

The machines came in three widths: a seven-wide, which had a 256-bit instruction issuing seven operations; a 14-wide with a 512-bit instruction; and a 28-wide with a 1,024-bit instruction. The wider processors were organized as multiple copies of the seven-wide functional units; the seven-wide group of functional units was called a cluster. A block diagram of the 7/300 is below ([Fig. 1](#)).

There were four functional units per cluster: two integer units and two floating units. In addition, each cluster could compute a branch target. An instruction was divided into two 65 ns *beats*. The integer ALUs could issue in the early and late beats of an instruction. The floating ALUs and branch unit could issue only in the early beat. Altogether, the cluster had the resources to issue seven operations for each instruction.

Most integer ALU operations were complete in a single beat. The load pipeline was seven beats. On the 300 series, the floating point pipelines were four beats. Branches issued in the early beat and the branch target was reached on the following instruction, effectively a two beat pipeline.

There are nine register files per cluster. Data going to memory was first moved to a store file. Branch banks were used to control conditional branches and the select operation.

**Multiflow Computer. Fig. 1** Block diagram of the 7/300

The instruction cache held 8K instructions. Each cluster had a slice of the cache, holding the instruction fields which control the cluster. There was no data cache.

The memory system supported 512 MB of physical memory with up to 64 way interleaving. The virtual address space was 4 GB.

There were two IO processors. Each supported a 246 MB/s DMA channel to main memory and two 20 MB/s VME busses.

**Code sample.** The code sample below contains two instructions of 14/300 code, extracted from the compiled inner loop of the  $100 \times 100$  LINPACK benchmark. Each operation is listed on a separate line. The first two fields identify the cluster and the functional unit

to perform the operation, the remainder of the line describes the operation. Note the destination address is qualified with a register-bank name (e.g., sb1.r0); the ALUs could target any register bank in the machine (with some restrictions). There was extra latency in reaching a remote bank.

*Data types.* The natural data types of the machine were 32-bit signed and unsigned integers, 32-bit pointers, 32-bit IEEE-format single precision, and 64-bit IEEE-format double precision. 16-bit integers and 8-bit characters were supported with extract and merge operations; bit strings with shifts and bitwise logicals; long integers by add with carry; and booleans with normalized logicals. There was no hardware support for extended IEEE precision, denormalized numbers, or gradual underflow.

Loads and stores were either 32 or 64 bits. Natural alignment was required for high performance; misaligned references were supported through trap code, with a substantial performance penalty.

Memory was byte addressed. Byte addressing eased the porting of C programs from byte-addressed processors such as the VAX and the Motorola 68000. The low bits of the address were ignored in a load or a store, but were read by extract and merge operations.

*Memory system and data paths.* The Multiflow Trace had a two-level interleaved memory hierarchy exposed

to the compiler. All memory references went directly to main memory; there was no data cache. There were eight memory cards, each of which contained eight banks. Each bank could hold 8 MB, for a total capacity of 512 MB. Memory was interleaved across the cards and then the banks. The low byte of an address determined its bank: bits 0–1 were ignored, bits 2–4 selected a card, and bits 5–7 selected a bank.

Data was returned from memory on a set of global busses. These busses were shared with moves of data between register files on different clusters; to maintain full memory bandwidth on a 28/30, the number and placement of data moves needed to be planned carefully.

Each level of interleaving had a potential conflict.

- Card/bus conflict. Within a single beat, all references were required to be distinct cards and to use distinct busses. If two references conflicted on a card or a bus, the result was an undefined program error.
- Bank conflicts. A memory bank was busy for four beats from the time it was accessed. If another reference touched the same bank within the four-beat window, the entire machine stalled. To achieve maximum performance, the compiler was required to schedule successive references to distinct banks.

A 28/300 could generate four references per beat, and, if properly scheduled, the full memory bandwidth of the machine could be sustained without stalling.

*Global resources.* In addition to functional units and register banks, the Trace machines had a number of global shared resources that needed to be managed by the compiler.

- Register file write-ports. Each integer and floating register file could accept at most two writes per beat, one of which could come from a local ALU. Each branch bank could accept one write per beat. Each store file could accept two writes per beat.
- Global busses. There were ten global busses; each could hold a distinct 32-bit value per beat. The hardware contained routing logic; the compiler needed only to guarantee that the number of busses was not oversubscribed in a beat.
- Global control. There was one set of global controller resources, which controlled access to link registers used for subroutine calls and indirect branches.

*Integer units.* The integer units executed a set of traditional RISC operations. There were a number of features added to support trace scheduling.

- The most common code optimization in trace scheduling was to move operations above a conditional branch and execute them speculatively, before the branch condition was known. To support speculative execution, there was a set of *dismissible load* operations. These operations performed a normal load and also set a flag to enable the exception handler to know the load was being performed speculatively.
- All operations that computed booleans were invertible. Invertible branches enabled the trace scheduler to lay out a trace as straight-line code by inverting branch conditions as necessary.
- A 3-input, one output *select* operation ( $a = b ? c : d$ ) enabled many short forward branches to be mapped into straight-line code.

A conditional branch was a two-operation sequence. An operation targeted a branch bank register, and then the branch read the register. Separate register files for the branch units relieved pressure on the integer register files and provided additional operand bandwidth to support the simultaneous branch operations.

The two integer ALUs per cluster were asymmetric; only one could issue memory references.

Due to limits on the size of the gate arrays, each integer ALU had its own register file. This fact, coupled with the low latency of integer operations, made it difficult for the instruction scheduler to exploit parallelism in integer code. The cost of moving data between register files often offset the gains of parallelism.

*Floating units.* Each floating unit had register file with 15 64-bit registers available to the compiler. To keep the pipelines full, nine distinct destination registers were required for operations in flight. This left only six registers to hold variables, common sub-expressions, and the results of operations that are not immediately consumed.

There was no pipelined floating move. A move between floating registers took one beat and consumed a register write-port resource. This could prevent another floating point operation issued earlier from

using the same write-port; in some situations, a floating move could lock out two floating point operations.

*Instruction encoding.* The instruction encodings were large for code that did not use all of the functional units in each instruction. A *no-op* operation (NOP) indicated an unused functional unit. To save space in memory and on disk, object code was stored with NOP operations eliminated. Instructions were grouped in blocks of four, and the non-NOP operations were stored with a preceding mask word that indicated which NOPs have been eliminated. When an instruction was loaded into the instruction cache, it was expanded into its full width.

To save space in the instruction cache, an instruction could encode a multi-beat NOP, which instructed the processor to stall for the specified number of beats before executing the following instruction.

The large instruction format provided a generous number of immediate operands. The compiler used immediates heavily. Constants were never loaded from memory; they were constructed from the instruction word. Double precision constants were pieced together out of two immediate fields. The global pointer scheme used by most RISC machines was not required.

M

*Trap code.* Trap hardware and trap code supported virtual memory by trapping on references to unmapped pages and on stores to write-protected pages.

To prevent unwarranted memory faults on speculative loads, the compiler used the dismissible load operation. If a dismissible load trapped, the trap code would not signal an exception. If required, a translation buffer miss or a page fault was serviced, and, if successful, the memory reference was replayed by the trap code and the value was returned. Otherwise, a NAN or integer zero was returned. In all cases, computation continued. NaNs were propagated by the floating units, and checked only when they were written to memory or converted to integers or booleans. Correct programs would run correctly with speculative execution, but an incorrect program may have missed an exception that it would have signaled if compiled without speculative execution.

The hardware optionally supported precise floating exceptions, but the compiler could not move floating operations above conditional branches if this mode was in use. This mode was used when compiling for debugging.

The trap code supported access to misaligned data by piecing together the referenced datum from multiple 32-bit words. In doing so, it placed 8- and 16-bit quantities in the correct place in a 32-bit word so that extracts and merges would work correctly.

## Trace Scheduling Compiler

The Multiflow compiler supported standard C and FORTRAN and discovered instruction-level parallelism in ordinary code. The compiler created a schedule of execution for the program being compiled, modeling the behavior of the program as much as possible at compile-time. It addressed several challenges posed by the Multiflow Trace machines.

- *Find Parallelism.* There were a large number of pipelined functional units, requiring from 10–50 data independent operations in flight to fill the machine. This large amount of instruction-level parallelism required scheduling beyond basic blocks and also a strategy for finding parallelism across loop iterations.
- *Model the machine.* Machine resources could be oversubscribed, and the pipelines used resources in every cycle. The compiler needed to model precisely the cycle-by-cycle state of the machine even in situations where such a model was not critical for performance.
- *Schedule the memory system.* There was an interleaved memory system that was managed by the compiler. Card conflicts caused program error; bank conflicts stalled the program.
- *Schedule data motion.* Each functional unit had its own register file. It cost an operation to move a value between registers, although remote register files could be targeted directly at the cost of an extra beat of latency.

The compiler had a traditional three-phase design: front end, optimizer, and back end. The optimizer focused both on reducing computation and exposing instruction-level parallelism. The back end was organized around the trace scheduling algorithm.

*Front ends.* The compiler supported user-level directives to enable the programmer to pass additional information to the compiler. Loop unrolling directives specified how a loop should be unrolled. Inline directives selected

functions to be inlined. Memory-reference directives asserted facts about addresses to aid memory alias analysis. Trace-picking directives specified branch probabilities and loop trip counts. In addition, the front end could instrument a program to count basic block executions. The instrumentation was saved in a database which could be read back on subsequent compilations. This information was used to guide trace selection.

The compiler supported the Berkeley Unix run-time environment. Care was given to the data structure layout rules to ease porting from the VAX and the Motorola 68000. Despite the unusual architecture of the Multiflow Trace, it was easier to port programs from BSD VAX or Motorola 68000 systems to the Trace than to many contemporary RISC-based systems.

*The optimizer.* The goal of the optimizer was to reduce the amount of computation the program would perform at run-time and to increase the amount of parallelism for the trace scheduler to exploit. Computation was reduced by removing redundant operations or rewriting expensive ones. Parallelism was increased by removing unnecessary control and data dependencies and by unrolling loops to expose parallelism across loop iterations. The Multiflow compiler accomplished these goals with standard Dragon-book-style optimization technology enhanced with a powerful memory-reference disambiguator.

The optimizer was designed as a set of independent, cooperating optimizations that shared a common set of data structures and analysis routines. The analysis routines computed control flow (dominators, loops) and data flow (reaching defs and uses, live variables, reaching copies). In addition, the disambiguator computed symbolic derivations of address expressions. Each optimization recorded what analysis information it needed, and what information it destroyed. The order of optimizations was quite flexible; in fact, it was controlled by a small interpreter. The order of optimization was organized around two invocations of loop unrolling, to expose the maximum amount of parallelism. The order used for full optimization was as follows.

### Basic optimizations

- Expand function entries and returns
- Find register variables
- Expand memory operations
- Eliminate common sub-expressions

Propagate copies  
 Remove dead code  
 Rename temps  
 Transform ifs into selects  
  
 Prepare for first loop unrolling  
   Generate automatic assertions  
   Move loop invariant  
   Find register memory references  
   Eliminate common sub-expressions  
   Transform ifs into selects  
   Find register expressions  
   Remove dead code  
  
 First unroll  
   Unroll and optimize loops  
   Rename temps  
   Propagate copies  
   Simplify induction variables  
   Eliminate common sub-expressions  
   Propagate copies  
   Remove dead code  
  
 Second unroll  
   Unroll and optimize loops  
   Rename temps  
  
 Prepare for Phase3  
   Expand function calls  
   Walk graph and allocate storage  
   Analyze for dead code removal  
   Remove assertions  
   Remove dead code  
   Expand remaining IL operations  
   Propagate copies  
   Remove dead code  
   Rename temporaries

Loops were unrolled by copying the loop body including the exit test. Unlike most machines, the Trace had a large amount of branch resource, and there was no advantage to removing exit branches. By leaving the branches in, the compiler avoided the short-trip count penalty caused by preconditioning. In addition, loops with data dependent loop exits that could not be preconditioned (e.g., while loops) were unrolled and optimized across iterations. For loops with constant trip-count, all but one exit test was removed, and short-trip count loops were unrolled completely.

Loops were unrolled heavily. A loop needed to be unrolled enough to expose sufficient parallelism within the loop body to enable the instruction scheduler to fully utilize the machine. Unrolling was controlled by a set of heuristics which measured the number of operations in the loop, the number of internal branches, and the number of function calls. A loop was unrolled until either the desired unroll amount was reached or one of the heuristic limits was exceeded. The default unrolling in FORTRAN for a Trace 14-wide was 16; at the highest level of optimization, the compiler unrolled by 96.

The compiler did not perform software pipelining, which would have reduced the need for such large unrollings. The large size of the Trace instruction cache limited the benefits of software pipelining.

*The back end.* The output of optimizer was a flow graph of operations lowered to machine level. The back end performed functional-unit assignment, instruction scheduling, and register allocation. The work was divided into four modules: the *trace scheduler*, which managed the flow graph and assured inter-trace correctness; the *instruction scheduler*, which scheduled each trace and assured intra-trace correctness; the *machine model*, which provided a detailed description of the machine resources; and a *disambiguator*, which performed memory-reference analysis.

*Trace scheduler.* The trace scheduler performed the following steps:

*Step 1.* The trace scheduler estimated how many times each basic block in the flow graph would be executed. The execution estimates were calculated from loop trip counts and the probabilities of conditional branches. The estimates were obtained from either a database collected during previous executions of the program, user directives, or heuristics.

*Step 2.* The trace scheduler performed the following loop until the entire flow graph has been scheduled.

- Using the execution estimates as a guide, the trace scheduler picked a trace (a sequence of basic blocks) from the flow graph. The trace scheduler first selected a seed, the yet-to-be-scheduled block with the highest execution estimate. The trace was grown forward (in the direction of the flow graph) and then backward from the seed; in each step, the trace scheduler selected a basic block that satisfied the

current trace-picking heuristic. If no basic block satisfied the current heuristic, the trace ended. Traces always ended when the trace scheduler reached an operation that was already scheduled or an operation that was already on the trace. Also, traces never crossed the back edge of a loop.

- The trace scheduler passed the trace to the instruction scheduler. The instruction scheduler returned a machine language schedule. The instruction scheduler is discussed in more detail below.
- The trace scheduler replaced the trace with the schedule in the flow graph and, if necessary, added copies of operations to compensate for code motions past basic block boundaries. Compensation code was necessary if an operation moved below a branch out of the trace or above the target of a branch into the trace.

Speculative execution, moving an operation above a branch, did not produce compensation code. This was the most common code motion in the Multiflow compiler. High priority operations from late in the trace were moved above branches and scheduled early in the trace. The instruction scheduler would perform such a move only if it was safe: An operation could not move above a branch if it wrote memory or if it set a variable that was live on the off-trace path. The hardware provided special *dismissible* operations and support for suppressing or deferring the exceptions generated by speculative operations.

*Step 3.* The trace scheduler emitted the machine language schedules in depth first order. This ordering gave the effect of profile-guided code layout, since traces were selected along the most frequently traveled paths in the program.

The trace scheduler also provided the instruction scheduler the global context for a trace. The instruction scheduler scheduled one trace at a time, but it required information about neighboring traces for correctness and to optimize the performance on inter-trace transitions. The functional-unit pipelines on the Multiflow computer used machine resources in every cycle; the trace scheduler communicated to the instruction scheduler the state of the machine pipeline on entry to the trace. Similarly, it passed information about memory references in flight, to avoid bank stalls.

The trace scheduler and the instruction scheduler also exchanged the register bindings at each trace entry and exit point, enabling incremental register allocation with a global view.

*Instruction scheduler.* The instruction scheduler transformed a trace of operations into a schedule of wide instructions. For each operation, the instruction scheduler assigned registers for the operands, assigned a functional unit for the operation, and placed the operation in a wide instruction. It used a three-step algorithm.

*Step 1.* The instruction scheduler built a data precedence graph (DPG) from the trace. Scheduling a trace rather than a basic block introduced very little complexity in the instruction scheduler. When building the DPG, edges were added to constrain some operations from moving above branches. After scheduling, the trace scheduler compensated for any global code motions performed by the instruction scheduler.

*Step 2.* The instruction scheduler walked the DPG and assigned operations to functional units and values to register banks. The scheduler made a tradeoff between parallelism and the cost of global data motion. To implement this tradeoff, the scheduler divided the DPG into components that contained a relatively small amount of parallelism and a large amount of shared data. The scheduler did a bottom-up traversal of the DPG, assigning functional units and register banks. The scheduler imposed a high cost for the use of more than one identical resource (e.g., a floating point unit) for a particular component in the DPG. This heuristic kept the members of the same component together in the same subset of the machine and achieved parallelism by spreading the components around the machine.

*Step 3.* The instruction scheduler performed list scheduling, creating the schedule and allocating registers. The scheduler created the schedule in forward order, starting with the first instruction. The scheduler maintained a list of data-ready operations and filled an instruction with the highest priority operations from the data-ready list, and then advanced to the next instruction.

On the Multiflow Trace machines, long pipelines and multiple operations per instruction made floating point registers a critical resource for generating high performance code. The instruction scheduler

performed register allocation, enabling the registers to be scheduled similarly to the other resources. List scheduling was well suited to integration with register allocation. At any point during the scheduling process, each of the registers was either occupied or available. When checking for resources to schedule a particular operation, the scheduler also included a check for a free register for operation's result. If all the resources were available to schedule the operation, the register, along with the other resources, was reserved. When there was no free register, the scheduler would either free a register or delay the current operation. Registers could be freed by spilling, by rematerialization, or by removing an earlier operation from the schedule. Heuristics for this decision were very important to performance.

The scheduler also scheduled the two-level interleaved memory system. The scheduler organized the memory references in a trace into equivalence classes based on the compiler's knowledge of their offsets relative to each other; the classes were formed by querying the disambiguator. Within an equivalence class, the scheduler understood the potential bank and card conflicts; between two different classes, nothing was known. The scheduler would batch memory references by equivalence class to avoid potential stalls. Batching groups of references increased register pressure, and heuristics were important to control this tradeoff.

*Machine model.* The Trace machines had limited hardware resource management and relied on the compiler to allocate machine resources and check for oversubscription. The compiler contained a detailed model of the machine. The model contained the set of operations and the mapping of each operation to functional units, register banks, and immediate fields. The latencies and resources required by each stage of an operation were represented. The model contained a graph of connections between machine elements and the latencies and resources required to traverse the graph. The model was organized to provide efficient access to the scheduler about the resources needed to schedule an operation.

*Disambiguator.* The compiler looked for fine-grained parallelism along a trace and within the body of an unrolled loop. The scheduler typically wanted to know if a load in the current iteration could move above a store in the previous iteration. This is a different question

than the one asked by a parallelizing compiler, which is interested in knowing if there exists a conflict between a load and a store across any of the loop iterations. Memory analysis was performed by a *disambiguator*, which tried to determine if two memory references refer to the same location or whether they refer to the same memory bank.

The disambiguator derived a symbolic equation of the address used in a memory reference; the terminals in the equation were constants and definitions (or sets of definitions) of variables in the program. Each derivation was normalized to a sum of products. To answer a question about two memory references, the disambiguator subtracted the two derivations and performed a GCD test. An assertion facility allowed the programmer pass additional information to improve accuracy.

The disambiguator also knew basic facts about how a variable was allocated and declared, and it used this information in its analysis as well. For example, a pointer cannot reference a variable whose address is never captured by the program.

*Calling sequence.* Multiflow used a pure caller-saves register partition; the values of registers were not preserved across a procedure call. Compiling for parallelism requires the use of many more registers than are used in sequential compilation, and typically register lifetimes do not cross function calls. On a wide machine, the saving and restoring of caller-saved registers could be intermixed with other operations before and after a call, and were frequently scheduled with minimal execution cost. Trace scheduling selected traces in priority order, enabling the saving and restoring of registers to be moved out of the most frequently executed paths in the program.

Multiflow used all of the registers in the first cluster for passing arguments and returning values. A total number of 53 integer values and 30 double precision floating values could be passed or returned in registers. Aggregates (e.g., C structures) could be passed and returned in registers. The large number of registers available for procedure linkage enabled a fast linkage to the 8-and 16-at-a-time math functions.

For C programs, the compiler passed arguments in both memory and registers; the called procedure read the arguments from registers, or from memory if required. The extra cost of passing arguments in both registers and memory was surprisingly small. The access

to arguments on procedure entry was often on the critical path, and the arguments could be read directly from registers. The storing of arguments at a call site was often not on the critical path, and it could be scheduled alongside other operations at little cost.

### Multiflow's Influence on the Industry

The Multiflow compiler technology was purchased by Intel, Hewlett-Packard, Digital Equipment Corporation, Fujitsu, NEC, Hughes, HAL Computer, and Silicon Graphics, as well as by several research institutions, including MIT and The University of Washington. Some purchased it for its highly capable compiler framework, which could be adapted to generate code for non-VLIW systems. Others bought it to aid in the development of VLIW architectures or to generate production compilers to accompany VLIW products. In the past two decades, several notable compiler product lines have been derived from the Multiflow compiler technology, in particular the compiler products from Intel, NEC, and Fujitsu. These compilers have received significant ongoing investment, and the original Multiflow implementation has been largely rewritten.

Multiflow was an important proof-of-concept of VLIW technology. The successful implementation of Multiflow's systems demonstrated that VLIW technology was viable, something that was not widely believed before Multiflow's engineering success. Texas Instruments had written of their skepticism before Multiflow; eventually, they were to develop VLIW processors that have had a strong position in cellular communications. VLIWs from various manufacturers are now commonplace in digital cameras, multifunction printers, network communication devices, computer graphics accelerators, televisions, digital video recorders, and other set-top boxes.

The Trace machines were a direct influence on the STMicroelectronics ST-231's architecture, developed by Fisher's team at HP. By 2010, nearly 100 million ST-231 parts were reported to be deployed in printers and video devices.

### Bibliographic Notes and Further Reading

Multiflow technology was derived from Josh Fisher's research. As a graduate student at New York University, he developed the idea of trace scheduling [4, 5]. As a professor at Yale, he extended the trace scheduling idea, designing a VLIW architecture [6] and a practical compiler [7]. The dissertations of John Ellis [3] and Alex Nicolau [13] describe the compiler in detail. Ellis's dissertation won the ACM Doctoral Dissertation Award, and his research compiler was a starting point of the work at Multiflow.

The first paper on Multiflow was published at ASPLOS in 1987[1], the same year the first Trace machines shipped. A retrospective on the never-completed 500 series is presented in [2]. A thorough description of the Multiflow compiler was published in a special issue of the Journal of Supercomputing devoted to instruction-level parallelism [11]. An experimental evaluation of the Multiflow compiler is presented in [10].

Linear equations solvers

## Definition

The multifrontal method is a direct method for solving systems of linear equations  $Ax = b$ , when  $A$  is a sparse matrix and  $x$  and  $b$  are vectors or matrices. The multifrontal method organizes the operations that take place during the factorization of sparse matrices in such a way that the entire factorization is performed through partial factorizations of a sequence of dense and small submatrices. It is guided by a tree that represents the dependencies between those partial factorizations. In the following, the multifrontal method is formulated first for finite-element analysis and later generalized to assembled sparse matrices.

## The Multifrontal Method

The multifrontal method is a direct method so that if the aim is to solve the equations

$$Ax = b, \quad (1)$$

where  $A$  is sparse, then this is done by performing the matrix factorization

$$PAQ = LU, \quad (2)$$

where  $P$  and  $Q$  are permutation matrices,  $L$  is a lower triangular matrix, and  $U$  is an upper triangular matrix. The solution to the Eq. 1 is then obtained through a forward elimination step

$$Ly = Pb,$$

followed by the backsubstitution

$$UQ^T x = y.$$

If the matrix  $A$  is symmetric, then the factorization

$$PAP^T = LDL^T \quad (3)$$

is used, where  $D$  is a block diagonal matrix with blocks of order 1 or 2 on the diagonal. The blocks of order 2 are required for stability when factorizing symmetric indefinite matrices. In the positive definite case,  $D$  can be diagonal and the Cholesky factorization

$$PAP^T = L_1 L_1^T$$

can be used where the diagonal entries of  $L_1$  are the square root of the entries in  $D$ . However, the Cholesky factorization is usually not used even in the positive definite case. This is more to avoid problems when the matrix is close to indefinite rather than to avoid taking square roots.

As mentioned later, the multifrontal method can also be used to perform a matrix factorization as a product of an orthogonal and upper triangular matrix.

## Finite-Element Analysis-Based Formulation

The multifrontal method can be regarded as a generalization of the frontal method. The frontal method was developed for the solution of sparse linear systems arising from finite-element problems. In such problems, the system matrix is defined as the sum

$$A = \sum_{\ell} A^{[\ell]} \quad (4)$$

of elemental matrices  $A^{[\ell]}$  that have nonzeros only at the intersection of the rows and columns corresponding to the variables associated with the element  $\ell$ . It is normal

to store the matrices  $A^{[\ell]}$  as small dense matrices whose rows and columns are indexed by the corresponding rows and columns of the matrix  $A$ . Thus, the summation in Eq. 4 should be thought of as an “expanded sum.” The operation in (4) is commonly referred to as the “assembly” and involves elementary summations

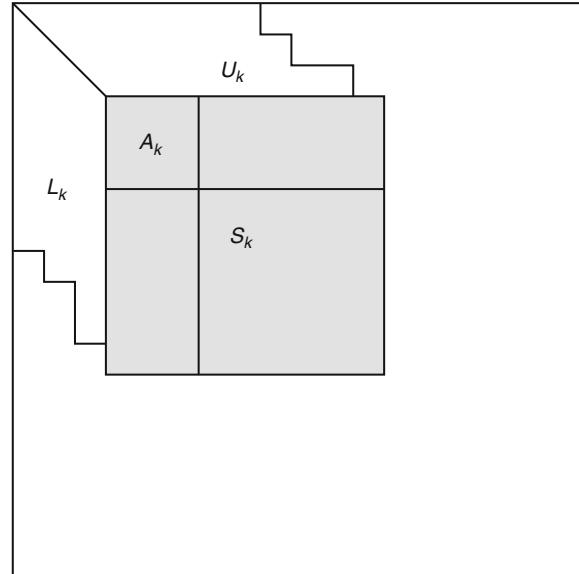

$$a_{ij} = a_{ij} + a_{ij}^{[\ell]}. \quad (5)$$

A value  $a_{ij}$  is said to be *fully summed* (or *fully assembled*) if all the operations (5) have been performed, and a variable is said to be fully summed if all the values in its row and its column are fully summed. The basic Gaussian elimination step

$$a_{ij} = a_{ij} - \frac{a_{ik}a_{kj}}{a_{kk}} \quad (6)$$

only requires that variable  $k$  is fully summed. The frontal method proceeds by successive steps where, at each step, a new element is assembled and variables are eliminated as soon as they become fully assembled. The main characteristic of the frontal method is that, at each step, all the operations are performed on a dense matrix, called a *frontal matrix*, whose rows and columns correspond to variables in the elements that have been assembled (commonly referred to as active variables). There are several benefits from using this approach. First, the elimination operations on a frontal matrix can be performed using efficient dense matrix kernels (Level-3 BLAS subroutines). Second, the stability of the factorization can be improved by applying pivoting techniques within the fully assembled variables of a frontal matrix. Third, the memory required for each step of the frontal method need only be enough to hold the frontal matrix, lending the method gracefully to limited memory environments. Fourth, it is relatively easy to use out-of-core techniques so that neither the factors nor the matrix need be held in memory.

Assuming that  $A$  is decomposed using an  $LU$  factorization (as in Eq. 2), Fig. 1 illustrates one step of the frontal method, as element  $k$  is assembled. The dark-shaded area represents the frontal matrix whose variables are split into assembled (in  $A_k$ ) and non-assembled variables. As the fully assembled variables are eliminated, the corresponding rows and columns end up in the  $U$  and the  $L$  factors, respectively, to form  $U_{k+1}$  and  $L_{k+1}$ . The next element  $k+1$  is then assembled with  $S_k$  (commonly referred to as a *contribution block*) which

**Multifrontal Method. Fig. 1** One step of the frontal method

corresponds to the Schur complement resulting from the elimination of the fully assembled variables.

The name “frontal” stems from the observation that the set of active variables forms a front that sweeps the problem domain element by element. Figure 2b shows the assembly and elimination process of the frontal method when applied to the regular finite-element problem depicted in Fig. 2a, with the element ordering  $a, b, c, d$ .

The  $A^{[\ell]}$  submatrix associated with an element  $\ell$  may contain fully assembled variables before being summed as in Eq. 4; this corresponds to the case where a variable only appears in one element, for example, a variable corresponding to an interior node of a finite element. In this case, it is possible to eliminate the fully assembled variables before assembling the element, the  $A^{[\ell]}$  term in Eq. 4 can be replaced by the resulting Schur complement. This is known as *static condensation*.

The multifrontal method takes this observation to a higher level in order to achieve a better exploitation of the sparsity structure of the matrix. Building upon the idea that variables that are internal to different subdomains (by which we mean elements or groups of elements) can be assembled and eliminated independently, this method basically amounts to having multiple fronts so that the set of variables that are fully assembled within a front does not overlap with the set

of active variables in any other front. In other words, if the frontal method corresponds to the left-to-right evaluation of the summation (4), where the order of the elements is critical for the performance, the multifrontal method corresponds to any valid bracketing of the same summation.

The multifrontal method is guided by a tree structure commonly referred to as an *assembly tree*, which expresses the way elements are assembled into the fronts. Considering the simple finite-elements problem in Fig. 2a, the assembly tree corresponding to the bracketing

$$(((A^{[a]} + A^{[b]}) + A^{[c]}) + A^{[d]})$$

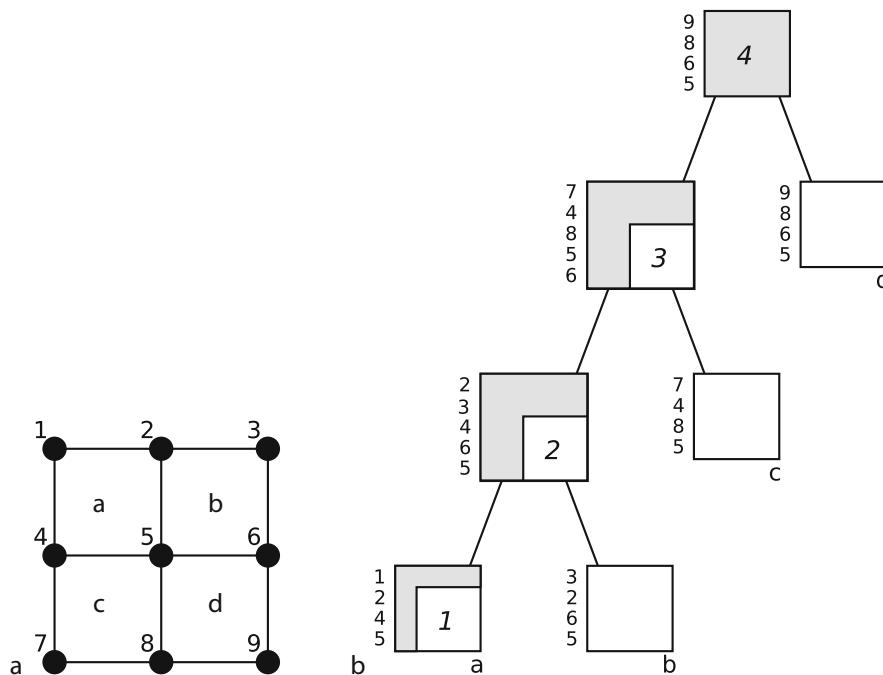

is shown in Fig. 3a; note that in this case the multifrontal method is equivalent to a frontal method (as shown in Fig. 2b) with static condensation. However, thanks to the higher flexibility of the multifrontal method, different bracketing schemes can be used to improve the memory required and the execution time. For example, if a nested dissection ordering is used on the simple problem in Fig. 2a the bracketing

$$((A^{[a]} + A^{[b]}) + (A^{[c]} + A^{[d]}))$$

would result, and thus the assembly tree in Fig. 3b would be obtained.

### Assembled Matrix Point of View

The multifrontal method can be used for factorizing quite general matrices, but first consider the case when  $A$  is symmetric and numerical pivoting is not required (e.g., when  $A$  is positive definite). Assume  $A$  is of order  $n$  and a sparsity preserving ordering is known. Consider a tree data structure on  $n$  nodes, each node corresponding to a column of  $L$  (say from the factorization (2)), built by setting a parent pointer for each node  $j$  as follows:  $p$  is the parent of  $j$  if and only if  $p = \min\{i > j : \ell_{ij} \neq 0\}$ . If no such  $p$  exists for a node  $j$ , then  $j$  is a root. The resulting tree structure is called the *elimination tree*. If  $A$  is irreducible, then the data structure is indeed a tree, otherwise it is a forest. A frontal matrix can be associated with each node of the elimination tree. As in the finite-element analysis case, the frontal matrices are permuted into a  $2 \times 2$  block structure where all variables from the (1,1)-blocks can be eliminated (i.e., they are *fully summed*) but the Schur complements (formed by the elimination of these fully summed entries on the

**Multifrontal Method. Fig. 2** The assembly and elimination process in the frontal method on a regular grid with four elements

(2,2)-block) cannot be eliminated until later in the factorization. The Schur complement computed at a node corresponds to the *contribution block* introduced in the finite-element analysis section. The variable at a node  $j$  becomes fully summed after all of the descendants of the node in the elimination tree have been eliminated.

By definition of the elimination tree, however, there is only one fully assembled variable in each frontal matrix. This prevents the use of efficient Level-3 BLAS routines for performing the elimination and update of the Schur complement and may result in fronts whose size is too small to achieve a good exploitation of the memory hierarchy available in modern processors. It is thus advantageous to combine or amalgamate nodes of the elimination tree. In the case where two or more columns of the  $L$  factor have the same structure below the diagonal (modulo a diagonal block), the corresponding variables can be amalgamated and thus eliminated within a single frontal matrix without introducing any additional fill-in. In the general case where columns of the  $L$  factor do not have the same structure, it is possible to perform amalgamation at the cost of additional fill-in; threshold-based strategies can be used in this case to perform amalgamation so that the cost of the introduced fill-in is overcome by the advantages of more efficient computations.

As a result of the amalgamation procedure, the elimination tree is transformed into an *assembly tree* whose nodes define the steps of the multifrontal method. At each step, values of the problem matrix are assembled together with the contribution blocks from the children nodes into a frontal matrix, the fully summed variables are eliminated and the corresponding Schur complement is formed in order to be assembled at the parent node (if any). The “Achilles heel” of sparse direct methods applied to general systems is that indirect addressing will be required. The multifrontal method cannot thus avoid this but the indirect addressing only occurs in the assemblies while all the arithmetic is performed using direct addressing as in the dense case, as in the case of frontal methods.

## Discussion

### Phases of Solution

Similar to other sparse direct methods, the solution of a linear system by means of a multifrontal method is

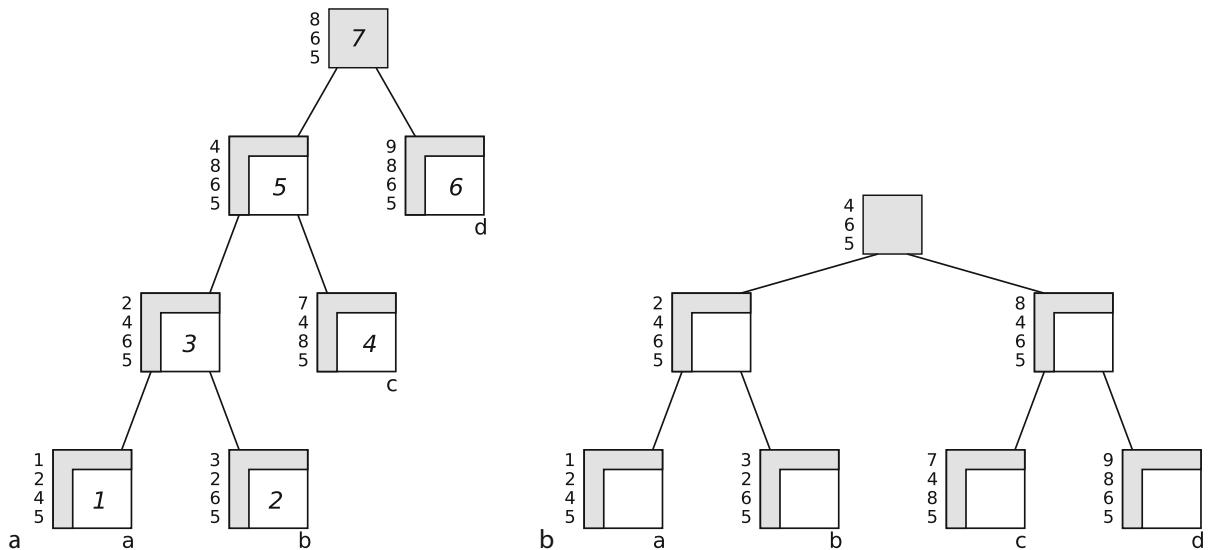

commonly achieved through three main phases: analysis, factorization, and solve. This subdivision enables the analysis and factorization phases to be performed only once when several linear systems with the same coefficients and differing right-hand side vectors are to be solved successively; similarly if several matrices with the same sparsity pattern are to be factorized, the analysis phase can be performed only once.

### Analysis

This step mostly consists of symbolic preprocessing operations prior to the actual factorization. These operations include the computation of a fill reducing pivotal order and a symbolic elimination process to determine the size of the factors and the frontal matrices. The ordering and matrix pattern will define a unique elimination tree but the important feature of the tree is that it only defines a partial ordering for the subsequent matrix factorization and this freedom can be used to great effect to reduce memory costs and to enable the efficient exploitation of parallelism.

### Factorization

The actual numerical factorization takes place in this step. From the memory point of view, implementations of the multifrontal factorization commonly use three “logical” areas of storage: one for the factors, one to stack the contribution blocks, and one for the current frontal matrix. The idea of using a stack stems very naturally from the fact that, in a sequential environment, the nodes of the elimination tree can be processed using a *postorder* (all nodes within any given subtree are numbered consecutively). During the tree traversal, the storage required by the factors always grows while the stack memory (containing the contribution blocks) can both increase and decrease. When the partial factorization of a frontal matrix is completed, a contribution block is pushed on to the stack, increasing the stack size; on the other hand, when a frontal matrix is formed and assembled, the contribution blocks of its children are popped out of the stack, decreasing the stack size. This pattern of memory use permits a natural extension to out-of-core execution. First, the computed factors of the frontal matrices can be moved to secondary storage after they are computed (they are not needed until the solve phase). Second, the stack memory has a natural locality, thanks to the postorder.

**Multifrontal Method. Fig. 3** Finite-element problem and examples of associated assembly trees. Fully assembled variables are shown with a dark-shaded area within each frontal matrix

Because the order in which the tree is traversed can have a significant impact on both the number of contribution blocks stored simultaneously on the stack and the working memory, great care must be taken to sort the siblings at each level of the tree. The rule of thumb followed in performing this operation can be illustrated in Fig. 3a (where the memory associated with factors that have already been computed is not taken into account). If the nodes of the tree are processed in the order 1-2-3-4-5-6-7, at most two contribution blocks and one frontal matrix must be stored. If, on the other hand, the nodes are processed in the order 6-4-2-1-3-5-7, then the peak memory requirement is for four contribution blocks and one frontal matrix.

During the factorization phase, pivoting may be performed to improve numerical stability. The normal numerical control for pivoting is the same for multifrontal methods as for most sparse direct methods, that is threshold pivoting. In the general case, the entry  $a_{ij}$  can be used as a pivot only if

$$\frac{|a_{ij}|}{\max_k |a_{kj}|} \geq u,$$

where  $u$  is a threshold parameter ( $0 < u \leq 1.0$ ). Clearly, in a frontal matrix, the pivot can only be chosen from the fully summed block so it is possible that not all

the fully summed block (the (1,1) block of the frontal matrix) can be eliminated at a particular node because of relatively large entries in the (2,1) block. The rows and columns corresponding to the fully summed variables which remain uneliminated are then added to the contribution block and assembled in the frontal matrix of the parent node. This gives rise to *delayed pivoting*. The elimination of delayed pivots may become possible at the parent node because the large entry could now be in the (1,1) block of the new frontal matrix, for example. It must be noted, however, that in case of delayed pivots, the size of the frontal matrix at the parent node is increased as well as that of the contribution block. For such a reason, the use of delayed pivoting requires complex dynamic data structures. In parallel implementations, dynamic scheduling strategies may be necessary to automatically adapt to such situations and this is done in the code ►MUMPS. A more recent alternative is to avoid delayed pivoting by using *static pivoting* where a pivot is still chosen even if it does not satisfy the threshold criterion but may be augmented in value to avoid instability. In this case, which is available in MUMPS as well as the other codes (SuperLU and PARDISO) described in this encyclopedia, iterative refinement or perhaps more sophisticated iterative techniques must be used to obtain an accurate solution.

## Solve

During this step, the triangular factors computed at factorization time are used together with the right-hand side vector or matrix to compute the solution of the problem by means of forward and backward substitutions. More precisely, the forward step uses a bottom-up traversal of the tree similar to the factorization, and the backward step uses a top-down traversal of the tree: starting from the root, each node computes the components of the solution corresponding to its fully summed variables and informs its children of the already computed components of the solution.

## Unsymmetric Matrices

The multifrontal method can be applied to unsymmetric matrices as well. If the matrix  $A$  is pattern symmetric, or nearly so (in which case the pattern of  $M = |A| + |A|^T$  can be used), then  $A$  can be treated as before. By generalizing the partial factorization of the frontal matrices to the rectangular case, special methods for unsymmetric matrices can be developed. This approach necessitates the use of directed acyclic graphs to represent the computational dependencies. Because of asymmetry, it can be shown that in general the compact representation of this acyclic graph is not a tree. It can still be beneficial to use the simplicity of the elimination tree structure (instead of the directed acyclic graphs) in the unsymmetric case, with special attention in order to detect and make use of asymmetry in the frontal factors.

Another approach is to generalize the notion of the elimination tree to unsymmetric matrices. This generalization provides a general framework to describe all unsymmetric multifrontal approaches.

The multifrontal method also extends to sparse QR factorization, typically used for least-square problems where the objective is to find an  $x$  that minimizes  $\|Ax - b\|$ .

## Parallel Execution

The multifrontal method presents many features that make it suitable for multiprocessor environments. Parallelism can be exploited at two different levels. First, two disjoint subtrees of the elimination tree can be processed in parallel, as there is no computational dependency between such subtrees. Second, the frontal matrices that are large enough can be factorized in

parallel using algorithms for dense linear algebra operations – such frontal matrices occur usually toward the end of the factorization process where nodes of the elimination tree that are close to the root are processed.

Effective scheduling and mapping strategies are necessary for exploiting the two sources of parallelism mentioned above. In a distributed-memory environment (see MUMPS), much attention has been paid to static mapping methods to map the tasks associated with the nodes of the tree to the processes. The *subtree-to-subcube* mapping is used to reduce the communication overhead in parallel sparse Cholesky factorization on hypercubes. This mapping mostly addresses parallelization of the factorization of matrices arising from a nested dissection-based ordering of regular meshes. The basic idea of the algorithm is to build a layer of  $p$  subtrees (where  $p$  is the number of processors) and then to assign to each processor  $p_i$  a subtree  $T_i$ . The nodes of the upper parts of the tree are then mapped using a simple rule: when two subtrees merge together into their parent subtree, their set of processors are merged and assigned to the root of that parent subtree. The method reduces the communication cost but can lead to load imbalance on irregular assembly trees. A bin-packing-based approach has then been introduced to improve the load balance on irregular trees. Given an arbitrary tree, the improvement is achieved by finding the smallest set of subtrees which can be partitioned among the processors while attaining a given load balance threshold. In this scheme, starting from the root node, the assembly tree is explored until a layer of subtrees, whose corresponding mapping on the processors produce a “good” balance, is obtained (the balance criterion is computed using a first-fit decreasing bin-packing heuristic). Once the mapping of the layer of subtrees is done, all the processors are assigned to each remaining node (i.e., the nodes of the upper parts of the tree). This method takes into account the workload to distribute processors to subtrees. However, it does not minimize communication in the sense that all processors are assigned to all the nodes of the upper parts of the tree. The *proportional mapping* algorithm improves upon the two above algorithms. It uses the same “local” mapping of the processors as that produced by the *subtree-to-subcube* algorithm with the difference that it takes into account workload information to build the layer of subtrees. To be more precise, starting from the root node to which all the processors

are assigned, the algorithm splits the set of processors recursively among the branches of the tree according to their relative workload until all the processors are assigned to at least one subtree. This algorithm is characterized by both a good workload balance and a good reduction in communication.

In a parallel computing context, memory use is much more difficult to control and limit for two related reasons. First, it may not be possible to guarantee a postorder traversal of the tree while exploiting the tree parallelism since processes may work on different branches of the tree at the same time. Thus the use of a simple stack to hold the contribution blocks as in the sequential case is not possible. Second, as many processes are active during the factorization, the global memory requirement may increase compared to a sequential execution. The memory per process should decrease but the overall memory requirement may increase.

The solve step can also be executed in parallel by following the same computational pattern of the factorization phase, that is, the pattern induced by the elimination tree.

## Bibliographic Notes and Further Reading

Based on techniques developed for finite-element analysis by Irons [15] (and a technical report by Speelpenning dated 1978), Duff and Reid proposed the multifrontal method for symmetric [7] and unsymmetric [8] systems of equations. Eisenstat et al. [10] proposed another method with the same basic features as the multifrontal method. More recently, Eisenstat and Liu [9] have provided a new generalization of elimination trees for unsymmetric matrices using the notion of paths instead of edges to define a parent node in the tree. This generalized elimination tree leads to a general framework to describe how all existing approaches take the asymmetry into account. This includes the work of: Duff and Reid [8] and Amestoy, Duff, and l'Excellent [2] who apply the multifrontal method to unsymmetric matrices with symmetrized pattern; Davis and Duff [6] and Gupta [14] who do not use the assembly tree but use a directed acyclic graph to represent the computational dependencies; Amestoy and Puglisi [5] who work on a “symmetrized” assembly tree by making use of the structural asymmetry of the frontal matrices during the factorization phase.

Liu [17] provides an overview of the multifrontal method for symmetric positive definite matrices.

Liu [16] and Guermouche et al. [13] have explored the impact of the tree traversal on the memory behavior and proposed tree traversals that minimize the storage requirements of the method.

The mapping algorithms discussed in Sect. Parallel Execution are by George et al. [12], Geist and Ng [11], and Pothen and Sun [19]. Amestoy et al. [4] generalize and improve the heuristics in [11, 19] by taking memory scalability issues into account and by incorporating dynamic load balancing decisions for which some preprocessing is done in the analysis phase.

Memory management issues in the implementation of the multifrontal method are discussed by Amestoy and Duff [1]. Matstoms [18] and Amestoy, Duff, and Puglisi [3] discuss the multifrontal QR method in a multiprocessor environment.

### Definition

Multilisp is a parallel programming language, focused particularly on parallel symbolic computing, developed as a research project at MIT during the 1980's. The Multilisp language design and implementation projects served as a vehicle for exploring various ideas related to concurrency constructs, scheduling, parallel garbage

collection, speculative computation, and debugging tools for parallel programs.

## Discussion

### Introduction

The 1980s saw much experimentation with parallel programming models, as supercomputer performance and performance/price ratios both reached new heights amid a growing variety of SIMD and MIMD parallel machines, using both shared- and distributed-memory architectures, from various vendors. It became increasingly apparent that scaling laws for hardware would eventually favor parallel computing as the most cost-effective way to achieve high performance.

A growing recognition of the challenges of programming parallel machines also led to many parallel programming research projects targeting different hardware architectures and different application areas. Two key characteristics of an application that influence the choice of a parallel computing approach are the amount of parallelism available in the application (often related to the size of the data set) and the regularity of the available parallelism: whether the set of operations to be performed, and the dependences between them, have a simple structure largely independent of the data values, or are complex and data-dependent. “Regular” applications include various signal-processing problems as well as partial differential equation solutions over regular grids, while “irregular” applications include sparse matrix computations, mesh generation, computer algebra, discrete event simulation, and various heuristic search and optimization applications. Many irregular applications are termed “symbolic” because they emphasize navigating and creating complex data structures over performing arithmetic.

Some parallel programming projects focused on massively parallel computing for large numeric problems with a fairly regular structure, often a good match for vector or SIMD architectures. Multilisp was among a group of other projects that focused on exploiting parallelism in problems with a less regular structure. Multilisp itself was aimed at shared-memory MIMD architectures and oriented especially toward symbolic applications. The Multilisp team believed that the irregularity of these applications makes it too difficult to

preschedule operations or predetermine a good distribution of application data across the nodes of a distributed-memory machine, so a shared-memory MIMD architecture would be the best implementation target.

Most applications that were investigated for Multilisp offered moderate opportunities for parallel speedup, more in the tens than in the thousands. Such speedups were often not exciting enough in the era of the 1980s and 1990s, when sequential processor speeds were doubling every couple of years. In the present environment, clock speeds are increasing only slowly and multicore processors are the new vehicle for increasing computation throughput, so there may be a renaissance of serious interest in concepts first developed for Multilisp and its contemporary projects. Multicore processors are precisely the shared-memory MIMD model at which Multilisp and similar projects were targeted.

## Multilisp Semantics

The design of Multilisp is based on several major hypotheses:

1. The best route to a high degree of parallelism is to identify a very large number of concurrent computations and then inexpensively and efficiently schedule them across the available processors.
2. Functional programming is good for parallel computing because it eliminates bugs caused by unintended nondeterminacy, but controlled nondeterminacy is desirable in some applications.
3. For symbolic computations that work by traversing and building linked data structures, synchronization closely tied to the data structures is often the most natural.
4. Parallel programming is hard enough, so a parallel programming language implementation should automate clerical tasks that we know how to automate, notably heap storage allocation and garbage collection.

Point (1) creates a strong bias in favor of simple, lightweight concurrency and synchronization constructs. Point (2) drove the Multilisp team toward a design strongly influenced by the Scheme language [10], which includes side-effecting primitives but can be used very naturally in a “mostly functional” programming style, where side-effecting operations are used only at

the comparatively infrequent points where an imperative state change on an object is exactly what is needed. Point (4) seems uncontroversial from today’s vantage point, after the rise of Java in the 1990s popularized the notion that serious software can be written on a platform with garbage-collected heap storage, but in the 1980s, there was still great debate about whether garbage-collected systems like Lisp and Scheme could be used for “real work” like C and C++ could.

Scheme, a member of the Lisp family of languages, was an attractive starting point not only because it is consistent with point (2) above, but also because it is built on garbage-collected heap storage (point 4) and is widely used for building symbolic applications. Multilisp implementations differed somewhat in how faithfully they adhered to the details of the Scheme definition, but all of them were philosophically quite close to Scheme.

## Basic Concurrency Constructs

On top of the Scheme foundation, Multilisp adds two basic concurrency constructs: `pcall` and `future`, described in detail by Halstead [3]. `pcall` provides classic fork-join concurrency while `future` provides a form of data-flow concurrency. A Multilisp expression such as

$$(pcall F A B C \dots)$$

allows concurrent evaluation of the expressions  $F$ ,  $A$ ,  $B$ ,  $C$ , .... After waiting for all of these evaluations to return a value, the procedure value of the expression  $F$  is applied to the argument values resulting from evaluating  $A$ ,  $B$ ,  $C$ , .... The result of evaluating the `pcall` expression is thus equivalent to that of the sequential procedure call

$$(F A B C \dots)$$

except that the expressions  $F$ ,  $A$ ,  $B$ ,  $C$ , ... are evaluated concurrently.

`future` is a more radical construct that permits concurrency structures not possible with simple fork-join concurrency. A Multilisp expression

$$(future X)$$

permits a task to be spawned to evaluate the expression  $X$ , but immediately returns a placeholder for the result of that evaluation. When the evaluation of  $X$  yields a value, the `future` object essentially becomes that value. The `future` is said to *resolve* to the value of  $X$ .

The evaluation of  $X$  can proceed concurrently with the use of the placeholder value, until the point where the user actually needs some information about the value. An operation that actually needs information about a value is said to *touch* the value. Such an operation will have to block until the future resolves to a value, but especially in symbolic applications, often quite some time passes while a value is passed into or out of procedure calls, or is built into data structures and then retrieved, before the value is actually touched. Since the point where a value is touched can be remote in the program code, as well as in time, from the point where an evaluation was spawned, the `future` construct enables rich and complex concurrency structures to be easily specified that could not be specified using fork-join concurrency alone, fulfilling point (3) in the above list of design goals (closely linking synchronization with data structures). The `future` concept has its origins in the Actor systems of Baker and Hewitt [1].

Both `pcall` and `future` have the property that in a fully functional program (no side effects), inserting these constructs does not change the meaning of the program, so a programmer can feel free to insert them in whatever way best balances the exposure of concurrency with the concurrency management overhead costs.

In addition to the `pcall` and `future` constructs, which combine task spawning and synchronization, Multilisp also includes `replace` and `replace-if-eq` operations, similar to the classic atomic swap and compare-and-swap instructions, as building blocks for higher-level synchronization operators [3].

## Speculative Computing and Sponsors

The simplest use of the Multilisp constructs is just to use the concurrency primitives to relax the precedence constraints in a sequential algorithm, enabling the exact same set of operations to be performed with some parallelism on a parallel machine. A more aggressive approach is to use parallelism to speculatively launch new lines of inquiry, whose results may or may not be used depending on the results of other computations. Opportunities for such *speculative computing* are especially prevalent in search problems.

Speculative computing brings with it some new challenges. Usually, some speculative tasks are consid-

ered more valuable than others, and it is important to ensure that low-value speculative tasks do not consume resources to the extent of starving out higher-value speculative tasks or “mandatory tasks” that are not speculative. Also, estimates of the value of speculative tasks can change as a computation progresses and more information is learned about the problem being solved. An important special case of this is when the computation performed by a speculative task becomes moot because of information developed by other ongoing computations. Such *irrelevant* speculative tasks should be terminated gracefully so they will no longer consume resources. Conversely, a task initially thought to be speculative may become recognized as mandatory and deserving of the highest priority.

Managing speculation in a language like Multilisp is complex, however, because `future` can induce dependence relationships within a computation that are much more varied and tangled than the dependences that result from simple fork/join concurrency. This challenge can be addressed by introducing a higher-level construct to represent the relationships between various speculatively launched subcomputations of an overall computation. Osborne [14] investigated a *sponsor* model inspired by earlier work by Kornfeld and Hewitt [11]. In this model, each computational task is associated with one or more *sponsors* that represent the reason, or goal, for performing the computation and provide a place to store and update information about the urgency or importance of that goal.

Sponsors provide a natural framework for solving various problems with priority management. For example, a task that is blocked waiting for a future can add its own sponsor to the sponsorship of the task that is computing a value for the future. Similarly, a task waiting to enter a critical region can temporarily add its sponsor to the sponsorship of a task currently in the critical region. Both of these strategies prevent priority inversions (where higher-priority tasks are blocked by lower-priority tasks) by ensuring that any tasks whose results are awaited get the same claim on resources as the tasks that are waiting. Speculative subcomputations within a computation that is itself speculative can be represented using a tree structure of sponsors, where some sponsors are subordinated to other sponsors. Finally, a sponsor can be declared irrelevant if its associated speculative task has become moot, and this provides a natural way

to know which tasks should no longer receive execution resources.

While considerable progress was made in developing the capabilities of the sponsor model, the efficient implementation of sponsor-based speculative scheduling on a parallel machine remains an underexplored subject. However, the sponsor model seems useful not just for speculative computing but also as a model for “system programming” on a parallel machine, where multiple computational threads that share the machine’s resources execute on behalf of different users or different computations initiated by the same user, who may change his/her mind from time to time about the priority of the different computations or may even decide to abandon some of them completely.

### Futures and Continuations

The Multilisp project provided a framework for investigating various higher-level questions about how to carry familiar sequential programming capabilities into the world of parallel programming. One challenging area of investigation was how to reconcile the `future` construct with the “first-class continuation” mechanism embodied in Scheme’s `call/cc` construct [10]. The name of this construct is a contraction of “call with current continuation.” An expression such as `(call/cc f)` captures the continuation to which the value of this expression will be returned, reifies it as a procedure, and passes the resulting procedure as an argument to `f`. Subsequent computations, within `f` or elsewhere, can then cause a value `V` to be returned from the `call/cc` expression by passing `V` as an argument to the continuation procedure.

Many useful program structures can be built using `call/cc`, but it can also be used to produce various paradoxical behaviors, such as procedure calls that return more than once, possibly returning different values each time. Such behaviors conflict with the restriction that a `future` can only resolve once, to one value. Halstead [5] reviews various ideas for dealing with these conflicts, but in the end there was no definitive resolution.

### Errors and Exceptions

The handling of errors and exceptions is another challenge: what should happen if the computation `X` in `(future X)` ultimately attempts a division by zero, an

out-of-bounds array access, or even explicitly raises an exception? Modern languages for sequential programming provide mechanisms for catching such exceptions so execution can proceed down another path that deals with the condition. Typically these mechanisms work by unwinding the call stack back to a caller that catches the exception and specifies an action to take in response. With `future`, this idea is problematic because a caller that contained the `(future X)` expression may already have returned before the exception was raised.

Two solutions to this problem were investigated. One solution, described by Halstead and Loaiza [8], is for the exception in `X` to cause the `future` to resolve to an *exception value*. When an operation touches an exception value, the exception is raised again in that operation. Thus, exceptions propagate back through the data-flow structure of the program rather than through the control structure. An alternative possibility, outlined by Halstead [5] but never fully worked out, would use continuations (for example via a specified “error continuation” which would be called to signal an exception) in combination with the sponsor model (for abandoning or suspending computations rendered moot by the raising of the exception).

M

### Implementations

Over the course of the Multilisp project, three implementations were built. The first implementation, Concert Multilisp [3], ran on the Concert multiprocessor at MIT. While Concert Multilisp was a versatile testbed for many implementation ideas, it was based on a bytecode interpreter and therefore was not fast in absolute terms. The second implementation, MultiScheme [13], was based on the MIT Scheme system and ran on the BBN Butterfly multiprocessor. It also used a bytecode interpreter. The third implementation, Mul-T [12], was based on the T system from Yale and used T’s ORBIT compiler to generate native machine code. Mul-T ran on an Encore Multimax multiprocessor.

### Storage Management

Concert Multilisp included a copying, incremental garbage collector intended to allow as much concurrency as possible between garbage collection operations and computational operations [3]. To minimize synchronization and improve locality, each processor had

its own heap in which to allocate objects. Each processor's heap was divided into two *semispaces*: *oldspace* and *newspace*. During each garbage-collection cycle, all live objects were copied from *oldspace* to some processor's *newspace*. At the beginning of each cycle, all processors needed to synchronize to swap the roles of the two semispaces, but after a short period to copy objects in the root set, all processors could proceed independently, interleaving computational operations with housekeeping intervals for moving live heap objects from *oldspace* to *newspace*. This approach has the advantage of allowing all processors to be fully utilized without requiring the garbage-collection load to be spread evenly across them, but the cost on stock hardware of checking pointers loaded from the heap to ensure that they do not point into *oldspace* is significant and might be too great to tolerate in an implementation based on compiled code.

To avoid the cost of checking pointers loaded from the heap, both MultiScheme and Mul-T employed non-incremental garbage collectors that required all processors to suspend computational activities and synchronize, then focus exclusively on garbage collection until the garbage collection pass is done, at which point they can resume computation. This approach streamlines the execution of computational tasks but puts severe requirements on the evenness with which garbage-collection work can be distributed among the processors. The parallelism achieved during garbage collection in these implementations was not carefully tuned and is not conclusively stated in the published reports, but there was evidence that speedups of 10 or more were difficult to achieve.

The garbage collector was also called on to perform other housekeeping tasks. All Multilisp implementations used the garbage collector to splice out resolved futures, replacing pointers to the future object with pointers to the future's value, eliminating any subsequent costs for indirection through the future's placeholder object. MultiScheme also used the garbage collector to kill tasks that are working on resolving futures that have become inaccessible.

## Scheduling

In programs with large amounts of concurrency, unfolding the task-spawning tree breadth-first can require exponentially more resources than unfolding

the task tree depth-first. Therefore, depth-first scheduling is strongly preferred, once enough concurrency has been exposed to keep all processors busy. In practice, this means that when processing the expression (*future X*), execution of the parent task should be suspended and the evaluation of *X* should begin immediately. If there is already plenty of work to keep all processors busy, the parent task will still be suspended when the evaluation of *X* completes, and the execution of the parent task can be resumed at that point. This was the scheduling policy used in Concert Multilisp [3].

In the design of Mul-T it was observed that the implementation of this policy could be speeded up by skipping the creation of a child task, allowing the "parent" task to just continue into the evaluation of *X*. If another processor needs work before the evaluation of *X* completes, it can break into this task's stack and steal away the continuation of the computation beyond the *future* construct. This policy of *lazy task creation* [14] greatly reduces the cost of task management, since most potential task-spawning points never actually result in the creation of a new task. This policy was subsequently adopted, and put on a sound theoretical footing, by the MIT Cilk project [2]. It is also related to the "evaluate-and-die" mechanism of Glasgow Parallel Haskell [16].

The informally stated goal of the Mul-T implementation was to make *future* "no more expensive than a procedure call." With lazy task creation, this cost was reduced to 9-12 machine instructions in most cases [14], coming close to this goal.

## Debugging Tools

In sequential programming, it is important that programs both be correct and have the needed performance, and this is no less true in parallel programming. Multilisp's mostly functional nature is intended to assist in developing correct programs by reducing opportunities for nondeterminacy and supporting a development style where testing a program on a sequential machine will go a long way toward assuring its correct behavior on a parallel machine. Beyond that, it is useful to be able to execute programs in parallel and replay the same execution path later on, if a problem is noticed. The Multilisp team's MulTVision project [7] included a log-and-replay technique, implemented in Mul-T, which reduced logging costs substantially by logging only task

creations and side effects on shared data structures, which are not common in mostly functional programs.

While performance optimization is often important for sequential programs, it is critical for parallel programs, since performance is the main reason to target a program to a parallel machine in the first place. In a large program, however, it can be quite hard to understand the reasons for the observed performance on a parallel machine. MulTVision also included a logger for events such as task creation, blocking, and unblocking, and a visualizer for viewing the resulting execution traces. The project was disbanded before the value of these tools could be clearly demonstrated, but this is likely to become an urgent problem in software development for modern multicore architectures.

## Performance

Mul-T is the most significant of the Multilisp implementations from the standpoint of assessing Multilisp's actual potential to deliver real parallel speedup over the best sequential implementation. The extra costs in the Mul-T implementation, compared with the sequential T implementation, come principally from two sources: synchronization and task scheduling. The major component of the synchronization costs is the checks that must be included in every operation that touches its operands, to determine whether any of the operands is a future and, if so, to take the needed actions. The cost for this depends considerably on the nature of the program, but after some optimizations, an increase of about 65% in execution time due to touch checks was fairly typical [12]. It would be interesting to know how this measurement would look on today's machines. When combined with lazy task creation, Mul-T was measured as delivering performance for a range of benchmarks, on 16 processors, of up to about 13 times the performance of a sequential program running in the unmodified T system [14].

## Related Work and Influences on Other Projects

Several other parallel Lisp languages and implementations of the 1980s are reviewed by Halstead [5] and are briefly mentioned here. Qlisp was based on Common Lisp augmented with futures as well as several other concurrency constructs and was implemented at

Stanford University on an Alliant FX-8 multiprocessor. Butterfly Lisp (closely related to MultiScheme) and Parallel Portable Standard Lisp were implemented on the BBN Butterfly multiprocessor. Both rely primarily on futures for concurrency. Farther afield, Concurrent Scheme at the University of Utah was targeted to a distributed-memory MIMD multiprocessor, while Connection Machine Lisp was designed for the SIMD architecture of the Connection Machine.

In addition to influencing contemporaneous parallel Lisp systems that also used futures, ideas from the Multilisp project, particularly in the areas of synchronization, task scheduling, and garbage collection, have found their way into various other systems. Especially notable among these systems is the work-stealing scheduler of the MIT Cilk system [2], which was developed in the mid-1990s and continues in use to this day. Cilk has been used to build very large parallel applications, such as the competition-quality CilkChess program. Most recently, these ideas have been commercialized in Cilk++, a tool for programming present-day multicore processors.

## Bibliographic Notes and Further Reading

The basic principles behind Multilisp and Mul-T are outlined in [3] and [12], respectively. Lazy task creation, the essential idea that has been picked up in subsequent "work-stealing" schedulers, is described in [14]. Halstead [5] gives an extended overview of the entire parallel Lisp field as of 1990. Many members of the parallel Lisp and parallel symbolic computing communities gathered at a sequence of workshops held in 1989, 1992, and 1995. The proceedings of the first [9] and second [6] of these workshops include several papers discussing various aspects of the Multilisp project as well as papers about other contemporaneous projects mentioned in

this article. These volumes are thus a good starting point for further exploration of the literature.

## Multi-Threaded Processors

MARIO NEMIROVSKY

Barcelona Supercomputer Center, Barcelona, Spain

### Synonyms

Multi-streamed processors

### Definition

Opposed to standard single-threaded processors, in which only one software thread can be present and executed at any given time, Multithreaded Processors can hold multiple software threads which can be running simultaneously. The amount of information needed to be held per software thread is defined as the context. Therefore, a processor that can hold multiple contexts concurrently is defined as a Multithreaded Processor.

### Discussion

#### Introduction

In the continuing search for a higher level of performance, computer architects have been consistently pushing the speed of the system and the microarchitecture design. For instance, microprocessor speeds in the last 40 years have grown by 4,000 times while the instructions per clock have increased from 0.125 on the Intel 4004 to at least 3 per core on the Intel Xeons which have a 64-bit data width compared to the 4-bit 4004. Yet, the semiconductor technology and microarchitecture innovations that led to these processor performance gains have started to provide diminishing returns. As pulling out substantial performance benefits from these techniques starts turning increasingly tedious, higher processor efficiency becomes attainable through the exploitation of higher-level parallelism. It is important to take into account all the different levels at which parallelism can play a significant role so looking beyond Instruction Level Parallelism (ILP) is Thread Level Parallelism (TLP). A thread is a process with its

own instruction and data. These processes can be totally independent or have different levels of sharing.

A multithreaded processor is able to concurrently execute instructions of different threads within a single pipeline. Multithreading could be applied either to increase performance of multiprogramming or multithreaded workloads or to increase performance of a single program.

Multithreaded processors interleave the execution of instructions of different user-defined threads in the same pipeline. This requires that multiple program counters and contexts be present, often stored in different register sets. The execution units are multiplexed between the running threads. Latencies that occur in the computation of a single instruction stream (also known as bubbles) are filled by the instructions of another thread. Context switching within the running threads of the hardware is automatically assigned.

A multithreaded processor capable of executing multiple instructions from different instruction streams (i.e., threads running within the hardware) simultaneously is called simultaneous multithreaded (SMT) processor. SMT is the confluence of multithreading techniques on a wide superscalar processor so that the hardware pipeline is used more efficiently.

M

#### Classification of Multithreading

##### Techniques

Multithreaded processors execute different instructions from different threads simultaneously within a same pipeline. At the early stages, multithreading techniques were developed for use in scalar processors and consisted of two types commonly known as Fine Grain Multithreading (FGMT) and Coarse Grain Multithreading.

In fine grain multithreading, every new instruction issue derives from a different thread so that no two instructions from the same thread are present in the pipeline at any given time. Furthermore, the overall efficiency of the processor is increased over standard scalar processors because the bubbles normally caused by high latency events get used by other threads. In order to have a high efficiency, at least as many threads as pipe stages are needed but if only one single thread is active, then the performance is  $1/n$  ( $n$  being the number of pipe stages) of a scalar processor. The hardware complexity on one

hand increases due to the need of replicating the context registers, however, on the other hand, the pipeline complexity becomes simplified because dependencies between instructions is almost nonexistent, since every instruction is from a different thread, so bypass logic, branch prediction, and out of order execution are not needed.

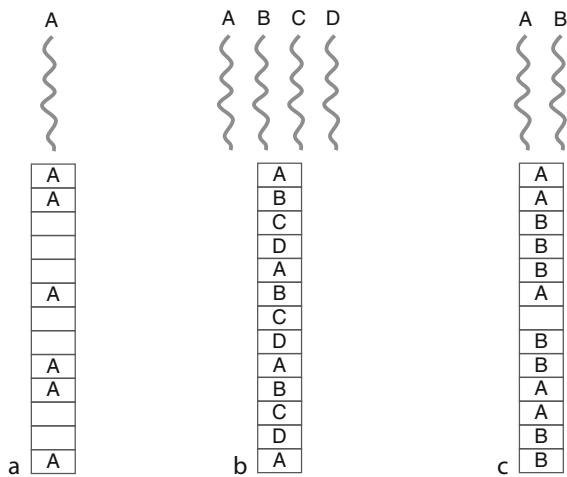

Coarse grain multithreading (CGMT), similarly can handle various threads in a single pipeline but every new issued instruction can derive from any thread independent of what thread instructions are currently in the pipeline. This implies that if a single thread is active, then the performance of that thread is the same as one would have achieved in a single-threaded processor. Coarse grain is beneficial in cases that require high performance similar to a single-threaded processor or systems where there are fewer software threads available. Although the complexity of a CGMT processor is larger than the FGMT, since it includes both multithreading hardware support plus the dependency checks and bypasses of a single-threaded processor, a CGMT requires less threads to remain efficient than the fine grain and is more efficient than a single-threaded processor when more than one thread is running.

The advent of superscalar processors created the possibility of executing several instructions at a time that could, by applying multithreading techniques, be derived from several threads leading to what is commonly known as simultaneous multithreaded (SMT). The amount of instruction bubbles that can be covered by SMT is generally greater than fine or coarse grain multithreading; however, the hardware cost complexity is also greater.

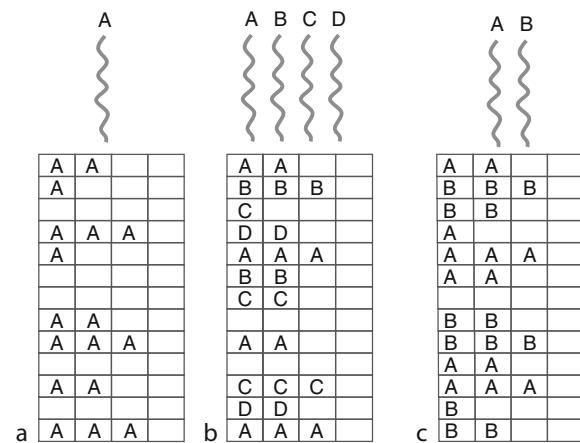

### Benefit of Multithreaded Processors

Multithreaded Processors (MTP) achieve higher performance than single-threaded processors by taking advantage of the thread level parallelism (TLP) and executing various threads to cover bubbles that get generated in the pipelines. These bubbles are the result of long latency instructions, data and control dependencies, cache misses, exceptions, etc. By covering these bubbles by executing instructions from other ready threads, MTPs can achieve much greater efficiency than their single-threaded counterparts.

In Fig. 1, it can be seen how the bubbles that get generated on a single-threaded scalar gets utilized by

**Multi-Threaded Processors. Fig. 1** (a) Single-threaded scalar, (b) fine grain multithreading scalar, and (c) coarse grain multithreading scalar

**Multi-Threaded Processors. Fig. 2** (a) Single-threaded super scalar, (b) fine grain multithreading super scalar, and (c) coarse grain multithreading super scalar

a fine grain multithreading (1b) and a coarse grain multithreaded processor (1c), whereas the superscalar version are represented in Fig. 2.

Nowadays, there is a significant amount of applications that feature a large quantity of thread level parallelism (TLP) making multithreaded processors a valued practical solution for achieving significant improvements in performance and power. Examples of applications with large TLP include video, gaming,

modeling, simulations, web searching, as well as web 2.0 applications.

There are two forms of attaining thread level parallelism. One way is to extract TLP from an application by splitting it into separate tasks that can be run in parallel, for example, splitting a video screen into sections and having them be executed in parallel. Additionally, thread level parallelism exists when several independent tasks arrive almost simultaneously, for instance with network processors, packets arrive very close to each other (i.e., packet bursts) and each packet can be processed in its own thread.

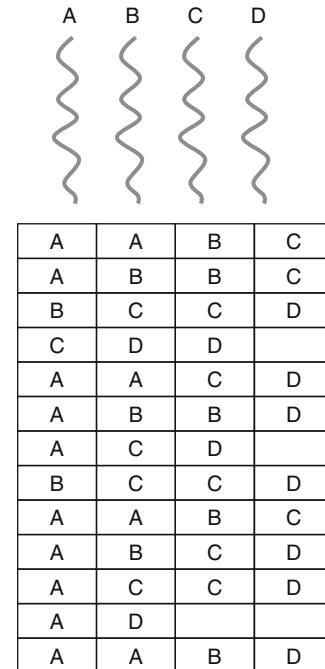

Multithreading can also be used to make a single thread run faster. Even if a thread cannot be separated into further parallel tasks or there are not many threads available, multithreading techniques such as multipath speculative execution and helping threads (explained in section Simultaneous Multithreading) can be used to accelerate the execution of single threads.

It is important to differentiate the use of multithreading from chip multiprocessors (CMPs). Multicores are made up of independent processors that normally only share a L2 cache while a multithreaded processor shares the processor pipeline yet has separate context registers for the threads. Furthermore, multithreading is used to augment the processor utilization by filling pipeline bubbles while multicores are just adding processors to the overall chip. In terms of resources needed to build multithreaded processors compared to multicore processors, the cost of adding a thread is much lower than adding a whole separate core. However, there is a performance saturation point for how many threads can be put into a single core after which the more threads added can actually cause performance degradation. Therefore what is commonly used is a blending of multithreading and multicore techniques which is discussed below.

### Fine Grain Multithreading (FGMT)

In an FGMT processor, in every cycle, instructions from a unique thread get issued and only when those instructions retire can new instructions from that same thread be issued.

For example, when a thread accesses memory, the thread does not get scheduled again until the memory transaction gets completed. This model requires at least as many threads as pipeline stages in the processor, and

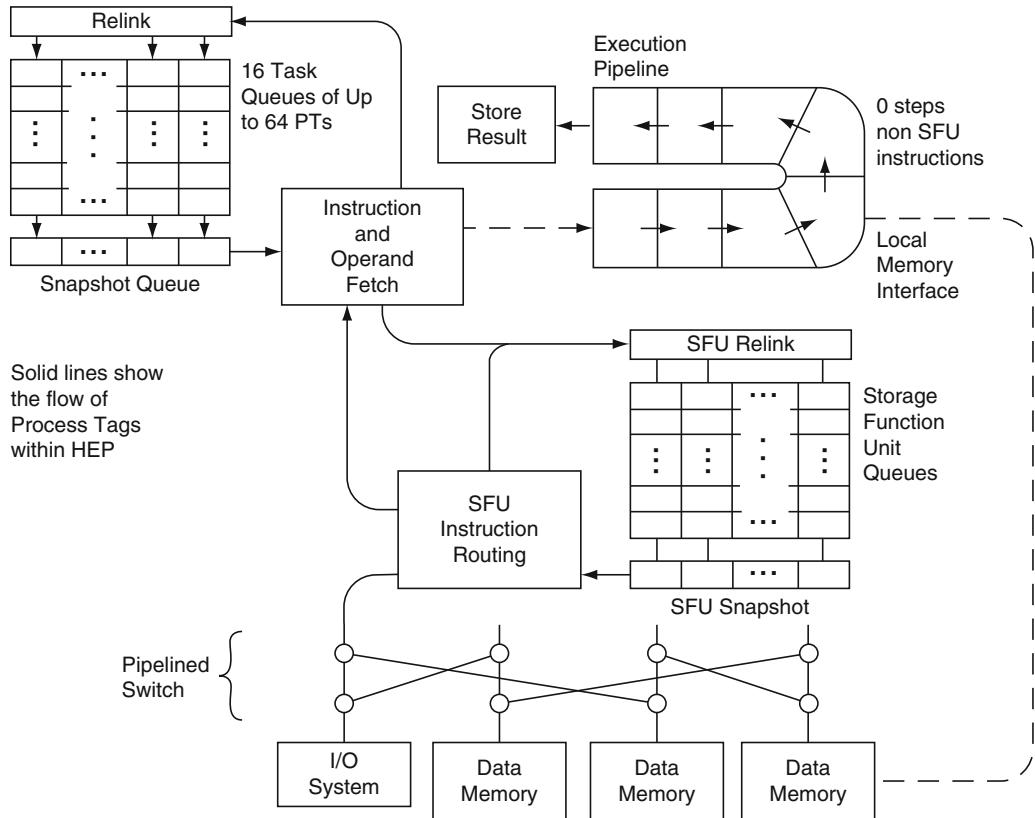

**Multi-Threaded Processors. Fig. 3** Simultaneous multithreading

M

adding a few more threads will allow the processor to tolerate higher latencies.

The first commercial FGMT computer was the Denelcor HEP [14, 21, 22] in 1978; however, in the 1960s, Control Data Corporation in their Peripheral Processors (PPs) of the CDC6600 [25] incorporated 10 threads (or 10 PP) that executed in a round robin fashion meaning that the execution units would execute one instruction cycle from the first PP, then one instruction cycle from the second PP, etc. This was done both to reduce costs and because accesses to memory required 10 PP clock cycles: when a PP accessed memory, the data was available next time the PP received its slot time.

The HEP system shown in Fig. 4 could have upto 16 processors with 128 threads per processor. It had an eight-stage pipeline that matched the minimum latency delay from memory fetches. Therefore, upto eight threads were in execution at any given time within a single processor. Furthermore, only a single instruction from a given process was permitted to be in the pipeline at any point in time.

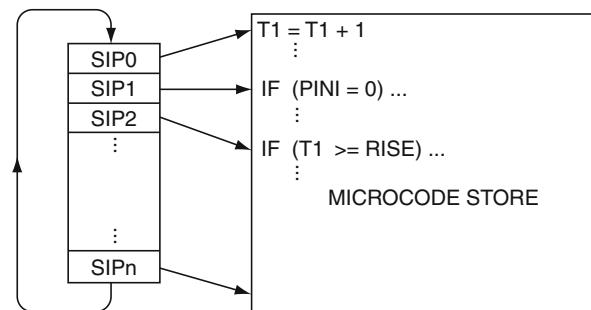

**Multi-Threaded Processors. Fig. 4** HEP-1 processor pipeline

In the late 1980s, Delco Electronics, a division of General Motors, introduced the first real-time fine grain multithreaded processor, and perhaps the most successful FGMT processor deployed since 1987, known as the Timer Input Output (TIO) [18]. It was designed as a two-stage pipeline with two levels of fine grain multithreading. The first level used a round robin method of choosing between the M. Instruction Processor (MIP) and the S. Instruction Processor (SIP). On the second level, the SIP on its own could hold up to 32 separate threads. The issue pattern resembled: MIM, SIM\_1, MIM, SIM\_2, MIM, SIM\_3, ... MIM, SIM\_32, MIM, SIM\_1. Figure 5 shows the SIP scheduler.

Other popular FGMT processors were the Horizon [24], the Cray MultiThreaded Architecture (MTA) [2], the Multilisp Architecture for Symbolic Applications (MASA) [8], and M\_Machine [15].

### Coarse Grain Multithreading

In Course Grain MultiThreading (CGMT) a single thread is executed until it encounters a high latency

**Multi-Threaded Processors. Fig. 5** The single instruction processor of the TIO

event at which point the hardware automatically performs a context switch to another thread. Examples of long latency events are page faults and L2 cache misses. In situations in which context switches can be performed very quickly, even small bubbles generated by such events as branches can be used to trigger a context swap. Even with a small number of threads high processor utilization can be achieved while if only

a single thread is being executed, then the processor performance is like that of a single-threaded processor.

CGMT is very useful in situations that many different processes need to be run not all of which have the same priority. A particular example of using CGMT for real-time processing was the DISC [19]. DISC was a CGMT processor that performed context switching in order to distribute processing power between the active threads. Also the MSpard [17] was targeting real-time systems.

Several processors use the CGMT technique: the MIT Sparcle [17], the MIT J-Machina [20], and the Rhamma processor [7].

### Simultaneously Multithreading

A superscalar processor where instructions can be issued from multiple threads in the same cycle is called Simultaneous Multithreaded (SMT). Figures 2 and 3 compare a superscalar, a CGMT, an SGMT, and an SMT. It is clear to visualize how these diverse techniques can take advantages of the bubbles that gets generated in a processor. SMT is the technique that has more flexibility to cover the inefficiencies of the single-threaded architectures. An SMT processor has more flexibility than CGMT or FGMT processors because it allows an instruction from any thread to be executed at any time while in parallel, an instruction from a different thread may also be executed.

The first work where SMT was proposed on top of a standard RISC processor (IBM RS6000 Power) was presented by Yamamoto in [29, 30]. This work extended the concept of FG and CG multithreading (then called *multistreaming*) technique to general-purpose superscalar processor architecture. In their work, an IBM Power processor was modified to produce an SMT processor capable of running up to 8 threads simultaneously. They also presented an analytical model of the processor. Another pioneering approach to SMT was the multithreaded processor created in the Media Research Laboratory of Matsushita Electric Ind. (Japan) [9]. However, it was the SMT process or architecture, proposed by D. Tullsen, S. Eggers, and H. Levy [26] at the University of Washington, Seattle, WA, which has given the name to the technique.

Another way to use multithreading is to increase the performance of sequential programs. A processor can spawn threads from a single thread and execute

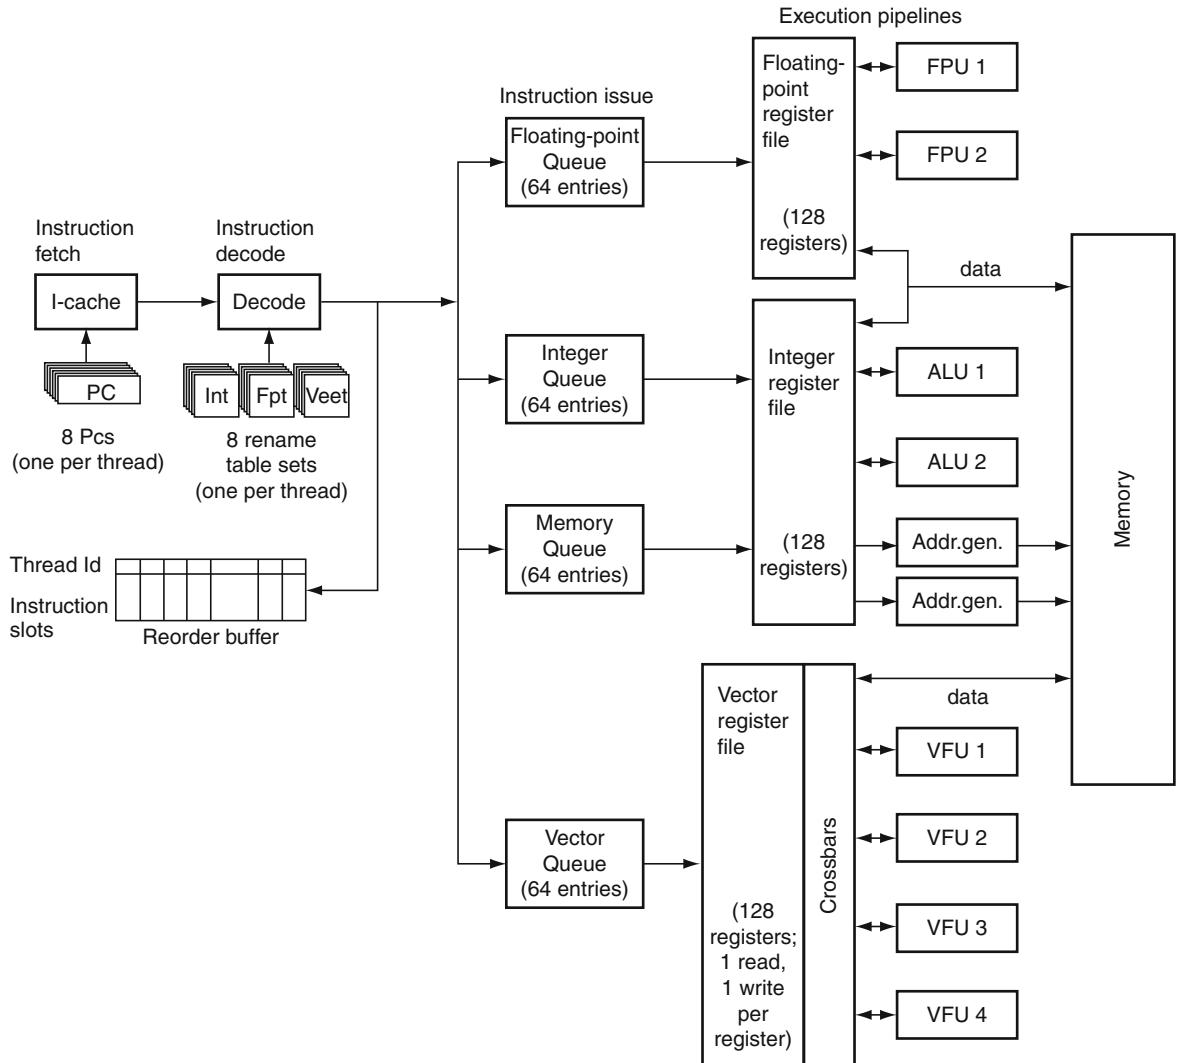

them speculatively concurrently with the main thread in order to accelerate the main program. Several SMT approaches fall in this area such as simultaneous subordinate microthreading [3], multiple path execution [28], the multiscalar processor [23], and the single-program speculative multithreading architecture [4].

Another interesting work on SMTs is the Simultaneous Multithreaded Vector (SMV) architecture [6], which combines simultaneous multithreaded execution and out-of-order execution with an integrated vector unit and vector instructions.

### Simultaneous Multithreading Commercial Processors

*Alpha21464.* Compaq unveiled its Alpha EV821464 in 1999 [12], a four-threaded eight-issue SMT processor. The out-of-order execution processor had a large on-chip L2 cache, a direct RAMBUS interface, and an on-chip router for system interconnect of a directory-based, cache-coherent NUMA (nonuniform memory access) multiprocessor. This 250 million transistor chip was planned for the year 2003. The project was abandoned, as Compaq sold the Alpha processor technology to Intel.

In 2001, Clearwater networks unveiled the CNP810SP processor [12] shown in Fig. 7. This core incorporates Simultaneous Multithreading (SMT) capabilities, whereby eight threads execute simultaneously, utilizing a variable number of resources on a cycle by cycle basis. In each cycle, anywhere from zero to three instructions can be executed from each of the threads depending on instruction dependencies and availability of resources. The maximum instructions per cycle (IPC) of the entire core is ten. In each cycle, two threads are selected for fetch and their respective program counters (PCs) are supplied to the dual-ported instruction cache. Each port supplies eight instructions, so there is a maximum fetch bandwidth of 16 instructions. Each of the eight threads has its own instruction queue (IQ) which can hold up to 16 instructions. The two threads chosen for fetch in each cycle are the two that have the fewest number of instructions in their respective IQs. Each of the eight threads has its own 31 entry register file (RF). Since there is no sharing of registers between threads, the only communication between threads occurs through memory. The eight threads are

**Multi-Threaded Processors. Fig. 6** Simultaneous multithreaded vector architecture

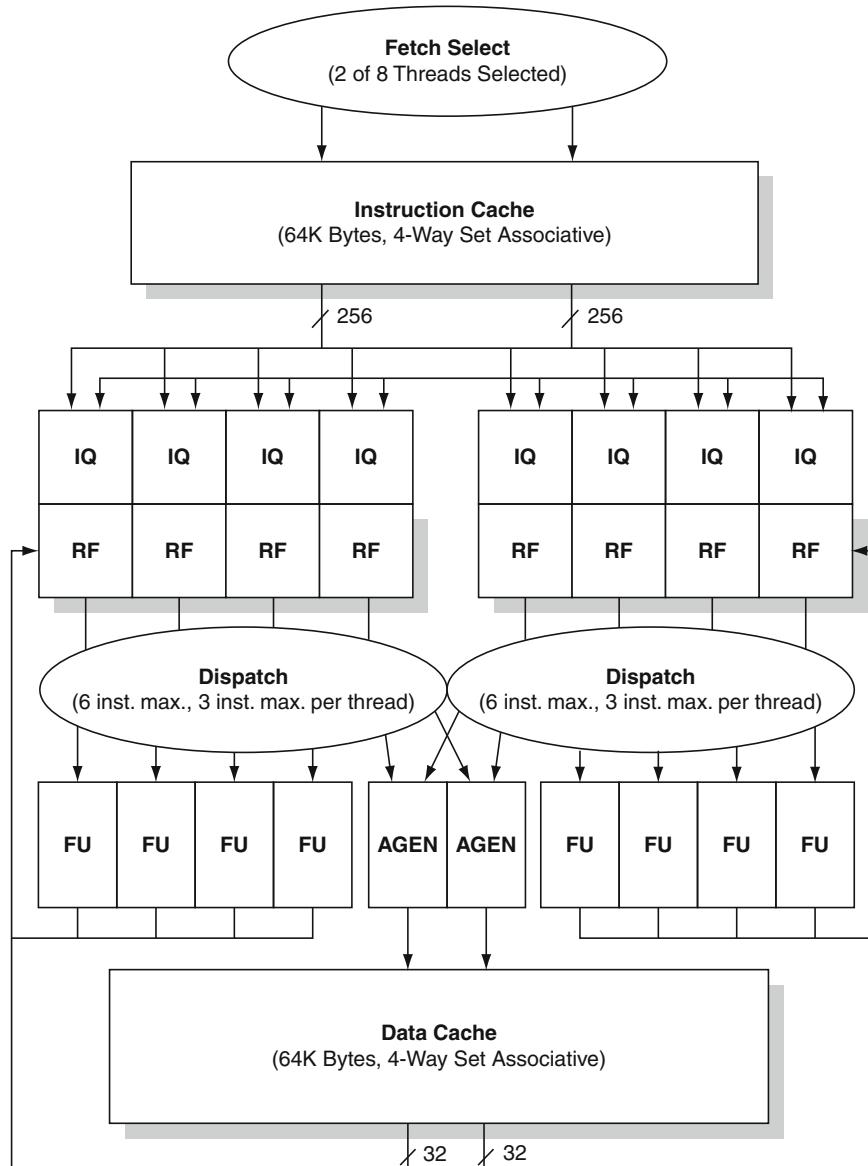

divided into two clusters of four for ease of implementation. Thus the dispatch logic is split into two groups where each group dispatches up to six instructions from four different threads. Eight function units are grouped into two sets of four, each set dedicated to a single cluster. There are also two ports to the data cache that are shared by both clusters. A maximum of ten instructions can be dispatched in each cycle. The function units are fully bypassed so that dependent instructions can be dispatched in successive cycles. Clearwater was out of business in 2001 by tape out date.

The UltraSPARCV, which exploited SMT, was able to switch between two different modes depending on the

type of work – one mode for heavy duty calculations and the other for business transactions such as database operations [11].

UltraSPARC T1 [10] is a microprocessor that is *both* multicore and multithreaded. The processor is available with four, six, or eight CPU cores, each core able to handle four threads concurrently. Thus the processor is capable of processing up to 32 threads concurrently.

UltraSPARC T2 [10] is a member of the SPARC family, and the successor to the UltraSPARC T1. The processor, manufactured in 65 nm, is available with eight CPU cores, and each core is able to handle eight

Multi-Threaded Processors. Fig. 7 The CNP810SP processor

threads concurrently. Thus the processor is capable of processing up to 64 concurrent threads.

Hyper-Threading Technology [16] proposed SMT for the Pentium 4-based Intel Xeon processor family to be used in dual and multiprocessor servers. Hyper-Threading Technology makes a single physical processor appear as two or more logical processors by applying the SMT approach. Each logical processor maintains a complete set of the architecture state, which

consists of the general-purpose registers, the control registers, the *advanced programmable interrupt controller* (APIC) registers, and some machine state registers. Logical processors share nearly all other resources on the physical processor, such as caches, execution units, branch predictors, control logic, and buses. Each logical processor has its own APIC. The interrupts sent to a specific logical processor are handled only by that logical processor.

## Multithreading on Power Efficiency

An important issue to discuss is power efficiency on multithreaded computers. As shown in the previous sections multithreaded processors fill these bubbles that get generated in the pipeline with useful instructions thus making the power per instruction overall more efficient. Speculation, used to achieve high performance on single-threaded machines, normally consumes not only power at the moment of computation but also at the moment of squashing if a misprediction occurs. Additionally, the hardware complexity of the predictors drain energy but multithreaded processors can make significant energy efficiency strides by not needing to implement as many predictors to achieve as high performance as single-threaded processors. Furthermore, a significant amount of logic used in superscalar design can be eliminated, such as out of order. In the case of FGMT, most of these logics which in turn represent additional power saving. On the other hand, the additional required context cost in multithreaded processors demands more power but in general this amount of power is not significant. Therefore, the overall power efficiency of multithreaded processors is much better than with single-threaded processors and explains why the technique is in use in the top-of-the-line power-efficient processors today.

## Pros

The major benefit of multithreading is the improvement of processor and memory utilization. Ideally as you add threads to the processor, the performance of the running thread will remain constant while the total system performance will be the sum of the performance of each thread. In real systems, as you add threads the performance of the running ones will degrade. In order to achieve performance increase throughout multithreading, it is important that the performance obtained by adding a thread should be larger than the performance degradation caused to the other threads. In many cases, threads could share code and/or data resulting in positive interference in the caches. In other words, as a thread needs a new piece of code it finds it in the instruction cache because a co-running thread had already requested it. Additionally, what will normally be a bubble in the execution pipeline can be easily used by a co-running thread to execute instructions without

causing penalties to the main running thread. The hardware complexity of the system can be reduced since it is the total system performance that is sought and not just the single thread performance, making complex microarchitecture designs (e.g., OOO execution, branch predictors, etc.) unnecessary.

## Cons

There are also a few issues to take into account before using multithreaded processors. If the performance of a single running thread is what has been sought, then the best way to use a multithreaded architecture is to use the “helping thread or speculative multithreading” [guri]. However, in a system where multithreading is used to achieve higher levels of system performance, it is important to notice that the individual performance of each thread will be, in general, lower than a thread will have when running alone. This is due to the fact that interference between threads will be mostly negative, causing trashing on the caches and TLBs, therefore increasing the misses and thread running time. It is essential to take advantage of thread interference by co-running threads with very low negative interference and high positive interference.

## Future Directions

Today, multithreaded multicore is pervasive in the industry. However, there are many areas that require further study, for instance, how to program these processors, how to map threads to streams, and how to perform run time debugging. These interesting challenges are the scope of work of various professionals and academics today, ensuring the extension of multithreading throughout the computing world which will branch out to also cover most areas of processing such as graphics, DSP, high performance, and low power.

In the future, asymmetric multithreaded processors, in which every thread could be specialized for a particular task, will start appearing.

## Bibliographic Notes and Further Reading

As stated earlier, multithreaded work began in the 1960s on the Control Data Computer (CDC600) Peripheral Control Processor; a description can be found in Design of a Computer – The Control Data 6600 [25]. The first FGMT paper by B. J. Smith, “A Pipelined Shared Resource MIMD Computer,” [22] in 1978 where he introduced the HEP machine followed a few years later in 1988 by the Horizon machine in “A Processor Architecture for Horizon,” Mark R. Thistle and B.J. Smith [24]. The DISC architecture which was a pioneer of SMT can be read in “DISC: dynamic instruction stream computer,” proceedings of the 24th annual international symposium on Microarchitecture [19]. There have been several valued reviews on multithreaded processors. A very complete one can be found in the book *Multithreaded Computer Architecture: A Summary of the State of the Art* by Robert A. Iannucci, Guang R. Gao, Robert H. Halstead Jr, and Burton Smith [13]. The book is divided in four parts covering from basic definitions up to compilation techniques. Additionally, Theo Ungerer, in 2003, has done a good examination of multithreaded processors in his paper “A survey of processors with explicit multithreading” [27].

MUMPS

## Definition

MUMPS (MULTifrontal Massively Parallel Solver) is a parallel library for the solution of sparse linear equations. It primarily targets parallel platforms with distributed memory, where the message passing paradigm MPI is used. MUMPS is a direct code, based on Gaussian elimination. It will solve sparse linear systems with

a real unsymmetric, symmetric positive definite, or symmetric indefinite coefficient matrix and will solve complex systems where the matrix is unsymmetric or complex symmetric. MUMPS has a large number of options, some to enhance functionality and some to improve performance or core memory usage. Whereas most direct solvers for distributed memory environments rely on static approaches where the computational tasks are known and assigned to the processors in advance, one of the main originalities of MUMPS is its ability to perform dynamic pivoting in order to guarantee numerical stability, leading to dynamic data structures and non-fully predictable tasks graphs. In order to handle these dynamic aspects, the management of parallelism is based on a fully asynchronous approach, and the computational tasks are defined and scheduled dynamically at runtime.

## Discussion

### Introduction

MUMPS (MULTifrontal Massively Parallel Solver) is a direct code, based on Gaussian elimination, for the solution of sparse linear equations on distributed memory machines, although a serial version is available.

With a direct code, the first step in solving a linear system of equations of the form

$$Ax = b \quad (1)$$

is to perform the matrix factorization

$$PAQ = LU, \quad (2)$$

where  $P$  and  $Q$  are permutation matrices,  $L$  is a lower triangular matrix, and  $U$  is an upper triangular matrix. The solution to the Eq. 1 is then obtained through a forward elimination step

$$Ly = Pb,$$

followed by the backsubstitution

$$UQ^T x = y.$$

When  $A$  is sparse, that is, when there are many zero entries in  $A$ , the computation will be organized so that  $L$  and  $U$  are also sparse, but there are in general significantly more nonzeros in  $L$  and  $U$  than in  $A$ .

If the matrix  $A$  is symmetric, then the factorization

$$PAP^T = LDL^T \quad (3)$$

is used, where  $D$  is a block diagonal matrix with blocks of order 1 or 2 on the diagonal. The blocks of order two are required for stability when factorizing symmetric indefinite matrices.

MUMPS uses the factorization (2) when the matrix is unsymmetric and the factorization (3) when the matrix is symmetric.

Before discussing the MUMPS code in more detail in the following sections, it is worth recalling how the steps given above for solving Eq. 1 are implemented within sparse direct codes. In most sparse direct codes, this is done in three steps, namely:

*Analysis:* In this step of the computation, the sparsity pattern of  $A$  (or, when the matrix is unsymmetric, of the pattern of  $|A| + |A|^T$ , where  $|A|$  is the matrix whose entries are the modulus of the corresponding entries in  $A$ ) is used to determine an ordering to maintain sparsity in the triangular factors,  $L$  and  $U$ . This is called the ordering phase. The analysis step then continues by organizing data structures so that the subsequent numerical factorization can be computed efficiently. The main part of this phase is often called *symbolic factorization*.

*Factorization:* In the next step, the factors  $L$  and  $D$  (or  $L$  and  $U$  in the unsymmetric case) are computed using the information from the analysis step. This is the most computationally intensive step and generally takes the most time to execute, although much work has been done to run this efficiently on parallel computers. If the matrix is positive definite, it is usually possible just to follow exactly the pivoting sequence obtained from the ordering phase. If, however, the matrix is unsymmetric or symmetric indefinite, then care must be taken to avoid numerical instability.

*Solve:* In this last step, the factors from the factorization step are used to solve the system through the forward and back substitutions shown above. While this step is computationally cheap, involving effectively only two arithmetic operations for each entry in the factors, it suffers greatly in performance because of the amount of data movement relative to this small amount of arithmetic.

Sparse direct codes differ in the way these steps are performed. MUMPS uses a multifrontal approach to effect these steps. The details of this approach are

discussed in another entry of this Encyclopedia. Later in this entry, a short history of the multifrontal developments that led to the first version of MUMPS is given at the beginning of ►section Origins of MUMPS. In the remainder of this section, the way MUMPS realizes the three steps indicated above will be discussed. MUMPS is as much a research project as a code, and this aspect is discussed in ►section Further Comments.

## General Comments

As said in the definition, MUMPS is a parallel code that uses MPI for message passing. It will solve linear systems with a real unsymmetric, symmetric positive definite, or a symmetric indefinite coefficient matrix and will solve complex systems where the matrix is unsymmetric or complex symmetric. Over the years, a large number of options have been developed, some to enhance functionality and some to improve performance. The range of functionalities of MUMPS is far greater than that of any of other sparse direct code at the present time. In addition to handling the very wide range of matrices listed above, MUMPS accepts the input matrix as a distributed assembled matrix or in elemental format, that is to say the matrix is represented as an expanded sum of small dense matrices each based on a single finite element or on a group of such elements.

The parallel model used by MUMPS relies on a dynamic and distributed management of the computational tasks (dynamic scheduling): each process is responsible for providing work to some other processes while at the same time acting as a worker for others. One outcome of such a distributed management is that the work is performed asynchronously so that computation and communication are very much overlapped. Since the main pivoting algorithms in the symmetric indefinite and unsymmetric cases will alter the order of computation of the factors and will usually change the data structures, MUMPS has from its early days always used dynamic scheduling [8]. While initially required to accommodate numerical pivoting, the dynamic scheduling approach is also a powerful tool for the control of memory usage and for efficiency in a multiuser environment where the load on the processors can have a significant influence on performance. In fact, much of the research activities related to MUMPS (summarized in ►section Further Comments) have been concerned with this aspect of the package.

Options exist to run the analysis step in parallel, including a priori scaling of the matrix, and both the factorization and solution phases can be run in parallel although uniprocessor versions for all phases are also available.

## Analysis Step

As discussed in ►section [Introduction](#), the analysis step consists of two main phases: the selection of a pivot ordering to maintain sparsity and the creation of data structures for the subsequent factorization and solution steps (the symbolic factorization). In MUMPS, the symbolic factorization phase produces the assembly tree that is used in the multifrontal factorization. In the analysis step, MUMPS does a static scheduling phase that distributes the nodes of the tree to the processes. This static phase attempts to balance arithmetic and storage over the processors but, for the reasons mentioned in the previous section, will need to be followed by dynamic scheduling in the factorization step. In particular, because of limited tree parallelism near the top of the tree, more than one process is required for each node that appears in that area: the process in charge of such a node will select dynamically other processes that will participate in the computations at that node, possibly among a set of candidate processors [9] chosen at analysis. Because one of the features of MUMPS is that the execution should fit within a memory area allocated at the beginning of the factorization, an accurate estimate of the memory required for the numerical factorization is required. Such an estimate is computed by each process at the analysis phase through a “symbolic” traversal of the tree where the algorithm mimics the memory requirements that will occur at the factorization step. This feature is available for both parallel and sequential execution. The accuracy of the estimate degrades depending on the amount of numerical pivoting which may happen during the numerical factorization, and on the dynamic behavior of the parallel factorization (which is by nature difficult to predict). In practice, allowing a small percentage increase to the estimate is sufficient.

For the ordering phase, there are several sparsity ordering methods available to MUMPS users, and there is an option for automatically choosing an ordering method based on the size and density of the matrix, the ordering packages available to MUMPS at installation time, and the number of processors being used. The

user can also input his or her own pivotal order. Note that the ordering option can have a significant impact on the shape of the assembly tree and on the memory requirements during the numerical phases [18, 19]. A range of ordering options is supported natively by MUMPS including the AMD (Approximate Minimum Degree) method and some variants of it, AMF (Approximate Minimum Fill), QAMD (Approximate Minimum Degree with detection of quasi dense rows), and PORD (Paderborn ORDering). Graph partitioning-based orderings are also supported by means of external software packages such as METIS or SCOTCH; these tools are usually capable of providing better orderings (based on nested dissection) for large-scale, three-dimensional problems. They are also recommended in the parallel case because they lead to reasonably wide trees with more parallelism than the ordering options natively supported by MUMPS.

Note that after the assembly tree is built, there is still room to improve the memory behavior of the solver by computing and using a tree-traversal that is optimal in terms of memory usage. This is done within MUMPS by using a variant of the algorithm proposed by Liu [20].

In the early days of the development of parallel sparse direct codes, little attention was paid to the analysis step because of its low cost relative to the factorization and solve phases. However, for two reasons this has become a more major concern in recent years. One reason is that the efficient parallelization of the factorize step means that if the analysis is still run on one processor then the elapsed time for this can be significant or even dominant if many processors are used for the factorization. The second reason is that on some multiprocessor machines there is insufficient memory on a single processor to hold even the integer information for the whole matrix.

Thus MUMPS now offers a parallel option for the analysis step [6]. After an initial redistribution of the matrix, a parallel, nested-dissection-based tool, such as PT-SCOTCH or ParMETIS, is used to compute a fill-reducing pivotal order. According to the partitioning induced by the separators computed during the ordering step, the subsequent symbolic factorization is executed in parallel through an algorithm based on the use of distributed quotient graphs. This approach proved to be very effective in reducing the memory requirements and in improving the elapsed time for the analysis phase.

Most of the analysis step requires only the pattern of the matrix. However, scaling is a preprocessing for improving some of the numerical properties of the matrix, and this requires also the numerical values. Among a number of scaling alternatives available in MUMPS, the following two are the most powerful ones. The first uses linear programming duality where the scaling operators are obtained from weighted bipartite matching algorithms. The computation of this scaling alternative is performed sequentially on a central processor. A particular example of this is in the indefinite case where scaling can be used to identify potential two by two pivots allowing the analysis to be continued on a reduced graph obtained by collapsing the nodes corresponding to those pivots [12, 13]. The second scaling is an iterative algorithm. At each iteration of this algorithm, each row and column of the current matrix is scaled so that it is normalized according to a predefined norm, where the scaling of the rows and the scaling of the columns are independent. The scaling for this transformation is then combined with the scaling at the previous iteration in order to obtain a scaling for the original matrix. This algorithm is implemented in MUMPS for distributed memory environments in such a way that the communication and computation requirements of an iteration are equivalent to the sum of those for sparse matrix-vector and sparse matrix transpose-vector multiplication operations with the same matrix.

### Factorization Step

The factorization step uses the tree and subsidiary information from the analysis to effect the numerical factorization. As mentioned earlier, a main feature of this phase is the dynamic scheduling that is used to balance work and storage at execution time when the initial mapping is not appropriate because of numerical or load balance considerations [8, 10]. So that each processor can take appropriate dynamic scheduling decisions, an up to date view of the load and current memory usage of all the other processors must be maintained. This is done using asynchronous messages, as described in [17]. The nodes of the tree can be processed on a single processor or can be split between several processors. In MUMPS, a one-dimensional splitting and mapping can be used within intermediate nodes and a two-dimensional splitting can be used at the root node. The root node is by default factorized using ScaLAPACK.

In the factorization step, before the actual numerical factorization, there are a range of options available to scale the matrix including a version which runs in parallel. The most important scaling options were described when discussing the analysis step, but it is interesting to perform scaling at the factorization step rather than at the analysis step when successive factorizations are performed on matrices that share the same structure.

In addition to using standard threshold pivoting (see article on the ►Multifrontal Method in this Encyclopedia) for indefinite and unsymmetric systems, there is an option to use a static pivoting approach where pivots that are too small to satisfy a threshold criterion are augmented to avoid instability. In this case, one can avoid the perturbations to the original analysis ordering caused by numerical pivoting, making the performance closer to that obtained for positive definite matrices. However, the factorization will be that of a perturbed matrix and so an iterative refinement method or other more powerful iterative method must later be used to obtain a satisfactory solution.

The use of threshold partial pivoting may lead to a dynamic modification of the size of the tasks that have to be processed. Indeed, pivots which, for reasons of numerical stability, cannot be eliminated from the frontal matrix at a given node of the assembly tree are delayed to the parent node inducing an increase in its size and cost. This issue requires complex memory management mechanisms dealing with dynamic data structures. In addition, the fact that the cost of the tasks may differ from the predictions made during the analysis phase requires the scheduling mechanisms to dynamically adapt the mapping. This is done within MUMPS by using dynamic schedulers which complete the partial scheduling produced at the analysis phase (see [10] for more details). This enables the code to react to load variations due to delayed pivots.

In addition to a standard factorization of the matrix as in Eqs. 2 or 3, other options are available in MUMPS. It is possible to request a partial factorization of the matrix in order to compute the Schur complement. Consider a matrix ordered and partitioned as

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}$$

and assume that the elimination is restricted to choose the pivots from the (1,1) block. Then the factorization

will proceed to compute the  $LU$  (or  $LDL^T$ ) factorization of  $A_{11}$  and to compute the Schur complement matrix  $A_{22} - A_{21}A_{11}^{-1}A_{12}$  which can then be returned to the user, either centralized on one processor, or distributed over the processors. This partial factorization feature is particularly powerful for problems where partitions of the above form are used, for example when using domain decomposition. Options exist to solve the whole system after the Schur complement system has been solved.

There is also an option to detect null or almost null pivots and compute the numerical rank of the matrix. In cases where the matrix is rank deficient, vectors from the null space can be returned at the solve step.

One of the main issues that commonly arises during the factorization of large scale problems concerns the amount of main memory required. Although parallelism represents a natural way of reducing the local memory requirements, this may still not be enough. Operating systems provide mechanisms that can handle transparently cases where an application requires more memory than available on the system. These techniques, commonly referred to as *virtual-memory* techniques, consist in extending the main memory using disk storage. Portions of data in the main memory, so-called pages, are swapped out of main memory to the disk when they are unlikely to be used soon (for example, based on a least recently used policy). They are brought back to main memory if later access to them is required. Although these techniques apply transparently to any application, relying on them normally results in considerable performance loss, since the swapping of pages is done according to general policies that cannot fully exploit the access pattern to data in an application.

Instead of this mechanism, MUMPS provides an *out-of-core* feature [2] that greatly reduces main memory consumption by saving the factors on disks. Although not available in the current version of MUMPS, specific strategies for the traversal of the elimination tree could be used in order to limit the amount of data moved to and from the disk [3]. Also because of a clever use of asynchronous I/O operations which allow an overlap of computations with disk accesses, the out-of-core feature only has a relatively small impact on the performance of the factorization phase while delivering great benefits in terms of memory consumption. The numerical robustness provided by partial pivoting

used in MUMPS is fully guaranteed even when the out-of-core feature is enabled.

### Solve Step

The solution phase, that is the forward and back substitution using the matrix factors, also exploits parallelism relying on the computational pattern defined by the elimination tree. Performance gains can also be achieved when there are multiple right-hand sides. The resulting solution vector(s) can be left as a distributed vector or can be returned as a centralized vector. If the matrix is unsymmetric, the solution of the transpose equations can be obtained using the same factorization.

Considerable performance gains can be achieved in MUMPS when sparse (perhaps multiple) right-hand sides are supplied since the solution phase only requires parts of the factors. In fact, nonzero values in the right-hand sides induce paths in the elimination tree which identify the portions of the factors involved in the solution phase. In the case of multiple, sparse right-hand sides, MUMPS uses grouping strategies in order to optimize the exploitation of such paths. In an out-of-core context, the grouping of sparse right-hand sides aims to maximize the overlap of these paths which is equivalent to minimizing the amount of data loaded from disks, and thus the number of expensive I/O operations [4].

As mentioned above, the solve step of MUMPS also provides an option for returning either all or specific vectors from the null-space basis.

### Postprocessing Step

In common with many of its precursors, MUMPS offers further information on the solution after it has been computed. Options exist to return information on the residuals, the condition number of the matrix, and an estimate of the error and iterative refinement can be used to improve the solution by solving equations of the form

$$A\delta x = r$$

where  $r$  is the residual

$$r = b - Ax$$

and then correcting the solution by  $\delta x$ .

### Origins of MUMPS

MUMPS started in 1996 with the PARASOL Project which was an Esprit IV European project. MUMPS

implements a multifrontal method (see the ► [Related Entry](#)) and was inspired by an experimental prototype of an unsymmetric multifrontal code for distributed-memory machines using PVM [15]. That experimental prototype was itself inspired by the code MA41, developed by Amestoy during his Ph.D. thesis [5] at CERFACS under the supervision of Duff. MA41 exploits vector computers and shared-memory multiprocessor environments to solve unsymmetric linear systems. Going back further in the past, MA41 started from the work of Duff, who designed a parallel version of the unsymmetric code from Duff and Reid (HSL code MA37 [14] developed at the Harwell Laboratory). This parallel code was run primarily on the Alliant FX/8 [11].

The PARASOL Project consisted of a consortium of six software providers that included teams at CERFACS, INPT(ENSEEIHT)-IRIT, and RAL, and four application-based users of the software. MUMPS, so named because of the target of massive parallelism using the MPI message passing protocol, was the sole direct code in the project which also included linear solvers based on domain decomposition (including a FETI implementation) and multigrid. The first functionalities of MUMPS were developed to meet the requirements of the industrial partners most of whom worked with finite-element models [7]. All the software produced by this project was in the public domain although by the end of the project, in September 1999, most were still almost at a prototype level.

Since the first prototype of MUMPS at the end of the PARASOL project (1999), MUMPS has been supported by research institutions (CERFACS, CNRS, INPT-IRIT and INRIA) and projects (academic or industrial), that have helped to develop new functionalities over the years. This development of the MUMPS package (including development of new features, maintenance, integration of research work, support to users and project management) has been led by the teams of Patrick Amestoy (INPT) at IRIT Toulouse and Jean-Yves L'Excellent (INRIA) at LIP-ENS Lyon. Some developments also involve members of the LaBri laboratory in Bordeaux, France, and of the French research institute CNRS, while CERFACS has contributed by financing research related activities through Ph.D. grants. Both postdoctoral and engineer positions have been directly financed by CNRS and INRIA, and MUMPS

has also been supported by a large number of contracts, projects and grants including

- International projects like the France-Berkeley Fund in collaboration with the University of California, Berkeley or the Egide-Aurora project in collaboration with the University of Bergen, Norway or the Multicomputing project in collaboration with the University of Tel Aviv, Israel
- Projects financed by research institutions like CNRS, INRIA or ANR like the ANR-SOLSTICE project
- Contracts financed by private institutions and industries such as Samtech

### Further Comments

MUMPS is both a software platform and a research project that has developed many new and innovative techniques for the parallel solution of large sparse linear systems. Several Ph.D. theses have been obtained by students directly connected to MUMPS [1, 16, 21, 22]. Some of the major current research interests include further work on out-of-core implementation, on memory scalability, on sparse right-hand sides, and on combinatorial aspects related to preprocessing and analysis. One way in which this stimulating symbiosis between code development and research can be seen is in the restricted availability of prototype versions of the code and the use of experimental parameters which both help the research efforts in addition to acting as a beta-test for new features.

MUMPS is coded in Fortran 90 and C and uses MPI for message passing. It calls standard codes from the BLAS, BLACS, and ScaLAPACK so that some additional fine multi-threading can be obtained by using appropriate versions of the BLAS.

Single and double precision versions are supported for both real and complex systems.

MUMPS supports all variants of UNIX systems including Linux, and Microsoft Windows thanks to a port developed by MUMPS users.

There are interfaces to MUMPS from Fortran 90, C, C++, MATLAB and SCILAB. The code will run on 64-bit architectures and exploits long integers that are becoming increasingly needed as the size of problems being solved by direct solvers continues to increase.

The MUMPS software is continually updated both to correct any bugs and also to add new functionality.

The current version (as of November 2009) is Release 4.9.2, which is in the public domain. Up-to-date information including the MUMPS Users' Guide and information on downloading the package can be obtained through the web pages <http://graal.ens-lyon.fr/MUMPS> or <http://mumps.enseeih.t.fr/>. MUMPS is currently downloaded by approximately a 1,000 users per year from these web sites. MUMPS is interfaced or included (and redistributed) within various commercial and academic packages such as Samcef from Samtech, FEM-Town from Free Field Technologies, *Code\_Aster* from EDF, IPOPT, PETSc (see the ►PETSc (Portable, Extensible Toolkit for Scientific Computation) entry in this Encyclopedia).

### Definition

Myrinet is a family of high-performance network interface cards (NICs) and network switches produced by Myricom, Inc. (Myrinet® and Myricom® are registered trademarks of Myricom, Inc.) Some salient features of Myrinet are that it utilizes wormhole switching and emphasizes fully programmable NICs and simple switches.

### Discussion

#### History

The Myrinet network [3] is a direct descendent of Caltech's Mosaic C multicomputer [11] and USC/ISI's ATOMIC local-area network (LAN) [6]. The Mosaic C was based on custom processors that integrated a network interface, router, and simple CPU onto a single die. Although the Mosaic C processor was intended to be used as the building block for a massively

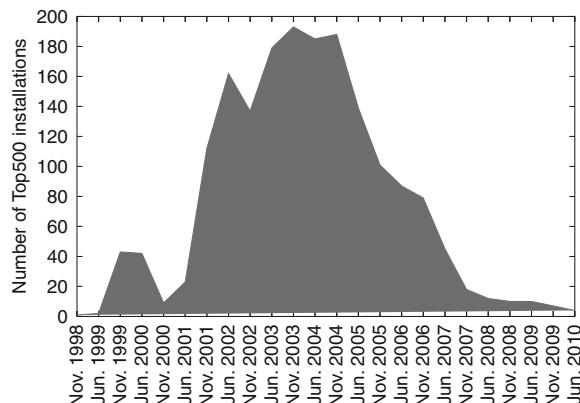

parallel processor, the ATOMIC project investigated using Mosaic C processors in a LAN setting as intelligent NICs – protocol processors – as a means for providing high-speed communication to nodes with more powerful CPUs. The project was deemed a success, and members of the Caltech and USC/ISI teams formed Myricom, Inc. to enhance and commercialize the technology.

The first Myrinet product was released in 1994 and utilized separate NICs and switches, in contrast to the Mosaic C's integrated system. The NICs initially comprised a 16-bit microcoded processor called the LANai and 128 KiB of static random-access memory (SRAM). As in ATOMIC, the NICs resided on an I/O bus. The switches were based on 4- or 8-port crossbars. Connectivity was via copper cables, and the link data rate was 640 Mb/s (76.3 MiB/s) in each direction.

The second-generation Myrinet network (1996) replaced the 16-bit microcoded LANai 2.3 with a 32-bit pipelined LANai 4, increased the NIC's on-board SRAM to 4 MiB, made some physical changes to the cabling (supporting both "LAN" and "SAN" configurations and both copper and optical cables) and to the signaling and encoding mechanisms, doubled the link data rate to 1,280 Mb/s (1.2 GiB/s) in each direction, and added support for the PCI bus. 16-port Myrinet switches became available. During Myrinet's second generation, the LANai processor went through numerous performance enhancements and major revisions, ending with the LANai 9, whose core is still in use in recent Myrinet products.

The third-generation product, Myrinet 2000, appeared in 2000 and further increased the data rate to 2,000 Mb/s (1.9 GiB/s) in each direction. Within that same generation, Myricom began supplying a "converged" architecture that continued to support the extant Myrinet cables and protocols while adding support for Gigabit Ethernet cables and protocols. This required altering most parts of the LANai (most noteworthy excluding the processor proper) to support multiple interfaces, resulting in the LANai XM, XP, and 2XP, each with a different tally of host and external interfaces. Support for the PCI-X I/O bus was also added.

Finally, the fourth-generation Myrinet product, Myri-10G, increased the data rate to 10,000 Mb/s (9.3 GiB/s), added support for the PCI Express bus,

**Myrinet. Fig. 1** Myrinet's popularity in the HPC community

and upgraded the convergence products from Gigabit Ethernet to 10 Gigabit Ethernet via new LANai Z8E, 2ZS, and Z8ES implementations.

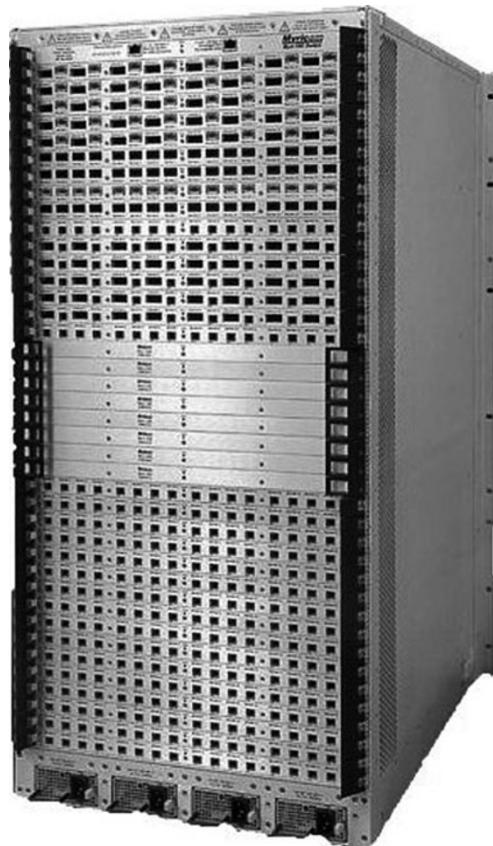

According to the Top500 list (<http://www.top500.org/>), Myrinet's popularity in the high-performance computing (HPC) community peaked in November 2003 with 193 of the world's 500 fastest supercomputers using a Myrinet network. However, as the Top500 data show, Myrinet's presence in the Top500 list dropped rapidly starting in 2005 (Fig. 1). At the time of this writing (June 2010), InfiniBand and Gigabit Ethernet have largely cornered the HPC interconnect market.

## Hardware

A Myrinet network consists of NICs and switches. Each computer on the network contains a NIC (possibly more than one). NICs are responsible for transferring data (bidirectionally) between main memory and the nearest switch. Switches are responsible for transferring data from their input ports to their output ports, where a port can be connected to either a NIC or another switch. Within a chassis, switches are connected to each other via a backplane, and between chassis, switches are connected via cables.

## Switches

Each individual switch contains some routing logic and a crossbar (a 32-port crossbar in the Myri-10G product). In principle, switches support arbitrary network topologies. That is, as far as the switch hardware is concerned, any switch can be connected to any other switch or NIC. This was originally convenient for local area network (LAN) settings, in which desktop computers

**Myrinet. Fig. 2** A fully populated 512-port Myri-10G enclosure (reproduced with permission from [http://www.myri.com/Myri-10G/switch/configuration\\_guide.html](http://www.myri.com/Myri-10G/switch/configuration_guide.html))

could simply be connected to the nearest switch without concern for topology. Today, Myrinet switches come in integrated chassis pre-wired into a regular, folded-Clos topology. In an HPC environment, multiple Myrinet chassis are usually also networked into a folded-Clos topology to provide high bisection bandwidth. Figure 2 shows a fully populated 512-port Myri-10G enclosure, which measures 21U (approximately 37 in. or 93 cm) in height. This unit contains a total of 48 switches, with 32 exposing half of their ports externally and routing the other half to a row of 16 all-internal “spine” switches.

Myrinet switches employ wormhole switching, which is fairly uncommon in cluster networks, although the technique had previously been used in a number of massively parallel processors (MPPs) such as the nCUBE3, Intel Paragon, and Cray T3D. Wormhole switching means that switches do not need to buffer an entire incoming packet before sending it out. Rather, as

each flit (*flow control digit* – one 8-bit byte in Myrinet) arrives at a switch, it can immediately be sent downstream. In fact, a packet’s first flit can reach the destination NIC before the source NIC has transmitted the packet’s final flit.

## Network Protocols

ANSI/VITA 26-1998 [4], the ANSI standard that defines Myrinet, specifies the network’s behavior at various layers of the Open System Interconnection (OSI) communication model. At the OSI data-link layer, Myrinet employs link-level flow control to prevent upstream NICs or switches from overwhelming a downstream NIC or switch. For example, if two packets arriving at a switch target the same output port, one packet will be allowed to proceed while the other is delayed. The switch sends a STOP symbol to the sender to instruct it to stop sending data. When the target port is free, the switch then sends a Go symbol to allow the sender to resume transmission. The other data-link-layer symbols are GAP and BEAT. GAP indicates that no data is being sent and that the link is between packets. The next data byte to arrive after a GAP is therefore the first byte of a new packet. GAP symbols obviate the need to specify a maximum transmission unit (MTU) size in hardware. Unlike most other networks, Myrinet allows packet frames to be arbitrarily large, although ANSI/VITA 26-1998 allows implementations to limit MTU sizes – but to no less than 4 MiB [4]. BEAT is a heartbeat symbol sent every 10 µs to indicate that data are being transmitted correctly (e.g., that the sender is not stuck repeatedly sending the same value).

At the OSI network layer, Myrinet packets are defined fairly simply. Each packet contains a number of routing bytes followed by a number of data bytes, followed by an 8-bit cyclic redundancy check (CRC-8) byte. Myrinet is a source-routed network, which means that the NIC that initiates a packet specifies the complete route to the destination NIC. Each packet begins with one routing byte per intermediate switch. Because there can be any number of switches between NICs, the number of routing bytes in a packet varies accordingly. In early versions of Myrinet, each routing byte specified an absolute port number. For example, a routing byte of {3} means that the packet should exit the subsequent switch from port 3. The network-layer protocol was later modified to use relative port numbers, which can be positive or negative. For example, a routing byte of {3}

means that if the packet enters a switch on port 4, it should exit on port 7. The advantage of relative addressing is that reverse routes are easy to calculate; a NIC needs only to invert the signs and reverse the order of the bytes. For example, if NIC A sends a packet to NIC B through three intermediate switches using routing bytes {+2, -4, +3}, then NIC B can send a packet to NIC A through the same three switches using routing bytes {-3, +4, -2}. Each switch discards the routing byte at the start of the packet and forwards the remaining bytes downstream. When the packet reaches its destination NIC it is not preceded by any routing bytes.

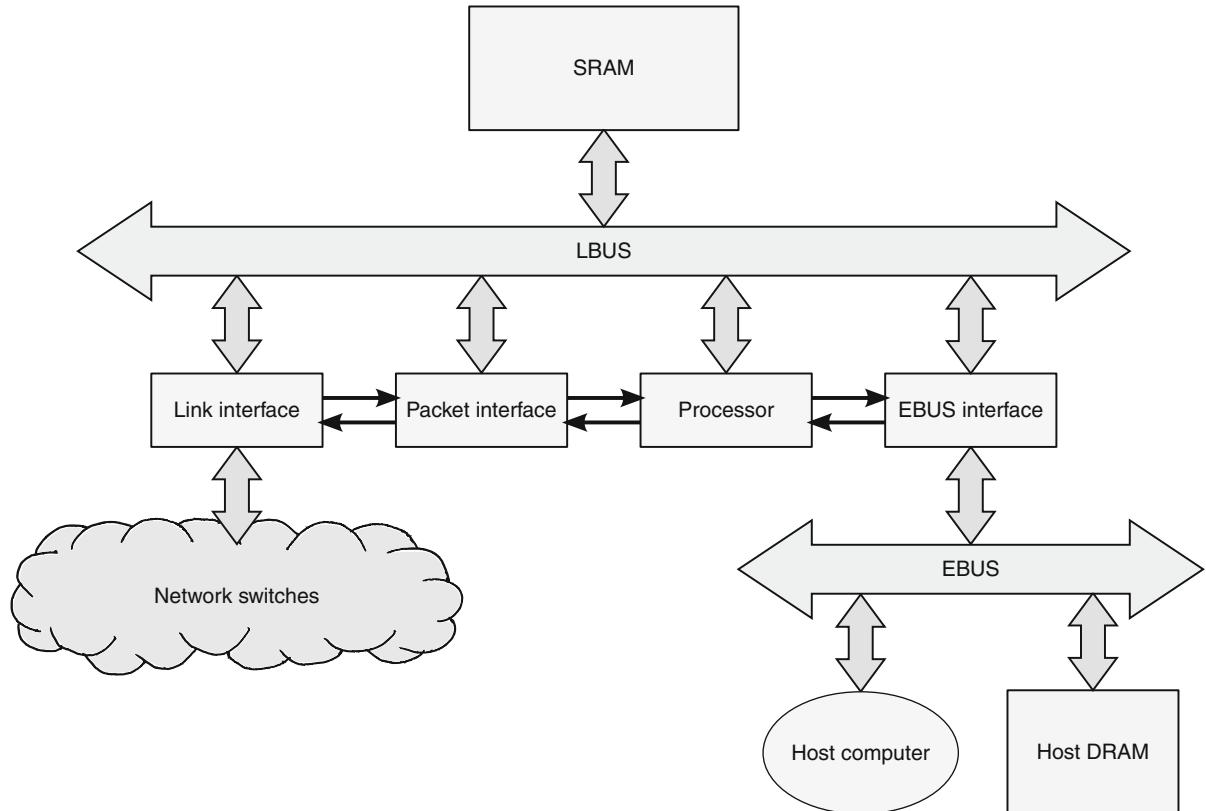

The packet’s data payload follows the routing bytes. The data begin with a four-byte packet type (two bytes for the primary type, two bytes for the secondary type) to indicate to the destination NIC what software layer is expected to handle the packet. For example, packet type 700F<sub>H</sub> indicates a topology-mapping packet used by the MX messaging layer [9], and packet types 0200<sub>H</sub>–0207<sub>H</sub> are used for various purposes by the Illinois Fast Messages messaging layer [10]. While the use of packet types is technically not required by the hardware, ANSI/VITA 26-1998 dictates its use to prevent software from mistaking one higher-level protocol’s packets for another’s. Myricom maintains a registry of packet types, and customers can request values dedicated to their own messaging layers.

The final byte of a Myrinet packet is a CRC-8 that covers the entire packet (routing bytes and data payload). It is inserted by the NIC that initiates the packet and is checked by each switch on the routing path and by the destination NIC. Because each switch modifies the packet by removing a header byte, each switch replaces the incoming CRC-8 byte with a new CRC-8 byte while sending the packet downstream.

## Network Interface Cards

One of Myrinet’s design philosophies is to keep the switches simple and fast and put all of the communication “smarts” into the endpoints. Hence, a Myrinet NIC is not a passive device controlled by the host computer’s operating system, as was typical for local area networks when Myrinet was first introduced, but rather an active entity that can autonomously manage data transfers between the network and host memory.

The basic NIC architecture is illustrated in Fig. 3. The main units shown in that figure are a link interface, which connects the NIC to an external switch; a

**Myrinet. Fig. 3** Block diagram of a Myrinet NIC

packet interface, which manages the transfer of packets to and from the network; a custom processor, which controls all aspects of the NIC; an EBUS (External BUS) interface, which manages the transfer of data to and from the host's I/O bus (e.g., PCI Express); and a small quantity of high-speed, multiported SRAM connected directly via an LBUS (Local BUS). The link interface, packet interface, processor, and EBUS interface are integrated onto a single chip called the LANai. Throughout the generations of Myrinet, the link interface adapted to Myrinet's ever-faster link speeds; the packet interface began including support for network types other than Myrinet (viz. Ethernet and InfiniBand) and in some instances doubled to two packet interfaces per NIC; the processor changed from being 16-bit microcoded to being 32-bit pipelined and underwent various modifications to the instruction set and clocking; the EBUS interface tracked each new I/O bus technology; and the SRAM switched from asynchronous

to zero bus turnaround (ZBT) technology for a speed boost and also increased in size from 128 KiB (with 16 bits/byte) to 4 MiB (with 8 bits/byte) with a maximum address space of 8 MiB. All of those implementation changes notwithstanding, the basic NIC architecture represented by Fig. 3 has remained largely unchanged across all versions of Myrinet.

The LANai processor utilizes a typical reduced instruction set computer (RISC) instruction set with a few additional features to support its role in managing communication. There is no floating-point unit. Because the processor pipeline is non-interlocked and because all memory is constant-latency SRAM, it is relatively easy to reason about LANai performance: Exactly one instruction is issued every cycle.

The software running on the LANai, known as the Myrinet Control Program (MCP), generally works by initiating direct memory access (DMA) transfers between local SRAM and either host DRAM or the

network. LANai SRAM can be mapped into the host's address space, so programmed I/O – word-by-word writes from the host to LANai SRAM or word-by-word reads from LANai SRAM to the host – is also possible. The LANai provides various features in hardware to perform these tasks with minimal overhead. DMA transfers between host memory and LANai SRAM are performed by writing source and destination addresses into a set of special memory-mapped registers. These registers are also mapped into host memory, so the host can control parts of the NIC hardware independently from the LANai. Dedicated hardware in the EBUS interface can generate CRC-32 values of data as it is copied between host memory and LANai SRAM. DMA transfers between the network and LANai SRAM are performed by writing starting and ending addresses into special send and receive registers. Messages being sent can comprise multiple DMA requests; a “final ending address” register designates the end of a message. CRC-32 values can be computed on both incoming and outgoing data and can be injected into an outgoing message at a specified location.

As a simple example of data transmission, the following code is all that is needed to send a msglen-byte message from buffer message:

#### C code

```
SMP = (void *)message;
SMLT = (void *)&message[msglen];
```

#### LANai assembly code

```
! Put msglen's value in r7.
 ld [_msglen],%r7
! Put message's address in r6.
 mov _message,%r6
! r6 is the DMA's starting address.
 st %r6,[0xFFFFFEF0]
! Put message's address in r8.
 mov _message,%r8
! Point r6 just pass the message.
 add %r7,%r8,%r6
! Initiate the send.
 st %r6,[0xFFFFFFF08]
```

Address FFFFFEF0<sub>H</sub> corresponds to special register Send-Message Pointer (SMP), which points to the start of the message. Address FFFFFF08<sub>H</sub> corresponds to special register Send-Message Limit, with the Tail (SMLT), which points to one byte past the last byte of the message. Storing a value in the SMLT register triggers the DMA from LANai SRAM into the network. Note that the preceding code assumes that the message begins with the requisite routing and packet-type bytes. Waiting for send completion is simply a matter of polling the interrupt status register, ISR, until the SEND\_INT bit is set:

#### C code

```
while ((ISR & SEND_INT_BIT) == 0)
;
```

#### LANai assembly code

```
! Store SEND_INT's bit offset in r13.
 mov 8,%r13
! Load ISR into r6.
L3: ld [0xFFFFFE50],%r6
! Delay until r6 is ready.
 nop
! Delay until r6 is ready.
 nop
! Test r6's SEND_INT bit.
 and.f %r6,%r13,%r0
! Try again if not set.
 beq L3
```

The nop instructions are necessary because the LANai has a non-interlocked processor pipeline.

The LANai supports two execution contexts, “user” and “system,” each with its own program counter and other registers. Context switching is extremely fast and can be performed either synchronously via an explicit machine instruction (punt) or asynchronously from user to system context in response to a hardware interrupt. The LANai signifies DMA completion, message availability, timer wraparound, and various other conditions by setting a bit in the ISR. The MCP can choose to poll the ISR for status changes or request that

modifications to certain bits trigger an interrupt, which the system context can subsequently handle.

## Software

### Communication-Layer Design Issues

Because the LANai is fully programmable and development tools are readily available, it is possible to implement any number of low-level communication layers. These can provide different feature sets, different semantics, and make different performance tradeoffs. In fact, there have been a wide variety of low-level, software communication layers developed over the years not only by Myricom – the so-called Myrinet API followed by GM (Glenn’s Messaging) followed by MX (Myrinet Express) – but also by researchers at numerous institutions. Research communication layers targeting Myrinet include Active Messages (AM), the Basic Interface for Parallelism (BIP), the BullDog Myrinet Control Program (BDM), Fast Messages (FM), Hamlyn, Link-level Flow Control (LFC), ParaStation2, PM, Trapeze, U-Net, Virtual Memory-Mapped Communication (VMMC), as well as the Message-Passing Interface (MPI) implemented atop various Myrinet-specific MPICH channel devices. All of those are designed to be user-level communication layers, meaning that the operating system has essentially no involvement in the critical path of communication. However, traditional, operating-system-based Internet Protocol (IP) communication can run atop Myricom’s low-level communication layers. Each of the communication layers listed above must address issues of memory pinning, data transfer, reliability, and route discovery, among others.

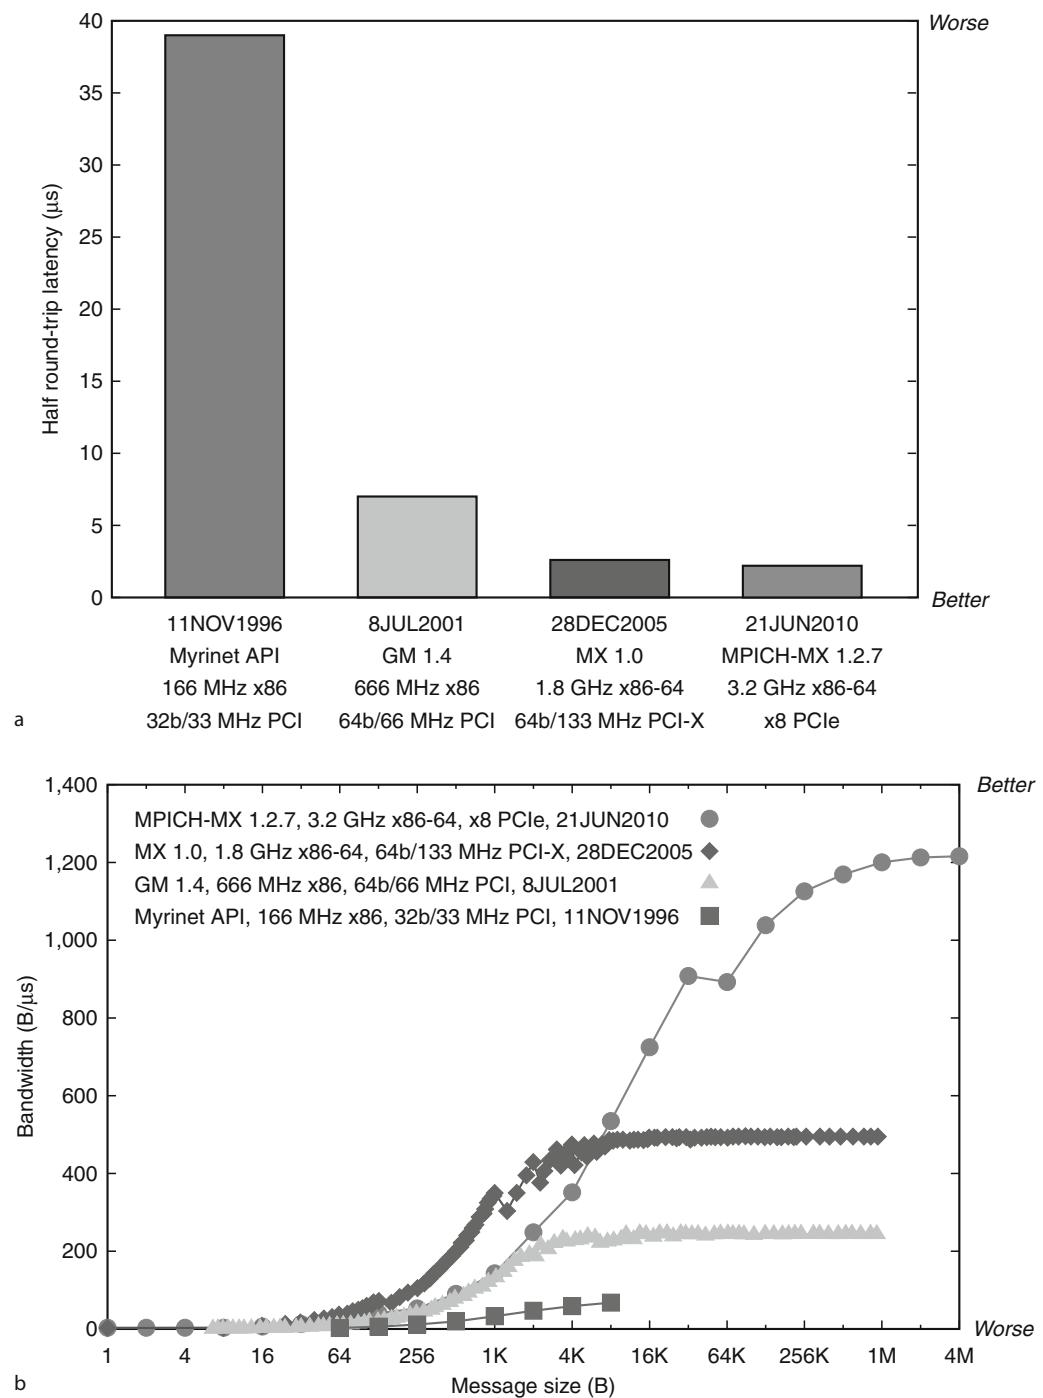

The LANai can transfer data only to and from physical addresses in the host. Consequently, the host operating system must ensure that memory pages that may be accessed by the LANai are “pinned,” making them ineligible for being swapped out to disk and replaced by another page. Some communication layers have the operating system pin a fixed region of addresses at initialization time, let the LANai transfer data only to/from that region, and use host software to copy data to/from that region into arbitrary (non-pinned) buffers provided by the application. Other communication layers modify the operating system to respond to LANai interrupts, pin pages on demand, and notify the MCP of the physical addresses to use.

LANai-initiated data transfers to/from the host must be performed using the LANai’s DMA mechanism. However, host-initiated data transfers can use either DMA or programmed I/O (word-by-word reads or writes). DMA-based transfers tend to have a higher startup cost but lower per-byte cost while programmed I/O-based transfers tend to have a lower startup cost but a higher per-byte cost. Programmed I/O-based transfers can address arbitrary host memory and can therefore avoid copying data to/from a pinned region or asking the operating system to pin a region of memory before the transfer begins.

Related to data transfers is event notification: Is data ready to be processed? The LANai and the host can each signal the other with interrupts, which are asynchronous but, particularly in the case of the LANai interrupting the host, exhibit high overhead due to operating-system involvement and costly context switches. The alternative is to poll memory for state changes. While a single poll is faster than a single interrupt, polling must be performed frequently to avoid delaying communication progress.

Myrinet provides reliable data transmission in the sense that it never intentionally discards data. However, software communication layers must ensure that there is always a place to store incoming data. Most communication layers implement some form of flow control to prevent data buffers from overflowing. However, some simply discard incoming data if there is no place left to store it and let higher layers of software or the application itself detect the data loss and induce a retransmission.

Because Myrinet is a source-routed network, an MCP needs to know the precise path to every NIC in the cluster so it can inject the correct routing bytes into the network. Some communication layers simply read a configuration file that enumerates these paths and instruct the MCP accordingly. This works well for smaller networks with fairly static topologies. Other communication layers implement route discovery. In Myrinet, route discovery has to be performed entirely by software, either by the MCP or by the host with the MCP’s assistance. Route discovery works essentially by performing a breadth-first search of the network: First, all possible one-hop destinations are queried for existence, followed by all possible two-hop destinations, and so forth. Because this can be a time-consuming

**Myrinet.** Fig. 4 Myrinet historical performance (a) latency, (b) bandwidth

operation for large networks, route discovery is performed only occasionally.

## Performance

[Figure 4](#) aggregates historical performance data that have appeared on [Myricom's Web site](#) over a span of 14 years. [Figure 4a](#) presents messaging latency, measured as half the average time for a minimal-sized message to be sent back and forth between a host process on each of two computers. [Figure 4b](#) presents the messaging bandwidth, measured as the average rate at which a message of a given size can be sent back and forth between a host process on each of two computers.

The data represent multiple generations of low-level Myrinet software, Myrinet NIC hardware, Myrinet switch hardware, host CPUs, and I/O buses. Consequently, performance improvements cannot be attributed to the evolution of a single component. Rather, [Fig. 4](#) should be interpreted as portraying the performance that one could have expected from a Myrinet cluster with typical hardware and typical vendor-supplied software at four points in time from November 1996 to June 2010. As [Fig. 4](#) shows, a cluster running a recent version of MPICH-MX on recent Myrinet hardware can expect to see a minimum of 2.2 µs one-way message latency and a maximum of 1,215 MB/s of communication bandwidth – both a factor of 18 improvement over a state-of-the-art Myrinet cluster from 14 years earlier.

The data presented in [Fig. 4](#) represent only Myricom's software. Myrinet software from third-party research institutions often outperformed the corresponding offering from Myricom, generally by utilizing novel data structures and by removing nonessential, high-overhead features. As a point of comparison, contemporaneously with the Myrinet API observing a minimum latency of 39 µs, Fast Messages, Active Messages, and PM all observed a minimum latency of 10 µs or less. In fact, some of Myrinet's uniqueness from a software perspective is that the LANai's programmability makes Myrinet a suitable platform for experimentation with communication-layer design.

## Bibliographic Notes and Further Reading

One of Myricom's few peer-reviewed publications is an overview of Myrinet that appeared in a 1995 issue of IEEE Micro [3]. Although the paper describes the first commercial implementation of Myrinet, much of what it says is still applicable to more recent incarnations of Myrinet. Details of Myrinet's OSI data-link layer and OSI network layer appear in the Myrinet standardization document, ANSI/VITA 26-1998 [4]. Various aspects of the LANai architecture and physical characteristics are covered by Myricom white papers [7, 8].

The LANai's origins are in Caltech's Mosaic C multicomputer [11]. Both contain a simple processor, a memory interface, and an integrated network interface with instruction-set support. However, the Mosaic C targets large-scale direct networks and therefore additionally integrates a dimension-order router for 2-D mesh networks onto the die. In contrast, the LANai targets indirect networks of arbitrary topology and therefore delegates routing to an external switching fabric. USC/ISI saw the potential for utilizing Mosaic C components in a LAN setting and constructed their ATOMIC LAN as a proof of the concept [6]. In a sense, Myrinet is a commercial implementation of the ATOMIC network architecture. An interesting part of Felderman et al.'s ATOMIC paper [6] is its exposition of the challenges of route discovery on a network topology that is not guaranteed to be either symmetric or consistent. (Myrinet networks are symmetric but not necessarily consistent.)

Myrinet has been the target platform for a wealth of software communication layers such as Fast Messages [10], Active Messages II [5], and Myrinet Express [9]. Two papers published in November 1998 contrast many of the Myrinet communication layers that

were current at that time. Bhoedjang et al. discuss the design decisions underlying user-level communication layers, step through a simple communication layer for Myrinet, and show how numerous Myrinet communication layers address various implementation alternatives [2]. Araki et al. take a more performance-oriented approach, presenting a LogP (latency, overhead, gap, processes) analysis of multiple Myrinet communication layers and drawing conclusions about how various communication-layer features impact communication time [1].

## NAMD (NAnoscale Molecular Dynamics)

LAXMIKANT V. KALÉ, ABHINAV BHATELE, ERIC J. BOHM,  
JAMES C. PHILLIPS  
University of Illinois at Urbana-Champaign, Urbana,  
IL, USA

### Definition

NAMD is a parallel molecular dynamics software for biomolecular simulations.

### Discussion

#### Introduction

NAMD (NAnoscale Molecular Dynamics, <http://www.ks.uiuc.edu/Research/namd>) is a parallel molecular dynamics (MD) code designed for high-performance simulation of large biomolecular systems [1–4]. Typical NAMD simulations include all-atom models of proteins, lipids, and/or nucleic acids as well as explicit solvent (water and ions) and range in size from 10,000 to 10,000,000 atoms.

NAMD employs the prioritized message-driven execution capabilities of the Charm++/Converse parallel runtime system (<http://charm.cs.illinois.edu>), allowing excellent parallel scaling on both massively parallel supercomputers and commodity workstation clusters. NAMD is distributed free of charge as both source code and pre-compiled binaries by the Theoretical and Computational Biophysics Group (<http://www.ks.uiuc.edu>) of the University of Illinois Beckman Institute. NAMD development is primarily funded by the NIH through the Resource for Macromolecular Modeling and Bioinformatics. NAMD has been downloaded by over 36,000 registered users, over 8,000 of whom have downloaded multiple releases.

#### Biomolecular Simulation

The interactions between atoms in a biomolecular system are modeled with a combination of classical (non-quantum) terms. Each atom is assigned a static partial charge (a fraction of an electronic charge) based on the difference between its nuclear charge and the nearby electron density given its molecular configuration. Standard  $1/r$  electrostatic interactions between these partial charges are added to a Lennard-Jones potential, which combines a  $1/r^6$  van der Waals attractive potential with a short-range  $1/r^{12}$  repulsive term. The effects of covalent bonds are represented by harmonic terms applied to the distance between directly bonded atoms, angles formed by a pair of bonds to a common atom, and dihedral angles formed by chains of four bonded angles. Dihedral terms may also be sums of cosines, and harmonic terms are applied to enforce planarity of four atoms in the case of so-called improper dihedrals. Parameters for the Lennard-Jones and bonded terms are based on the element type of each atom, as well as its bonds to hydrogen or other heavy atoms.

In preparing to simulate a biomolecular system with NAMD, atomic coordinates of the proteins, nucleic acids, and/or lipids of interest are obtained from known crystallographic or other structures. Missing parts of the structure may be modeled based on homologous molecules of known structure. Any aggregates must then be assembled, such as embedding a protein in a membrane or binding a hormone receptor to DNA. A periodic block of water is replicated to cover the entire structure up to the boundaries of the desired periodic cell, water molecules within a few Angstroms of the structure are removed, and the remaining water is merged into the structure. In order to neutralize the electrical charge of the system and obtain a proper salt concentration, some water molecules are replaced with  $\text{Na}^+$  and  $\text{Cl}^-$  ions in a manner that minimizes electrostatic energy.

Using the potential function, the initial atomic coordinates are adjusted to eliminate initial close contacts

and large forces that would destabilize the system. The Newtonian equations of motion, with modifications to control temperature and pressure, are then integrated by symplectic and reversible methods using a time step of 1 femtosecond (or 2 fs if water molecules and bonds to hydrogen atoms are held rigid). A typical simulation may be 1–10 ns (1–10 million steps), and long simulations may be a microsecond or more.

Although the symplectic property of the standard explicit Verlet integrator allows energy to be well conserved over long trajectories, a thermostat is typically used to initially equilibrate the simulation to a given temperature and then to control heating due to integrator energy drift. Molecular dynamics simulations are chaotic in the sense that the specific trajectory is highly dependent on the initial coordinates and velocities. Therefore, the goal of the simulations is to characterize typical conformations and fluctuations, and to extract thermodynamic properties such as free energy differences.

## NAMD Features

NAMD 2.x has been in production use for over a decade and has been developed in a highly active user environment. As a result of user requirements, NAMD has acquired a wide variety of simulation features. NAMD relies on the capabilities of its sister program VMD (Visual Molecular Dynamics, <http://www.ks.uiuc.edu/Research/vmd>) for the setup, visualization, and analysis of simulations. VMD reads and writes a wide variety of file formats and is used extensively for visualizing and analyzing the output of MD codes besides NAMD, as well as other experimental and computational data. VMD can connect to a running NAMD simulation, allowing the user to apply forces to steer the simulation using the mouse or a haptic interface.

NAMD supports non-periodic and periodic boundary conditions, including non-orthogonal cells and periodicity in only one or two dimensions. Minimization is performed using the conjugate gradient algorithm. Atoms may be fixed or restrained to an initial position to stabilize a structure during minimization and equilibration. Both three-point and four-point water models (TIP3P and TIP4P) are supported. Water molecules and bonds to hydrogen atoms may be held rigid to increase the maximum stable time step. Velocity

rescaling and Langevin dynamics constant temperature methods and Berendsen and Langevin piston constant pressure methods may be applied to provide an NVT or NPT ensemble.

Free energy of conformational change surfaces or potentials of mean force may be studied along an arbitrary number of user-defined collective variables via a variety of methods, including meta-dynamics, the adaptive biasing force method, umbrella sampling, and steered molecular dynamics. Alchemical transformations, in which the chemical structure of a molecule is modified, may be studied via free energy perturbation or thermodynamic integration methods.

Special support is provided for the analysis of cryo-electron-microscopy data via molecular dynamics flexible fitting. In this method, an experimentally derived electron density map is transformed into a potential on a grid. The molecular structure is restrained via additional bonded terms and simulated to allow the atoms to conform to the grid potential. This allows the combination of atomic-resolution x-ray crystallographic structures with lower-resolution cryo-electron-microscopy data and has been particularly useful in the study of large structures with complex motions such as the ribosome.

An important goal of NAMD is to provide a uniform user interface (as far as possible) across all platforms, from laptops and desktops to clusters and massively parallel Cray XT and IBM Blue Gene supercomputers. Within the limits of memory and scalability, any simulation can be run on any number of processors. The program's spatial decomposition method is adjusted from full-sized to half-sized patches in one, two, or three dimensions as the number of processors increases. Similarly, the particle-mesh Ewald FFT decomposition is switched from slabs to pencils and spanning trees are used for coordinate and force messages. While manual tuning options are available, they are only beneficial at the limits of parallel scalability – most users happily ignore them.

## Parallel Design and Implementation

The sequential algorithm in most molecular dynamics applications is similar. The simulation time is broken down into a large number of very small time steps (typically 1 or 2 fs each). At each time step, forces on every

atom are calculated due to every other atom. Acceleration and velocities for the particles are obtained from the forces, based on which the new positions of the particles are calculated. This is repeated every time step. Two kinds of forces are to be calculated: (1) forces due to bonds and (2) non-bonded forces. If the nonbonded forces are calculated pairwise for all pairs of atoms, it results in a naïve  $\mathcal{O}(n^2)$  implementation. Most MD applications use an optimization where forces are not calculated explicitly beyond a certain cutoff distance. For atoms that lie beyond the cutoff distance, forces are calculated by using the particle-mesh Ewald (PME) or Gaussian spread Ewald (k-GSE) method. In these methods, the electric charge of each atom is transferred to electric potential on a grid that is used to calculate the influence of all atoms on each atom.

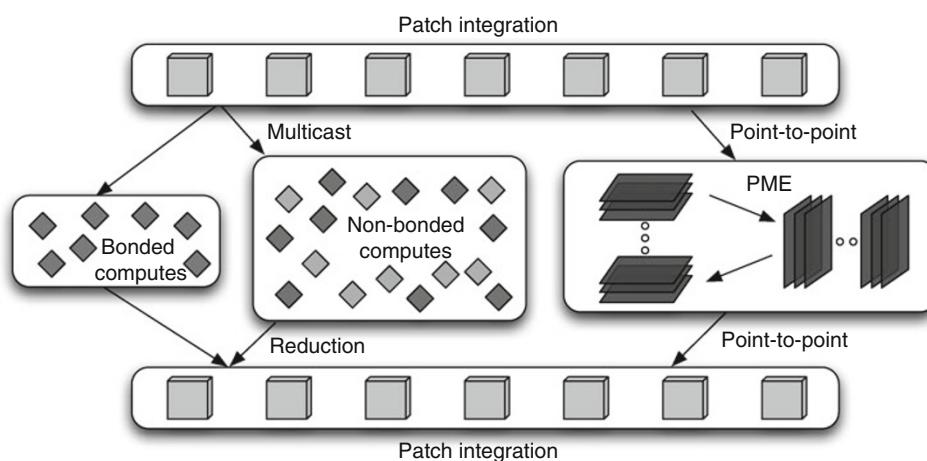

Parallelization of the algorithm mentioned above has been traditionally done in various ways (a good survey can be seen in Plimpton et al. [5]). Some of them are outlined here:

- Atom Decomposition: All atoms in the simulation box are distributed among the processors and each processor is responsible for the force calculations of the atoms it holds.
- Force Decomposition: The force matrix is distributed across the processors for parallelization.
- Spatial Decomposition: The three-dimensional simulation box is spatially divided among the processors and each processor is responsible for the atoms within that area.

Atom and force decomposition have high communication to computation ratios and spatial decomposition has problems of limited parallelism and load imbalance. For NAMD, a hybrid between spatial and force decomposition was developed, which combines the advantages of both [6]. Similar methods have been used in MD packages such as Blue Matter and Desmond.

The simulation box consisting of a spatial distribution of atoms is divided into smaller cells called “patches.” The dimensions of each patch are roughly equal to  $r_c + \text{margin}$  where  $r_c$  is the cutoff distance and  $\text{margin}$  is a small constant. This ensures that atoms within a cutoff radius of each other stay within neighboring patches over a few time steps. Patches are assigned to some processors (typically the number of patches is much smaller than the number of processors). Force calculations for each pair of patches is assigned to a different object called a “compute.” The number of computes in a simulation is much larger and they are load balanced across all the processors. Computes responsible for nonbonded force calculations within the cutoff radius account for most of the computation time in NAMD. Computes can be assigned to any processor irrespective of where the associated patches are placed.

**Figure 1** shows the communication and computation involved in a time step. At the beginning of a time step, patches send their atoms to the respective computes (nonbonded, bonded, and PME). The computes do the force calculations and send the forces back to the patches. The patches calculate velocities and new

NAMD (NA noscale Molecular Dynamics). **Fig. 1** Flow diagram showing the computation of forces in NAMD every step

positions for their particles and then this process is repeated. The load balancing framework in Charm++ is used to adaptively balance work units or computes across processors. The runtime instruments the load of each compute for a few time iterations and then uses this information to move work units around. The first load balancing phase migrates many computes based on a greedy strategy but the subsequent phases do refinement-based balancing. On machines such as IBM Blue Gene/L and Blue Gene/P, the load balancer also uses topology information to optimize communication and minimize contention.

## Performance

NAMD was designed more than 10 years ago but it has withstood the changes in technology because of its parallel-from-scratch, migratable-objects-based design. The strategy of hybrid decomposition coupled with adaptive overlap of communication and computation, supported by dynamic load balancing has helped NAMD scale to very large machines. NAMD can be run on most parallel machines due to the portability of the CHARM++ runtime. It can be run on any number of processors and has no powers-of-two restrictions

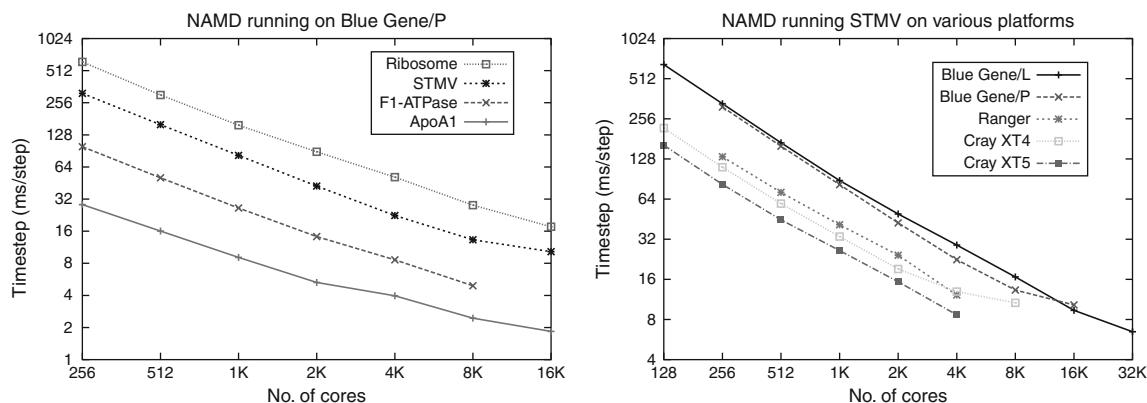

on the number. Another important feature of NAMD is that it performs well for a wide range of molecular system sizes.

**Table 1** shows the four molecular systems for which benchmarking results are being presented. Important configuration parameters such as the cutoff distance used and duration of each time step (in femtoseconds) are listed. These systems represent a wide range of sizes from 92 thousand atoms to 2.8 million atoms. The left plot in [Fig. 2](#) shows the performance of NAMD on the Blue Gene/P machine at Argonne National Laboratory (ANL). Four different lines show the strong scaling performance of NAMD for the chosen molecular systems from 256 to 16,384 cores. For ApoA1, one can simulate 47 ns per day when running on 16,384 cores of Blue Gene/P. Simulation of ribosome, a 2.8 million atom system, has an efficiency of 55% at 16,384 cores compared to the performance at 256 cores.

NAMD is used by biophysicists and chemists at most national laboratories for biomolecular research. **Table 2** presents architectural specifications of some of the machines NAMD has been run on and demonstrated to have good performance. Of these, the Cray XT5 system (Jaguar) at ORNL is currently the fastest

**NAMD (NA noscale Molecular Dynamics).** **Table 1** Molecular systems used for benchmarking NAMD

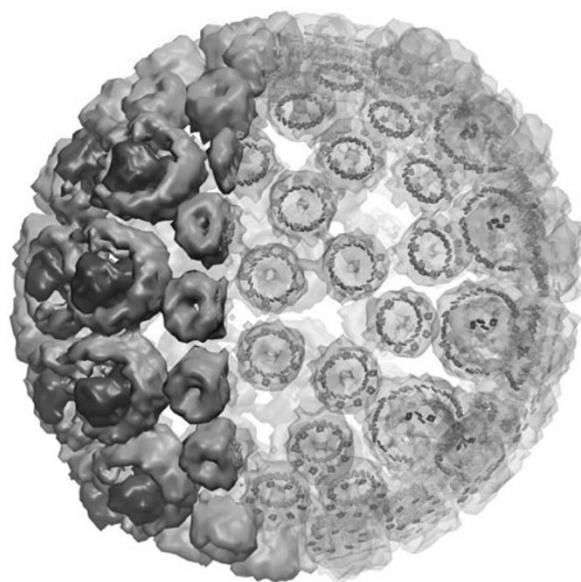

| Molecular system | Atom count | Cutoff (Å) | Simulation cell (Å <sup>3</sup> ) | Time step (fs) |
|------------------|------------|------------|-----------------------------------|----------------|
| ApoA1            | 92,224     | 12         | 108.86 × 108.86 × 77.76           | 1              |
| F1-ATPase        | 327,506    | 12         | 178.30 × 131.54 × 132.36          | 1              |
| STMV             | 1,066,628  | 12         | 216.83 × 216.83 × 216.83          | 1              |
| Ribosome         | 2,820,530  | 12         | 264.02 × 332.36 × 309.04          | 1              |

**NAMD (NAnoscale Molecular Dynamics). Fig. 3** Structural model of a photosynthetic chromatophore vesicle, a biological light-harvesting machine (shown are the constituent proteins: 101 LH2 complexes surrounding 18 dimers of LH1-reaction center complexes). The system contains approximately 4,000 bacteriochlorophylls. Proteins are shown as semitransparent on the right-hand side to display the bacteriochlorophyll network. Image generated with VMD by Melih Sener based on work by himself, Jen Hsin, Chris Harrison, and Klaus Schulten

supercomputer in the world (as per the November 2009 Top500 list). NAMD has a small memory footprint and hence it can simulate a range of molecular systems on machines with limited memory (such as the IBM Blue Gene machines). However, scientists are now planning to simulate 25–100 million atom systems using NAMD. This will be discussed further in the Future Directions section.

Figure 2 (right plot) shows the benchmarking results for NAMD on five supercomputers at four different sites. They are representative of IBM machines, Cray machines, and Infiniband clusters. The molecular system being simulated is the one million atom STMV (Satellite Tobacco Mosaic Virus). NAMD clearly scales well on all these machines. Using 4,096 cores of the Cray XT5 machines, one can simulate around 10 ns per day for the STMV system.

## Conclusion

Molecular dynamics simulations are hard to parallelize because of the relatively small size of molecular systems and because one needs to run for millions of time steps to simulate a small period in the life of a biomolecule. NAMD has been used as an MD package for many years now and has withstood the changes in technology. Its fundamentally parallel design based on migratable CHARMM++ objects, supported by dynamic load balancing, has made it possible to scale NAMD to the machines of the petascale era. NAMD is continually being used to simulate larger and larger molecular systems, which pose new challenges for parallelization on large supercomputers. Recent modifications to NAMD such as parallel input/output and hierarchical load balancing have made this possible.

## Future Directions

Supercomputers are becoming larger each year with very little increase in the computational power of each individual processing core. Biomolecules are of fixed size, which places NAMD's required performance characteristics in the “strong-scaling” category. This constrains future research for this style of molecular dynamics to either the study of systems sufficiently

large to perform well on future machines, maintaining consistent performance improvements for ever-decreasing computation granularity, or integration with other methods in multi-physics models. Efforts are being put in all of those approaches.

NSF's Blue Waters project, a sustained Petaflop/s machine due to enter production in 2011, includes an MD benchmark acceptance test of 100 million atom system of DOPS, DOPC, and curvature-inducing protein BAR domains in water solvent. Support for running this system, already two orders of magnitude larger than is typical, has been added to NAMD and performance tuning for this system on the Blue Waters architecture is ongoing. Systems of similar size, such as the photosynthetic chromatophore shown in Fig. 3, will leverage these technologies to meet cutting edge science goals and permit the study of large structures for at least tens of nanoseconds of simulation time.

The NAMD and CHARMM++ development efforts continue to improve strong scaling performance through a variety of overhead reduction schemes and to adapt the software to make use of the network and computation resources idiosyncratic to new supercomputer architectures.

## Bibliographic Notes and Further Reading

A good survey of parallelization techniques for MD programs can be found in Plimpton et al. [5]. Snir discusses the communication requirements of force and spatial decomposition and proposes a hybrid algorithm similar to that of NAMD [7]. Other MD packages similar to NAMD are CHARMM, AMBER, GROMACS, Blue Matter, and Desmond.

The paper by Kale et al. [3] was awarded the Gordon Bell award at Supercomputing 2002. Detailed performance benchmarking of NAMD and recent algorithmic changes to enable scaling to large machines can be found in [1] and [8].

## Definition

The NAS Parallel Benchmarks (NPB) are a suite of parallel computer performance benchmarks. They were

originally developed at the NASA Ames Research Center in 1991 to assess high-end parallel supercomputers [2]. Although they are no longer used as widely as they once were for comparing high-end system performance, they continue to be studied and analyzed a great deal in the high-performance computing community. The acronym “NAS” originally stood for the Numerical Aeronautical Simulation Program at NASA Ames. The name of this organization was subsequently changed to the Numerical Aerospace Simulation Program, and more recently to the NASA Advanced Supercomputing Center, although the acronym remains “NAS.” The developers of the original NPB suite were David H. Bailey, Eric Barszcz, John Barton, David Browning, Russell Carter, LeoDagum, Rod Fatoohi, Samuel Fineberg, Paul Frederickson, Thomas Lasinski, Rob Schreiber, Horst Simon, V. Venkatakrishnan, and Sisira Weeratunga.

## Discussion

The original NAS Parallel Benchmarks consisted of eight individual benchmark problems, each of which focused on some aspect of scientific computing. The principal focus was in computational aerophysics, although most of these benchmarks have much broader relevance, since in a much larger sense they are typical of many real-world scientific computing applications.

The NPB suite grew out of the need for a more rational procedure to select new supercomputers for acquisition by NASA. The emergence of commercially available highly parallel computer systems in the late 1980s offered an attractive alternative to parallel vector supercomputers that had been the mainstay of high-end scientific computing. However, the introduction of highly parallel systems was accompanied by a regrettable level of hype, not only on the part of the commercial vendors but even, in some cases, by scientists using the systems. As a result, it was difficult to discern whether the new systems offered any fundamental performance advantage over vector supercomputers, and, if so, which of the parallel offerings would be most useful in real-world scientific computation.

In part to draw attention to some of the performance reporting abuses prevalent at the time, the present author wrote a humorous essay “Twelve Ways to Fool the Masses,” which described in a light-hearted way a number of the questionable ways in which both

vendor marketing people and scientists were inflating and distorting their performance results [1]. All of this underscored the need for an objective and scientifically defensible measure to compare performance on these systems.

At the time (1991), the only widely available high-end benchmark was the scalable Linpack benchmark, which while it was useful and remains useful to this day, was not considered typical of most applications on NASA’s supercomputers or at most other sites. One possible solution was to employ an actual large-scale application code, such as one of those being used by scientists using supercomputers at the NAS center. However, due in part to the very large programming and tuning requirements, these were considered too unwieldy to be used to compare a broad range of emerging parallel systems. Compounding these challenges at this time was the lack of a generally accepted parallel programming model – note this was several years before the advent of the Message Passing Interface (MPI) and OpenMP models that are in common usage today.

For these reasons, the NAS Benchmarks were initially designed not as a set of computer codes, but instead were specified as “paper and pencil” benchmarks defined in a technical document [3]. The idea was to specify a set of problems only algorithmically, but in sufficient detail that the document could be used for a full-fledged implementation complying with the requirements. Even the input data or a scheme to generate it was specified in the document. Some “reference implementations” were provided, but these were intended only as aids for a serious implementation, not to be the benchmarks themselves. The original rules accompanying the benchmarks required that the benchmarks be implemented in some extension of Fortran or C (see details below), but otherwise implementers were free to utilize language constructs that give the best performance possible on the particular system being studied. The choice of data structures, processor allocation, and memory usage was (and are) generally left open to the discretion of the implementer.

The eight problems consist of five “kernels” and three “simulated computational fluid dynamics (CFD) applications.” The five kernels are relatively compact problems, each of which emphasizes a particular type of numerical computation. Compared with the simulated

CFD applications, they can be implemented fairly readily and provide insight as to the general levels of performance that can be expected on these specific types of numerical computations.

The three simulated CFD applications, on the other hand, usually require more effort to implement, but they are more indicative of the types of actual data movement and computation required in state-of-the-art CFD application codes, and in many other three-dimensional physical simulations as well. For example, in an isolated kernel, a certain data structure may be very efficient on a certain system, and yet this data structure would be inappropriate if incorporated into a larger application. By comparison, the simulated CFD applications require data structures and implementation techniques in three physical dimensions, and thus are more typical of real scientific applications.

## Benchmark Rules

Even though the benchmarks are specified in a technical document, and implementers are generally free to code them in any reasonable manner, certain rules were specified for these implementations. The intent here was to limit implementations to what would be regarded as “reasonable” code similar to that used in real scientific applications. In particular, the following rules were presented, and, with a couple of minor changes, are still in effect today (these rules are the current version):

- All floating point operations must be performed using 64-bit floating point arithmetic (at least).
- All benchmarks must be coded in either Fortran (Fortran-77 or Fortran-90), C, or Java, with certain approved extensions. Java was added in a recent version of the NPB.
- One of the three languages must be selected for the entire implementation – mixed code is not allowed.
- Any language extension or library routine that is employed in any of the benchmarks must be supported by the system vendor and available to all users.
- Subprograms and library routines not written in Fortran, C, or Java (such as assembly-coded routines) may only perform certain basic functions [a complete list is provided in the full NPB specification].

- All rules apply equally to subroutine calls, language extensions, and compiler directives (i.e., special comments).

## The Original Eight Benchmarks

A brief (and necessarily incomplete) description of the eight problems is given here. For full details, see the full NPB specification document [3].

*EP.* As the acronym suggests, this is an “embarrassingly parallel” kernel – in contrast to others in the list, it requires virtually no interprocessor communication, only coordination of pseudorandom number generation at the beginning and collection of results at the end. There is some challenge in computing required intrinsic functions (which, according to specified rules, must be done using vendor-supplied library functions) at a rapid rate.

The problem is to generate pairs of Gaussian random deviates and tabulate the number of pairs in successive square annuli. The Gaussian deviates are to be calculated by the following well-known scheme. First, generate a sequence of  $n$  pairs of uniform  $(0,1)$  pseudorandom deviates  $(x_j, y_j)$  (using a specific linear congruential scheme specified in the benchmark document). Then, for each  $j$ , check whether  $t_j = x_j^2 + y_j^2 \leq 1$ . If so, set  $X_k = x_j\sqrt{(-2\log t_j)/t_j}$  and  $Y_k = y_j\sqrt{(-2\log t_j)/t_j}$ , where the index  $k$  is incremented with every successful test; if  $t_j > 1$ , then reject the pair  $(x_j, y_j)$ . In this way, the resulting pairs  $(X_k, Y_k)$  are random deviates with a Gaussian distribution. The sums  $S_1 = \sum_k X_k$  and  $S_2 = \sum_k Y_k$  are each accumulated, as are the counts of the number of hits in successive square annuli.

The verification test for this problem requires that the sums  $S_1$  and  $S_2$  each agree with reference values to within a specified tolerance, and also that the ten counts of deviates in square annuli exactly agree with reference values.

*MG.* This is a simplified multigrid calculation. This requires highly structured long-distance communication and tests both short- and long-distance data communication.

The problem definition is as follows. Set  $v = 0$  except at the twenty specified points, where  $v = \pm 1$ . Commence an iterative solution with  $u = 0$ . Each of the four

iterations consists of the following two steps, in which  $k = 8$ :

$$\begin{aligned} r &:= vAu \quad (\text{Evaluate residual}) \\ u &:= u + M^k r. \quad (\text{Apply correction}) \end{aligned}$$

Here  $M^k$  denotes the following V-cycle multigrid operator:  $z_k := M^k r_k$ , where if  $k > 1$  then

$$\begin{aligned} r_{k-1} &:= Pr_k \quad (\text{Restrict residual}) \\ z_{k-1} &:= M^{k-1} r_{k-1} \quad (\text{Recursive solve}) \\ z_k &:= Qz_{k-1} \quad (\text{Prolongate}) \\ r_k &:= r_k Az_k \quad (\text{Evaluate residual}) \\ z_k &:= z_k + Sr_k, \quad (\text{Apply smoother}) \end{aligned}$$

else

$$z_1 := Sr_1. \quad (\text{Apply smoother})$$

The coefficients of the  $P$ ,  $M$ ,  $Q$ , and  $S$  arrays, together with other details, are given in the benchmark document.

The benchmark problem definition requires that a specified number of iterations of the above V-cycle be performed, after which the  $L_2$  norm of the  $r$  array must agree with a reference value to within a specified tolerance.

**CG.** In this problem, a conjugate gradient method is used to compute an approximation to the smallest eigenvalue of a large, sparse, symmetric positive definite matrix. This kernel is typical of unstructured grid computations in that it tests irregular long-distance communication, employing unstructured matrix vector multiplication.

The problem statement in this case is fairly straightforward: Perform a specified number of conjugate gradient iterations in approximating the solution  $z$  to a certain specified large sparse  $n \times n$  linear system of equations  $Az = x$ . In this problem, the matrix  $A$  must be used explicitly. This is because after the original NPB suite was published, it was noted that by saving the random sparse vectors  $x$  used in the specified construction of the problem, it was possible to reformulate the sparse matrix-vector multiply operation in such a way that communication is substantially reduced. Therefore this scheme is specifically disallowed.

The verification test is that the value  $\gamma = \lambda + 1/(x^T z)$  (where  $\lambda$  is a parameter that depends on problem size) must agree with a reference value to a specified tolerance.

**FT.** Here, a 3-D partial differential equation is solved using FFTs. This performs the essence of many “spectral” codes. It is a rigorous test of heavy long-distance communication performance.

The problem is to numerically solve the Poisson partial differential equation (PDE)

$$\frac{\partial u(x,t)}{\partial t} = \alpha \nabla^2 u(x,t),$$

where  $x$  is a position in three-dimensional space. When a Fourier transform is applied to each side, this equation becomes

$$\frac{\partial v(z,t)}{\partial t} = -4\alpha\pi^2|z|^2v(z,t),$$

where  $v(z,t)$  is the Fourier transform of  $u(x,t)$ . This has the solution

$$v(z,t) = e^{-4\alpha\pi^2|z|^2t}v(z,0).$$

The benchmark problem is to solve a discrete version of the original PDE by computing the forward 3-D discrete Fourier transform (DFT) of the original state array  $u(x,0)$ , multiplying the results by certain exponentials, and then performing an inverse 3-D DFT. Of course, the DFTs can be rapidly evaluated by using a 3-D fast Fourier transform (FFT) algorithm.

The verification test for this problem is to match the checksum of a certain subset of the final array with reference values.

**IS.** This kernel performs a large integer sort operation that is important in certain “particle method” codes. It tests both integer computation speed and communication performance.

The specific problem is to generate a large array by a certain scheme and then to sort it. Any efficient parallel sort scheme may be used. The verification test is to certify that the array is in sorted order (full details are given in the benchmark document).

**LU.** This performs a synthetic computational fluid dynamics (CFD) calculation by solving regular-sparse, block ( $5 \times 5$ ) lower and upper triangular systems.

*SP.* This performs a synthetic CFD problem by solving multiple, independent systems of nondiagonally dominant, scalar, pentadiagonal equations.

*BT.* This performs a synthetic CFD problem by solving multiple, independent systems of nondiagonally dominant, block tridiagonal equations with a  $(5 \times 5)$  block size.

These last three “simulated CFD benchmarks” together represent the heart of the computationally intensive building blocks of CFD programs in most common use today for the numerical solution of three-dimensional Euler/Navier-Stokes equations using finite-volume, finite-difference discretization on structured grids. LU and SP involve global data dependencies. Although the three benchmarks are similar in many respects, there is a fundamental difference with regard to the communication-to-computation ratio. BT represents the computations associated with the implicit operator of a newer class of implicit CFD algorithms. This kernel exhibits somewhat more limited parallelism compared with the other two.

In each of these three benchmarks, the same high-level synthetic problem is solved. This synthetic problem differs from a real CFD problem in the following important aspects:

1. Absence of realistic boundary algorithms
2. Higher than normal dissipative effects
3. Lack of upwind differencing effects
4. Absence of geometric stiffness introduced through boundary conforming coordinate transformations and highly stretched meshes
5. Lack of evolution of weak solutions found in real CFD applications during the iterative process
6. Absence of turbulence modeling effects

Full details of these three benchmark problems are given in the benchmark document, as are the verification tests.

## Evolution of the NAS Parallel Benchmarks

The original NPB suite was accompanied by a set of “reference” implementations, including implementations for a single-processor workstation, an Intel Paragon system (using Intel’s message passing library) and a CM-2 from Thinking Machines Corp. Also, the original release defined three problem sizes: Class W (for the sample workstation implementation), Class A

(for what was at the time a moderate-sized parallel computer), and Class B (for what was at the time a large parallel computer). The Class B problems were roughly four times larger than the Class A problems, both in total operation count and in aggregate memory requirement.

After the initial release of the NPB, the NASA team published several sets of performance results, for example, [4, 5], and in the next few years, numerous teams of scientists and computer vendors submitted results.

By 1996, several of the original NPB team had left NASA Ames Research Center, and, for a while, active support and collection of results lagged. Fortunately, some other NASA Ames scientists, notably William Saphir, Rob Van der Wngaart, Alex Woo, and Maurice Yarrow, stepped in to continue support and development. These researchers produced a reference implementation of the NPB with MPI constructs, which, together with a few minor changes, was designated NPB 2.0. Then a Class C problem size was defined as part of NPB 2.2.

Another enhancement was the addition of the “BT I/O” benchmark. In this benchmark, implementers were required to output some key arrays to an external file system as the BT program is running. Thus, by comparing the performance of the BT and BT I/O benchmarks, one could get some measure of I/O system performance. This change, together with the definition of Class D problem sizes, was released in 1997 and designated NPB 2.4.

In 1999, NASA Ames researchers Haoqiang Jin, Michael Frumkin, and Jerry Yan released NPB 3.0, which included an OpenMP reference implementation of the NPB.

In 2002, Rob van der Wngaart and Michael Frumkin released a grid version of the NPB. In the next year or two, several additional minor improvements and bug fixes were made to all reference implementations, and Class E problem sizes were defined. Reference implementations were released in Java 3.0 and High-Performance Fortran, and a “multi-zone” benchmark, reflective of a number of more modern CFD computations, was added. These changes were designated NPB 3.3, which is the latest version on the NASA Web site.

Full details of the current version of NPB, as well as the actual documents and reference implementations, are available at: <http://www.nas.nasa.gov/Resources/Software/npb.html>

## Definition

N-body computation refers to a class of simulation methods that model the behavior of a physical system using a set of discrete entities (e.g., atoms, astrophysical

bodies, etc.) and a set of interactions among them (coupling potentials). These simulations are typically time dependent. In each timestep, attributes of the discrete entities are updated (typically force, acceleration, velocity, and position), and the process is repeated, to study spatiotemporal evolution of the system.

## Discussion

### Introduction

Many interesting physical problems can be modeled as the time-evolution of a set of interacting, classical objects (assumed to be point masses). The behavior of these particles is governed by Newton's second law. A series of seminal efforts by, among other notables, Newton, Euler, Lagrange, Hamilton, Delaunay, and Sundman demonstrated the difficulty of analytically solving the problem for systems comprised of more than two bodies. Simulation techniques solve the equation for many bodies by discretizing time and integrating particle behavior over discrete timesteps. These particles are treated as point masses, interacting through specified potentials. Systems of interest, though small in terms of macroscopic or astronomical scales, normally comprise of a large number of particles (up to  $10^9$  or more). The tools of statistical mechanics have been developed to analyze the macroscopic (average) properties and behavior of such large systems. While powerful in the context of many problems, statistical mechanics is ill-suited to the study of smaller structures, such as nanoparticles and interactions of individual molecules. N-body simulations are able to overcome these limitations, providing powerful simulation methodologies.

N

### Computational Techniques and Algorithmic Considerations

Astrophysical simulations are classical applications of N-body methods. In these simulations, interacting particles are large-scale stellar structures (stars, stellar clusters, galaxies, galaxy clusters, dark matter, etc. [33, 34]) interacting through long-range gravitational forces. Range here refers to the distance dependence of the potential function. At the other end of the spatiotemporal spectrum, one may model atomic-scale systems to understand physical properties of materials or behavior of molecular systems. Individual particles in such

systems correspond to atoms, and coupling potentials span long-range electrostatics and short-range Lennard-Jones potentials. In molecular scale systems, properties are modeled using customized coupling potentials. While the overall structure of computation is similar for these diverse  $N$ -body simulations, there are significant differences in the nature and computational cost of interactions and required time resolution. The computational challenges in astrophysical simulations stem largely from the long-range nature of the gravitational force, whereas atomistic simulations involve a variety of complex interaction potentials. This article discusses  $N$ -body methods primarily in the context of atomistic simulations. Where relevant, it highlights differences with respect to astrophysical simulations and the implications thereof.

In molecular dynamics (MD), the system is modeled as a set of point charges (particles) whose evolution in time is governed by classical mechanics. Potentials are used to simulate electrostatics, harmonic bonds, hard sphere repulsion, and other types of interactions. Simulations may also be performed using a Monte Carlo (MC) approach. As its name suggests, the MC technique relies on a randomized process, appropriately sampling an ensemble to infer statistical quantities.

The physical environment modeled in a simulation further constrains the computational approach. For example, simulations may be performed under different collections of microstates (ensembles). Under the microcanonical ensemble (NVE) particle number ( $N$ ), volume ( $V$ ) and total energy ( $E$ ) are held constant. The isochoric-isothermal canonical ensemble (NVT) maintains constant temperature ( $T$ ) by placing the system in contact with a thermal reservoir. This requires the implementation of a thermostat such as Anderson [36], Nose-Hoover [35], or Berendsen [37]. The isobaric-isothermal canonical ensemble (NPT) adds a piston to the canonical ensemble. The volume of the system is allowed to vary in order to maintain a constant pressure ( $P$ ). Different barostats such as Berendsen [37] and Parrinello-Rahman [38] may be used for this purpose.

In a general  $N$ -body problem, forces and potentials governing the motion of particles can be classified as short- or long-range. Short-range potentials decay faster than the growth of the volume element

in three dimensions (i.e., they approach zero faster than  $1/r^3$ ) [31]. Consequently, they can be appropriately truncated for a desired level of accuracy. Long-range forces, on the other hand, do not decay as rapidly – requiring either expensive computation or algorithmic techniques for reducing the complexity. Note that a simple all-to-all computation of long-range forces would result in an  $O(N^2)$  complexity per timestep. Algorithmic techniques typically rely on hierarchical decompositions to aggregate/approximate the impact of distant particle clusters, thereby reducing overall complexity. Methods such as Barnes–Hut (BH) [3] and Fast Multipole Methods (FMM) [10] rely on these principles to reduce the  $O(N^2)$  complexity to  $O(N \log N)$  and  $O(N)$ , respectively.

## Parallelization Challenges

In parallelizing  $N$ -body simulation, two primary considerations motivate the choice of how the computation should be decomposed into different processes. First the load on each processor should be approximately equal. Second, the system should be decomposed in order to minimize interprocess communication, which is a primary consideration for computational efficiency. A number of decomposition techniques satisfy these constraints to varying degrees.

*Domain Decomposition:* In domain decomposition, the physical system is divided into regions of space. A constituent particle falling within a specified volume is assigned to the corresponding processor. Inter-processor communication is needed for computing forces on boundary particles, as well as to “push” particles at the end of the timestep. Since timesteps are small, the system does not change drastically from one timestep to the next. For this reason, the communication associated with pushing particles at the end of a timestep is typically low. Great care must be exercised to reduce the communication overhead. Load balancing an  $N$ -body simulation with domain decomposition is most easily achieved when the system consists of identical particles and uniform density. In this case, an equipartitioning of the space into processor subdomains ensures load balance. Since systems of interest are rarely so

simple, more sophisticated domain decomposition techniques are required.

One such technique is oct-tree decomposition. In this method, the simulation box is recursively divided until the desired number of particles are contained within each subdomain. The oct-tree is rebuilt when necessary to achieve desired load balance. Implementation and maintenance of the oct-tree decomposition method is much more complicated than equipartitioning of the space.

Another domain decomposition technique that ensures dynamic load balance is the staggered decomposition method used by GROMACS [14]. Here the processor subdomains are aligned in one dimension, but staggered in the other two dimensions. Based on the cpu time taken by each processor at any timestep, processor boundaries slide to obtain an even work-load distribution. Due to sliding boundaries and staggered arrangement of processors, interprocessor communication is complicated.

**Particle Decomposition:** In a particle decomposition, particles are assigned to processors for the duration of the simulation. This method yields good load balancing despite nonuniform density and is best suited to systems with minimal translational motion, for example, simulations of solids. Communication overhead, however, may be high when the neighborhood of atoms is rapidly changing.

**Interaction Decomposition:** Interaction decomposition assigns specific interactions to each processor, resulting in load balance. Communication is minimized since any interacting atoms are handled by the same processor. Despite its desirable characteristics, the implementation of an interaction-based decomposition is often difficult, since it requires prior knowledge of the number and nature of interactions.

**Zonal Decomposition:** A recently developed algorithm [15] greatly reduces communication costs. In this method, spatial decomposition is the primary approach. In addition to local atoms, buffer atoms are communicated so that all interactions are computed locally. Inclusion of buffer atoms is based on interactions rather than spatial location. Note that at present time zonal methods are limited to pair-wise interactions.

## Boundary Conditions

In typical large-scale simulations, one does not simulate the entire domain, but rather a small “cutout” of the domain. A small subdomain assumed to be surrounded by infinitely replicated domains in each direction is simulated. This yields the boundary conditions for the system. The above-mentioned scenario (infinite replicated domains) is referred to as a periodic boundary condition. Periodic boundary conditions lead to problems with long-range potentials, as all (infinitely many) of the periodic images interact with the system. Specifically, electrostatic interactions which decay as  $1/r$ , need to be handled with a method that accounts for infinitely many periodic images. Most commonly, the Ewald method [32] is used for this purpose. Implementation of this method requires the use of a reciprocal lattice. The complexity of this computation stems from underlying Fourier transforms.

Periodic boundaries also lead to difficulty in defining and computing external pressure. For pair-additive potentials, the virial expansion can be used to calculate pressure despite the implementation of periodic boundary conditions. Polarizable force fields and ab initio molecular dynamics must use a more computationally expensive approach [39].

N

## Parallel Implementation of N-body Methods

A number of important domain considerations influence the choice of algorithms, resulting computational complexity, structure, and parallelization strategy of  $N$ -body methods. The main factors that influence parallelization include (i) handling of long-range potentials, (ii) computation of short-range potentials, (iii) implementation of suitable boundary conditions, (iv) time-integration of the interaction, and (v) additional processing associated with particles (analysis routines, checkpointing trajectories, etc.). This section describes in more detail the nature of these computations and their parallelization.

## Interactions in N-Body Simulations

A molecular dynamics simulation begins with an initial geometry for the system. Normally, assuming equipartition of energy, each atom is assigned a random velocity based on the Maxwell–Boltzmann distribution.

The interaction potentials between atoms are then calculated. Forces are computed from the potentials using the equation

$$\vec{F} = -\nabla \phi,$$

where  $\vec{F}$  is the force and  $\phi$  the interaction potential. The resulting coupled differential equations are then integrated in order to determine the velocities and positions of each atom in the next timestep. Nearly 70–90% of processing time in an  $N$ -body simulation is spent in the computation of interaction potentials and forces. Parallelization of these computations is the major challenge in large-scale  $N$ -body simulations.

This subsection will focus on the methods for parallelizing the computation of interatomic interactions. These interactions are broadly classified in two types, viz bonded and nonbonded. Standard classical MD approaches treat bonds as invariants. Hence the parallelization of the computation of bonded terms is relatively straightforward, depending on the decomposition method. Nonbonded interactions, on the other hand, require more careful treatment. These terms are further classified as short range or long range. By their very nature, long-range interactions are more difficult to compute.

### Computation of Bonded Terms

Bonded interactions in molecular dynamics are typically modeled using a harmonic potential. Much as the compression or elongation of a spring changes potential energy, bond stretching and shrinking contributes to the overall energy of the system. These two-body terms, determined by the positions of bonded atoms and their types, must be computed at each timestep. In addition, higher order bonded terms such as three-body (angle) and four-body (torsion and dihedral) terms must be calculated. To compute bond and higher order terms, lists of all two-, three-, and four-body interactions are maintained. Using suitable indices, the position of each atom's bonded neighbors, and thus the corresponding forces can be computed. Since conventional molecular dynamics approaches do not model the process of bond-breaking or formation, these lists are static. For computing these terms, an interaction-based decomposition of the computation is preferred, since the interacting constituents are known and constant.

### Computation of Short-Range Terms

Typical coupling terms between bodies decay with distance. For example, electrostatic coupling potentials decay as  $1/r$ , gravitational interaction decays as  $1/r^2$ , Lennard-Jones potential decays as  $1/r^6$ , etc. Depending on the rate of decay and the required accuracy, it is possible to truncate these coupling terms. For example, Lennard-Jones potentials are often truncated at some multiple of  $\sigma$ , the distance at which the interparticle potential becomes zero. For typical molecular dynamics simulations, this is on the order of 10 Å.

Short-range interactions, due to their dynamic nature, typically require spatial decomposition to reduce computational cost. Computing short-range interactions for a particle requires complete knowledge of all particles within the neighborhood defined by the cutoff distance. If one assumes a constant (or bounded) particle density and a constant cutoff distance, it is easy to see that the number of short-range interactions is constant (or bounded) as well. The challenge is to identify all particles within the cutoff distance from a given particle.

Most interactions modeled are governed by central forces, depending only on the distance separating two bodies. Determining the distances between particles which is the most expensive part of a short-range computation, is achieved by use of neighbor lists. Since a brute force algorithm for neighbor list generation involves an  $O(N^2)$  computation, more efficient methods have been developed. For instance, a grid-based search is often utilized to reduce the complexity to  $O(N)$ . The granularity of the grid has a large effect on the net efficiency of the method. The grid method can further be improved by excluding a large number of computations within the grid based on the geometry. Careful consideration must be given to the design of neighbor lists in order to maximize cache performance. In molecular dynamics, particles typically do not have large displacements. For this reason, neighbor list generation can be delayed with the use of Verlet lists. Communication overhead for neighbor list generation can be further reduced by the use of a buffer zone, known as a skin, around processor boundaries.

While typical molecular dynamics simulations are consistent with a bounded particle density assumption, astrophysical  $N$ -body problems may not satisfy this

assumption. For such simulations, we must generalize the cell structure into an oct-tree decomposition of the domain. With suitably optimized oct-tree structures, we can realize  $O(N)$  complexity for short-range interactions for arbitrarily unstructured particle distributions as well. For a detailed discussion of these results, please see the work of Callahan and Kosaraju [4].

In some atomistic simulations such as ReaxFF [40], bond activity, and hence chemical reactivity, are explicitly modeled through the computation of a distance-dependent *bond order*. In effect, a bond order takes inter-atomic distances and computes the likelihood of bonds between pairs of atoms. This bond order is subsequently corrected to account for valency. In such cases, bond lists must be updated at each timestep and bonded interactions must be treated as short-range interactions.

### Computation of Long-Range Terms

Coupling potentials that are proportional to  $1/r$ , (e.g., electrostatic or gravitational potentials) introduce unacceptable errors when truncated. For this reason, these terms are handled separately. Naively computing long-range potentials on an all-to-all basis results in an  $O(n^2)$  complexity (since each of the  $n$  particles is impacted by every other particle). For large systems, this per-timestep complexity is not tractable. Consequently, a number of approximation techniques have been proposed to reduce complexity while incurring minimal error.

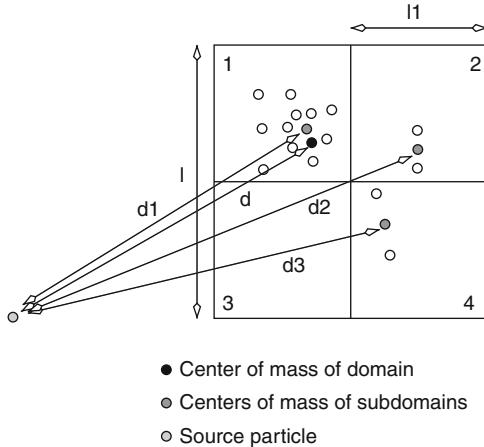

The basis for a family of approximation techniques is as follows: when a group of particles is sufficiently distant from an observation point, their impact can be approximated through a single interaction with the center of mass of the distant particle cluster. Indeed, when we compute the gravitational potential at a point on earth from the moon, we approximate the volume integral (over moons volume) by a point mass at the center of the moon. Since the radius of the moon is much less than its distance from earth, this approximation introduces controllable errors.

Many fast algorithms use this principle to reduce the computational complexity of  $N$ -body methods. These fast algorithms use a hierarchical representation of the domain using a spatial tree data structure. The leaf nodes consist of aggregates of particles. Each node in

the tree contains a series representation of the effect of the particles contained in the subtree rooted at the node. These representations are typically based on Taylor or Legendre polynomials. Interactions between nodes and particles are dictated by a multipole acceptance criteria (MAC). This criteria determines whether the error in a particular interaction is within acceptable bounds or not (can the moon really be treated as a point object with respect to the earth or not?). Different algorithms use different MAC. Selection of an appropriate MAC is critical to controlling the error in simulation. Methods in this class include those due to Appel [2, 5], Barnes and Hut [3], and Greengard and Rokhlin [8, 9, 10].

The Barnes–Hut method is one of the most popular methods due to its simplicity. It works in two phases: the-tree construction phase and the force-computation phase. In the tree-construction phase, a spatial tree representation of the domain is derived. At each step in this phase, if the domain contains more than one particle, it is recursively divided into eight equal parts. This process continues until each oct has a single element in it. The resulting tree is an unstructured oct-tree for arbitrary particle distributions. This tree is now traversed in post-order. Each internal node in the tree computes and stores an approximate representation of the particles contained in that tree. Once the tree has been computed, the force on each particle can be computed as follows: the multipole acceptance criteria is applied to the root of the tree to determine if an interaction can be computed; if not, the node is expanded and the process is repeated for each of the four (or eight) children. The multipole acceptance criteria for the Barnes–Hut method computes the ratio of the dimension of the box to the distance of the point from the center of mass of the box. If this ratio is less than some constant  $\alpha$  (a in Fig. 1), an interaction can be computed. The algorithm is illustrated in Fig. 1.

For a balanced tree, each of the  $n$  particles needs  $O(\log n)$  interactions. This results in a total computational complexity of  $O(n \log n)$ . However, the tree size can be made arbitrarily large by bringing a pair of particles closer. The corresponding tree needs a large number of boxes to resolve the pair into separate boxes. Due to this, the worst-case complexity of this technique is unbounded [1, 4]. However, using box-collapsing techniques (the box is first collapsed to the smallest box

**N-Body Computational Methods. Fig. 1** Illustration of the serial Barnes–Hut method

that contains all the particles in the subdomain), this complexity can be reduced to  $O(n \log n)$  [4]. In addition to box-collapsing, it has been shown that using binary decomposition of the domain (instead of quad or oct-tree decompositions) yields better aspect ratios and reduced operation-count for treecodes.

The fast multipole method (FMM) of Greengard and Rokhlin [10] is another hierarchical technique for computing  $n$ -body interactions. FMM computes the potential due to a cluster of particles at the center of well-separated clusters. This can then be disseminated to individual particle positions to determine required potentials. FMM therefore uses cluster-cluster interactions in addition to particle–cluster interactions. The computational complexity of FMM can be shown to be  $O(n)$  for well-structured particle distributions.

Several parallel formulations of hierarchical methods for long-range electrostatics have been proposed [6, 11, 12]. These methods generally rely on a spatially oriented domain decomposition for constructing hierarchical representations, as well as computing potential at each particle. Hierarchical representations of the domain are constructed in parallel as follows: each processor starts with an initial subdomain assigned (exclusively) to it. Processors construct a hierarchical representation (oct-tree) independently using only the particles assigned to it. In each processors’ oct-tree, it is possible to identify a minimal set of nodes such that all particles in the corresponding domains are exclusively assigned to a single processor. These nodes are referred

```

if ($l/d < a$)
 compute direct force interaction
 with the center of mass of domain,
else
 if ($l_1/d_1 < a$)
 compute direct force computation
 with center of mass of subdomain 1
 else
 expand subdomain 1 further.

```

Apply similar criteria to domains 2, 3, and 4.

to as branch nodes. It can be seen that hierarchical representations at and below the branch nodes are accurate. To construct a consistent image of the top part of the tree, branch nodes are broadcast to all processors. These nodes are inserted into each processor’s tree and the top part of the tree is recomputed by all the processors. This results in a data structure at each processor that is accurate at and above the branch nodes, as well as below local branch nodes.

Each processor can traverse this hierarchical representation to compute electrostatic potential at its assigned particles. The tree traversal phase can proceed in two different ways. As a tree is traversed, a processor may encounter nodes that are not present locally. In this case, the node may either be fetched from the remote processor (*data shipping*), or the particle itself may be shipped to the remote processor that holds the data (*function shipping*). The schemes of Singh et al. [11] and Warren and Salmon [12] are based on the data-shipping paradigm, whereas the scheme presented in [6] is based on a function-shipping paradigm. Function shipping simplifies the problem of addressing arbitrary nodes in a tree, since only branch nodes are remotely addressed. This is implemented using a hash table to access branch nodes. In data-shipping formulations, a processor may request an arbitrary node from a remote processor. Therefore, data-shipping formulations provide fast access to the entire data-set. This is typically accomplished by using the Morton key as a hash function.

In some applications particle distributions may be highly unstructured. In such cases, a naive domain partitioning potentially results in significant load imbalance or high communication overhead. To address this problem, space-filling curves such as the Peano–Hilbert ordering (costzones) and Morton ordering (also known as the Z-curve) are used. Particles are ordered in a list according to the space-filling curve and assigned to processors by partitioning the list so that each processor gets equal load. An estimate of the particles load can be derived by keeping track of the computation associated with the particle in the previous timestep. The motivation for using space-filling curves comes from the spatial proximity and the fact that both of these orderings number all particles in an oct before proceeding to subsequent octs. Furthermore, in data-shipping message passing formulations, space-filling curves allow easy location of arbitrary nodes in a tree without expensive pointer chasing.

The computation of long-range interactions is complicated by the application of periodic boundary conditions. Since these interactions cannot be easily truncated, naive computation of long-range interactions under periodic boundaries lead to an infinite number of terms. The Ewald sum is a method originally developed to calculate the electrostatic interaction in crystals. Systems with periodic boundary conditions mimic the infinite lattice of a crystal structure. Hence, the Ewald method is easily applied to molecular dynamics simulation. The Particle-Mesh Ewald summation decomposes the long-range potential into a short-range term that sums quickly in real space and a long-range term that sums quickly in the Fourier space. The latter term is computed using a Fast Fourier Transform, which contributes primarily to the computational cost of the method.

Parallel techniques for computing Fast Fourier transforms have been well studied in literature [7]. The scalability of these methods is critically impacted by the bisection bandwidth of the parallel platform on which they are implemented. For this reason, this part of the algorithm does not easily scale to large numbers of processors. One way of circumventing this scalability bottleneck is to execute the FFT separately on a subset of processors, while other processors execute other parts of the algorithm. Indeed, as we describe, a number of existing codes use this approach.

Since different interactions are ideally parallelized by different decomposition methods, the nature of interactions within an  $N$ -body computation determines the preferred method. Since spatial decomposition is often preferred in situations containing nonbonded interactions, bonded interactions must often be computed under non-ideal circumstances. The communication of neighboring atoms under spatial decomposition is further complicated by the existence of bonded interactions. Since bonded interactions require atoms several bonds away, these atoms must be communicated regardless of their distance from the processor boundary. Therefore, the generation of a list of skin atoms must also incorporate atoms in a 2-, 3-, and 4-body interaction across the subdomain, in addition to atoms within the cutoff distance.

## Some Major Public-Domain Efforts

### **GROMACS**

GROMACS is a freely available, open source molecular dynamics code in C distributed under the GPL. It was originally developed at the University of Groningen and is currently maintained by research groups in Europe. Parallelization of GROMACS has been significantly improved with the release of GROMACS 4 [14]. It relies on the eighth shell domain decomposition technique introduced by the D. E. Shaw group [15] to reduce communication bandwidth requirements. Processor domains are aligned along the  $x$  dimension, but staggered along  $y$  and  $z$  dimensions to facilitate dynamic load balancing.

N

### **NAMD**

NAMD [13] is a parallel molecular dynamics code designed primarily for the simulation of large biomolecular systems. It is written in C++, based on Charm++ parallel objects. NAMD works with popular biomolecular simulation force fields AMBER and CHARMM. The dynamic load-balancing procedure implemented in NAMD has a slow start, but performs well in the long run by scaling to a large number of processors. Recent benchmarks, however, show that NAMD scales worse than Desmond and GROMACS [14]. NAMD also offers biomolecular utilities in addition to common molecular simulation functionalities.

## Outstanding Challenges

### Long Timestep Approaches

One of the key challenges in scalable  $N$ -body computations is the serialization bottleneck of synchronized timesteps. Velocity Verlet is the most widely used scheme for integrating the Newtonian equations of motion in MD simulations due to its simplicity and symplectic nature. Studies of nonlinear stability indicate that the timestep lengths using Verlet integrators are upper bounded by  $\frac{P}{\sqrt{2\pi}}$  [19, 20], where  $P$  is the periodicity of the fastest oscillation in a given system. Considering the presence of Hydrogen atoms in most simulations, we would have  $P \approx 10$  fs, and so the timestep length  $\delta t$  should be less than 2.2 fs. In fact, timesteps of 2–5 fs are used in most classical MD simulations.

Lagrange multiplier-based constraining algorithms such as SHAKE [21], RATTLE [17], and LINCS [22] constrain the bond lengths and freeze the fastest oscillations in the target system, allowing for longer timesteps. However, these methods are not extensible to the next highest frequency oscillations due to strong vibrational coupling. Even though SHAKE and RATTLE are efficient serial algorithms, their parallel implementations do not currently scale well due to the iterative schemes needed for solving the linear systems involved. LINCS can, however, be made efficient and scalable [14].

Another way to achieve longer timesteps is hierarchical timestepping, also known as multiple timestep methods (MTS). These methods compute slower changing interactions less frequently, using nested loops, reducing average computation per timestep. MTS methods can be parallelized like regular MD methods, since they only change the frequency of computation of certain forces; the way these forces are computed stays the same.

### Accelerated Dynamics

Parallel MD does not scale to long timescales because of the time-serialization. Many interesting phenomena, however, take place at timescales beyond microseconds. Accelerated dynamics methods such as parallel replica dynamics, hyperdynamics, temperature accelerated dynamics, and on the fly kinetic Monte Carlo methods aim to extend the timescale limitations of

molecular simulations by exploiting ideas from Transition State Theory (TST) [23].

In a system with  $N$  atoms, the potential energy surface is a function in  $3N$  dimensions. This potential energy surface can be thought of as a composition of local minima separated by dividing surfaces. In a typical molecular simulation, the trajectory spends most of its time wandering around a basin making only infrequent escapes to neighboring basins (which intuitively corresponds to a significant conformational change or a reaction). Accelerated dynamics methods focus on capturing the jumps from one basin to another accurately while accelerating the trajectory through its path inside a single basin by alternate means.

Parallel replica dynamics [24] is the simplest and most accurate of the accelerated dynamics techniques. As the name suggests, it replicates a system across processors, goes through a short dephasing stage where correlations between these initially identical copies are annihilated, and lets each copy run independently. When an escape is detected at any of the processors, all processors except the one that detects the escape are stopped. The trajectory that made the escape is traced further to detect any correlated escapes. The method itself is inherently parallel. Communication is minimal but parallel efficiency is limited by both the dephasing stage (which does not advance the system clock) and the correlated event stage, during which only one processor computes. The system size to be simulated is bounded by the capabilities of a single node.

Hyperdynamics [25] is inspired by the basic concept of importance sampling. The potential energy surface in a simulation is modified by adding a nonnegative bias potential, which must be zero at/around the dividing surfaces. This way the energy barrier in front of a state transition is lowered giving rise to an enhanced rate of trajectory escapes. While the dynamics inside a basin become meaningless with the addition of a bias potential, the evolution from state to state is correct, because the relative TST rates for escape paths are not altered. The acceleration comes from the boosting of timestep lengths around the minima. In hyperdynamics, time is advanced at each step by the regular timestep length scaled by the inverse Boltzmann factor for the bias potential at that point. The ideal bias factor should be easy to compute and gives large boost

factors. Different bias potentials have been reported in literature: one that is based on the lowest eigenvalue of the Hessian [26], flat bias potential [27], and local bias potential [28]. Boost factors upto 10,000 have been reported using hyperdynamics [23].

A more approximate method is the Temperature Accelerated Dynamics (TAD) [29], which relies on harmonic TST approximation. The idea here is to run the simulation at a high temperature triggering more frequent trajectory escapes from a start basin. The times of escapes from the start basin are projected to their corresponding times at the original simulation temperature by using concepts from TST. Since the order of escapes at high temperature are different from those at the original temperature, once the earliest escape is detected with high probability, the TAD procedure is started again in the new basin. Boost factors achieved by TAD can be on the order of  $10^7$  thus reaching seconds of simulation time for certain systems [29].

The most important problem with accelerated dynamics methods is that they are practical only for small systems (tens to hundreds of atoms). Consequently, the underlying challenges associated with parallelization are not interesting. The most straightforward way of parallelization would be to couple the parallel replica dynamics with other accelerated methods such as hyperdynamics and TAD, that is, to use parallel replica scheme but instead of running regular MD on each processor, use hyperdynamics or TAD. Accelerated dynamics has been used to understand diffusion dynamics in solid state systems and folding of proteins. As these methods are further developed and used, scaling with system size and parallelization issues may emerge as important problems.

## NEC SX Series Vector Computers

HIROSHI TAKAHARA

NEC Corporation, Tokyo, Japan

## Synonyms

- [SIMD \(Single Instruction, Multiple Data\) Machines](#)

## Definition

The SX Series is the parallel vector supercomputer that has been provided by NEC as its flagship high-performance computing system. After the advent of its pioneering models of SX-1/2 back in 1983, NEC has continuously been enhancing this series toward the SX-9, which has the world's fastest single CPU core performance of 102.4 GFLOPS. It makes up 1 node system of 1.6 TFLOPS peak performance, which can be configured up to 512 nodes enabling almost petascale computing with the maximum vector performance of 839 TFLOPS. The technology basis of the SX Series has led to the realization of the Earth Simulator at JAMSTEC (Japan Agency for Marine-Earth Science and Technology) that has earned the number one position on the Linpack benchmark during 2002–2004 for five times in the row, as well as its successor model (renewed Earth Simulator) put into operational use in 2009. The SX Series has been utilized for a spectrum of applications ranging from scientific research and mission-critical weather forecasting to engineering and material design.

## Discussion

### History of the Supercomputer SX Series

In April 1983, NEC made an entry in the supercomputer market with its simultaneous announcement for the

first two models in the series: the SX-1 and the SX-2 – the world's fastest supercomputers at the time. The SX-2 achieved a peak performance of 1.3 GFLOPS (1.3 billion floating-point operations per second), marking the beginning of the era of gigaflop computing.

The successor model, SX-3, announced in April 1990 attained new world speed with its peak performance of 22 GFLOPS using four multiprocessors and maximum 5.5 GFLOPS per CPU. Offering a lineup of commercial application software, the SX-3 not only employed the shared-memory-type multiprocessor combined with the parallel processing technology, but also pioneered the era of open systems featuring a 64-bit SUPER-UX operating system, which was developed based on UNIX.

With an increase in expandability to a maximum of 512 processors, the SX-4 was announced in November 1994, achieving a maximum performance of 1 TFLOPS.

The SX-4 adopted CMOS for the CPU instead of conventional silicon bipolar LSI, which resulted in both reduced power consumption and higher density packaging, consequently leading to a cost reduction by allowing the user to utilize air cooling instead of previously used liquid-cooling systems. The system has enabled expansion in memory capacity by the use of DRAM instead of SRAM as the memory device and the consequent improvement in a price performance ratio combined with a comprehensive list of application software.

In June 1998, the SX-5, the fourth generation in this series, was unveiled. Doubling both the clock frequency and the number of vector pipelines, the evolved model achieved a CPU vector performance of 8 GFLOPS, resulting in the system peak vector performance of 4 TFLOPS with a configuration of parallel processing with 512 CPUs. The release of the fifth generation SX-6 in October 2001 enabled the integration in a single chip of what required 30 LSI chips in the previous CPU model (SX-5).

With 1,024 CPUs each having a maximum CPU performance of 8 GFLOPS, the SX-6 delivered a peak performance of 8 TFLOPS. Equipped with a maximum of 32 CPUs per node and a maximum of 256 GB of shared memory combined with automatic parallelization, the SX-7 introduced in October 2002 realized further ease of operation.

Also during this period, the delivery of the Earth Simulator, for which NEC was in charge of the hardware and basic software development, was completed. The Earth Simulator began operation in March 2002, and its performance not only stunned the world, but also has continued to make significant contributions to understanding challenging environmental issues such as global climate change and advancing a wide spectrum of scientific findings and industrial applications.

Shipping of the sixth generation SX-8 started at the end of 2004, achieving a CPU performance of 16 GFLOPS and a system peak performance of 65 TFLOPS with a maximum of 4,096 CPUs. Subsequently in October 2007, the seventh generation SX-9 was announced. Featuring the world's fastest 102.4 GFLOPS performance per single core, the large-scale shared memory up to 1 TB, and the interconnects with a data transfer rate of 128 GB/s, it can deliver near-PFLOP peak performance of 839 TFLOPS. In addition, the improved LSI technology and high-density packaging technology have reduced both power consumption and required installation space to approximately a quarter of that required for conventional supercomputers.

[Figure 1](#) shows the pictures of the major models of the SX Series. The evolution of the SX Series is summarized with its specifications in [Table 1](#).

## SX-9 Architecture

In subsequent sections, the description of the SX Series is made with the particular focus on the latest model

**NEC SX Series Vector Computers. Fig. 1** Pictures of the SX Series hardware

SX-9. The development of the SX-9 aims at facilitating both high performance for real application programs and economical operation.

The SX-9 has been developed with the following features:

### 1. Fast single-chip vector processor

Using the 65 nm CMOS technology, the SX-9 realizes 102.4 GFLOPS per processor – the world's fastest single core performance.

### 2. Multiprocessor system with excellent scalability

A single SX-9 node has a flat shared memory configuration for a maximum of 16 CPUs with a peak single-node performance of 1.638 TFLOPS and a maximum memory capacity of 1 TB. This shared memory node is interconnected with a special high-speed switch at a maximum of 128 GB/s per node, enabling configurations of up to a maximum of 512 nodes (839 TFLOPS) to provide both shared and distributed memory systems with excellent scalability.

### 3. Superior energy-saving and installation advantages

In addition to the reduced processor energy consumption and heat generation, the system adopts the high-efficiency cooling technology, resulting in improved system power consumption and easy installation.

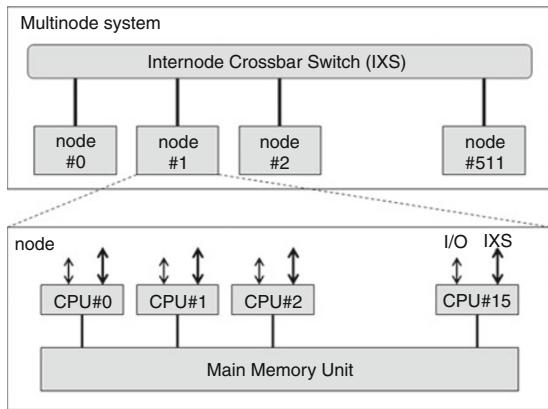

### Hardware Overview

Figure 2 shows the SX-9 system configuration. The product lineup ranges from a shared-memory type single-node model that tightly integrates a maximum of 16 CPUs and the main memory unit (MMU) into a multinode system model connecting each node in a cluster configuration via a high-speed internode cross-bar switch (IXS). The single-node system is available in two models: the model A with a maximum number of CPUs of 16 (1.638 TFLOPS), a maximum main memory capacity of 1 TB, and a maximum 32 input/output slots, and the model B with eight CPUs at a maximum performance of 819.2 GFLOPS, a maximum main memory capacity of 512 GB, and a maximum of 16 input/output slots. The multinode system interconnects 2–512 nodes in a cluster configuration via IXS with up to 8,192 CPUs.

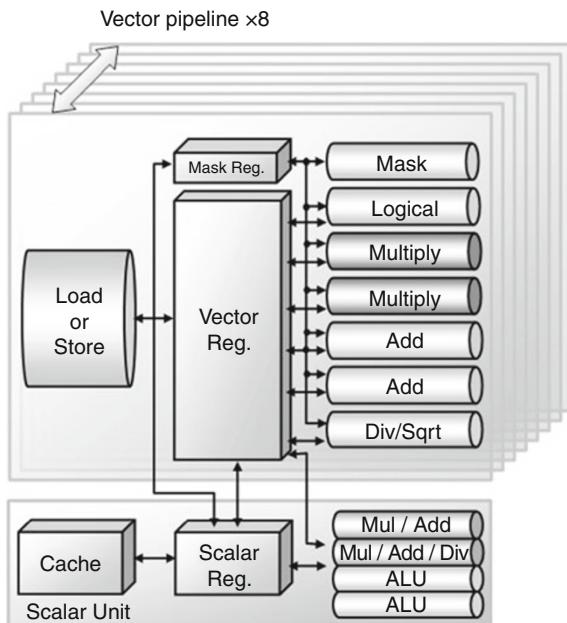

The CPU of the SX-9 uses eight sets of vector pipelines to achieve a peak performance of over 100 GFLOPS with a single unit. The memory with a maximum capacity of 1 TB can be shared by up to 16 CPUs, the maximum data transfer rate between the CPU and the MMU is 4 TB/s, and that between the I/O unit and the MMU is 64 GB/s × 2.

### Processor

The CPU is composed of a vector unit and a scalar unit, both of which are connected to the MMU through the processor-memory network. The SX-9 features the addition of the ADB (Assignable Data Buffer) within a

**NEC SX Series Vector Computers. Fig. 2** SX Series system configuration

**NEC SX Series Vector Computers. Fig. 3** SX-9 CPU configuration

CPU for the selective buffering of data. [Figure 3](#) shows the configuration of the CPU of the SX-9.

### Vector Unit

The vector unit is composed of the vector operation block and the vector control block.

### Vector Operation Block

The vector operation block has basic operations including the Logical, Multiply, Add, and Divide/Sqrt, as well

as the Mask and Load/Store functions. This block also includes 16 mask registers and 72 vector registers. The vector operation block supports the IEEE double and single-precision floating point data formats.

### Vector Operation Pipeline

The vector operation block consists of eight pipelines. To reduce the time to transfer the result of one vector operation to another operation, the vector unit has the enhanced data forwarding capability (chaining), improving the processing speed of programs with a short vector loop length. The vector pipelines have vector data compression and decompression capabilities for the efficient use of memory bandwidth.

### Vector register

The vector operation block has 72 vector registers. Each vector register consists of 256 64 bit-wide registers. The total capacity of the registers reaches 144 KB.

### Vector mask register

Some vector operations can be processed with a 256 bit mask, which can be switched to enable/disable the operation for each element corresponding to the mask bit. Mask bits are generated in the pipeline according to the result of logical operations. There are 16 mask registers prepared, each of which is 256 bit-wide.

### Vector control block

The SX-9 CPU has a vector control block which enables the out-of-order execution of vector instructions, contributing to hiding memory latency. Furthermore, this block controls chaining to perform vector processing with high efficiency.

### Scalar Unit

The scalar unit of the SX-9 employs the 64-bit RISC architecture that is compatible with the SX Series products and incorporates 128 general-purpose 64-bit registers and two 32 KB L1 caches for instructions and data. Its features are as described below.

### 6-way super-scalar configuration

The SX-9 uses a super-scalar configuration with a total of six execution pipelines (two for the floating-point arithmetic operations, two for integer arithmetic

operations, and two for memory operations), thus improving the performance of application codes with a high degree of instructionlevel parallelism.

### Instruction execution control

The out-of-order execution mechanism contributes to the high performance by executing instructions that become executable regardless of the instruction order. For the fast operation over a large domain, the SX-9 enables search and retrieval across up to eight branch instructions. It also adopts a speculative instruction execution mechanism that performs tentative execution of subsequent instructions before the actual execution of a branch instruction and restarts an instruction with the appropriate condition in a case when the branch prediction fails. In order to expand the instruction window in the out-of-order execution mechanism, the SX-9 has the reorder buffer entries enhanced to 64 entries.

### ADB (Assignable Data Buffer)

The ADB is located within a CPU for the selective buffering of data. The ADB enables a more efficient data transfer between the ADB and the vector unit with shorter latency than that between the processor and the memory, resulting in higher performance by storing frequently used data in the ADB and the reduced memory bank contention arising from the concurrent processing. The data stored in the ADB can be set to vector data only, scalar data only, or both vector and scalar data depending on the running application. The ADB for each vector load/store instruction is assigned for retaining the necessary data in the ADB as much as possible. A software-controlled prefetch instruction is supported.

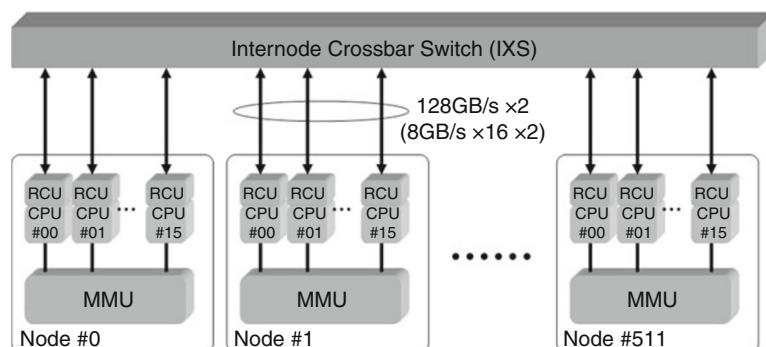

### Multinode Configuration

The multinode system of the SX-9 can connect up to 512 nodes by grouping shared-memorytype single nodes into clusters and connecting them to the IXS ultra-high-speed crossbar switch. The multinode system features not only a wide bandwidth of internode data transfer but also reduced communication latency by capitalizing on the RCU (remote access control unit), which is the IXS connection unit for each node. [Figure 4](#) shows the configuration of the SX-9 multinode system. Each node incorporates up to 16 RCUs, which are connected to the IXS via cables. Each RCU forms a single lane, which has two connection ports of  $4\text{ GB/s} \times 2$ , offering a transfer rate of  $8\text{ GB/s} \times 2$ . As a result, each node can incorporate a maximum of 16 lanes with 32 connection ports, and the total transfer performance reaches a maximum of  $128\text{ GB/s} \times 2$ .

### Main Memory Unit (MMU)

The MMU adopts the shared memory system and is composed of 512 MMU cards for its maximum configuration. The memory of the SX-9 has a large capacity thanks to the use of DDR-SDRAM (Double Data Rate-SDRAM) devices for all the MMUs.

The memory capacity per MMU card is 2GB, and the system supports the capacity from 256 GB up to 1TB. The MMU cards are capable of handling concurrent operations of memory access requests from the CPU with a data transfer rate of 8GB/s per MMU card, or a maximum of 4TB/s for the entire system. The maximum 32,768-way parallel memory interleaving is adopted for the efficient data transfer with DDR3-SDRAM.

NEC SX Series Vector Computers. [Fig. 4](#) SX-9 multinode system configuration

## I/O Processing Unit

All of the processors in the system are allowed to access all of the I/O devices. The SX adopts the direct I/O method, with which the memory in the host bus adapter (HBA) is accessed directly. The I/O interface can be selected according to the types of packaged channel cards, facilitating the system expansion. The I/O processing unit of the SX-9 is composed of the IO Features (IOFs: host bridge units) and the PCI Express control units. Up to 16 IOFs can be mounted per system and two PCI Express control units can be connected to each IOF. As each IOF is virtually represented as a singlechannel device, all of the functions incorporated in the IOFs can be set and modified at the desired timing from the software using the same access method as a general purpose channel card.

## Core Technology Behind the SX-9

Figure 5 summarizes some of the core technologies built into the SX Series for enhanced performance and ease of use. The SX Series has the advanced architecture of large-scale shared memory, high-speed data transfer between the CPU and the memory, and an ultra-high-speed network interconnecting nodes. One of the key

technologies indispensable to achieving higher system efficiency is the interconnection between processors. NEC has developed an optical interconnection technology that achieves a 20 Gbps signal transmission rate between two LSIs of a high-performance computer, thus surpassing the communication speed made available with the existing electrical transmission.

## Software Technology of the SX-9

### Outline of the SUPER-UX Operating System for the SX-9

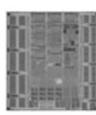

The SUPER-UX is an operating system based on the UNIX System V operating system that features functions inherited from the BSD and SVR4 2MP as well as enhancements of the functions required to support supercomputers. The SUPER-UX features the flexible resource management and the high parallel processing capabilities of kernels and I/Os in order to guarantee high scalability. Four page sizes are supported, which are 32 KB for general commands, 4 MB for compiler and system commands, and 64 and 256 MB for large-scale user programs. This strategy improves the execution performance of programs that use large arrays

and reduces the overheads in the memory management. The SUPER-UX of the SX-9 has expanded the user's virtual space to 8 TB, enabling an efficient layout of parallel programs and MPI programs. The SX Memory File Facility (SX-MFF) is also provided for high-speed I/O by building a conventional file system on the large-capacity memory as a disk cache.

### **Basic OS Functions**

The SUPER-UX supports not only large-scale multiprocessors with efficient resource management but also high-speed input/output and the sophisticated gang scheduling for maximizing parallel processing performance.

### **File Management Functions**

The SUPER-UX makes it possible to create large-scale files and file systems. While retaining the advantages of a standard UNIX system, it realizes a highspeed file system. The high-speed shared file system gStorageFS enables the efficient data transfer comparable to local file systems without involving the CPUs on remote servers. The NFS V3 compatibility is maintained as a user interface.

### **Batch Processing Functions**

The SUPER-UX supports the concepts of jobs (sets of processes) at the kernel level. NQSII is the batch processing system that enables appropriate processing by large-scale clusters, and JobManipulator is provided as an NQSII scheduler extension to maximize system operational efficiency with backfill scheduling. NQSII incorporates functional enhancements of NQS job management, resource management, and load balancing to adapt to cluster systems with the improved single system image (SSI) and system operability.

### **Operation Management Functions**

SUPER-UX supports a checkpoint/restart function for the interruption of a program in progress at a user-specified point and its smooth resumption. The unified operation management software provides the integrated management of multiple host machines on the network from a single machine, as well as automatic operation control, thus resulting in reduced operation cost.

### **Software Development Environment**

The compilers for Fortran, C, and C++ provide highlevel optimization and automatic vectorization/

parallelization features for maximizing the performance. The vector data buffering function, which utilizes the ADB, is open to the user, thus enabling highly effective memory access optimization. Both the MPI library and the HPF compiler are provided for comprehensive distributed memory programming. The PSUITE tool is also available for the GUI-based program development, debugging, and tuning.

### **Compiler and Library**

The SX-9 provides FORTRAN90/SX and C++/SX, respectively, a Fortran compiler and a C/C++ compiler; both feature vectorization and parallelization functions. HPF/SX V2 (a compiler for High Performance Fortran, which is a standard language for distributed parallel processing) is also provided, as well as MPI/SX and MPI2/SX (fully compliant with the distributed parallel processing interfaces MPI-1.3 and MPI-2.1). The system also supports a number of the Fortran 2003 features. Both FORTRAN90/SX and C++/SX support the OpenMP standard API for sharedmemory type parallel processing.

Two proprietary mathematical libraries are provided; one is the ASL scientific library aimed at a wide usage in scientific and engineering applications with enhanced performance on key functions, such as linear algebra and FFT. The other is MathKeisan, which collects a set of public domain mathematical library components, such as BLAS.

### **Application Program and Performance**

The application of the SX Series spans a wide spectrum of areas ranging from fundamental research such as nanomaterial sciences and environmental sciences to industrial designing, drug designing, and emerging life sciences. The SX Series realizes high performance on real application programs, as well as its well-balanced performance from various architectural perspectives. Meantime, the Earth Simulator at JAMSTEC has inherited the parallel vector architecture, realizing the peak performance of 131 TFLOPS with its updated model (160 nodes of SX-9/E). This system is ahead of the pack with respect to the HPC Challenge benchmark (HPCC), which is gaining popularity separately from the Linpack score. The updated Earth Simulator topped the Global FFT (Fast Fourier Transform), one of the measures of the HPC Challenge Awards,

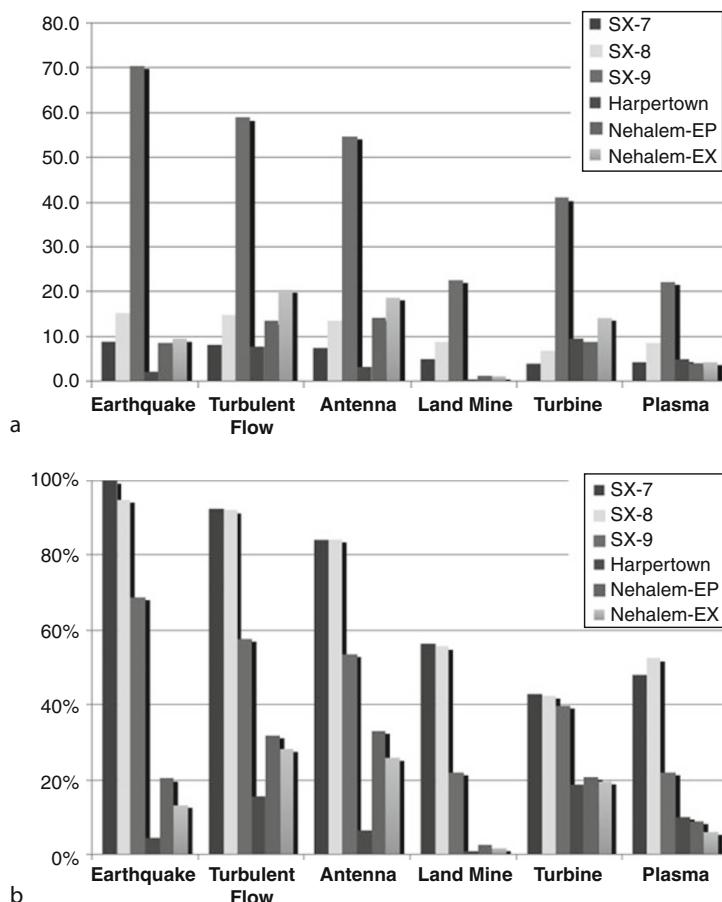

with the performance number of 11.876 TFLOPS. The HPCC is designed to give multiple measures on performance under the US governmental project, including such factors as memory bandwidth and interconnect, as well as processor capability, all of which are suitable to the evaluation of the capabilities of a computer more comprehensively.

The Earth Simulator showcases excellent performance and peak performance ratio on scientific application programs in such an area as earth environmental modeling.

**Figure 6** shows the performance numbers on real scientific applications evaluated for six benchmark programs on various computer platforms, including the SX Series. The target applications are: (1) the computations of inter-plate earthquakes in a subduction zone, (2) the turbulent flow based on the direct

numerical simulation, (3) the electromagnetic analysis about various antennas, (4) the land mine detection with the Synthetic Aperture Radar (Maxwell's equations), (5) the unsteady flows around a turbine based on the direct numerical simulation, and (6) the wave-particle interactions between electrons and plasma waves.

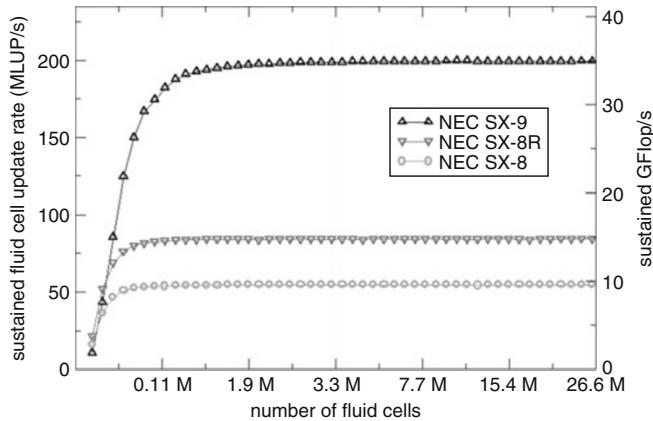

**Figure 6** includes the comparison of single CPU performance of these benchmark programs for various NEC vector supercomputers and Intel multicore processors (Harpertown, Nehalem-EP, and Nehalem-EX) as indicated in **Table 2**. The Nehalem processors are directly connected to the memory system, enabling efficient data transfer. Each application program is set up to utilize all the cores for the Intel processors. As clearly seen in **Fig. 6**, the SX-9 processor shows much higher performance over other processors due to its high

**NEC SX Series Vector Computers. Fig. 6** Comparison of single-core performance for scientific application programs. (a) Measured performance (GFLOPS), (b) Peak performance ratio (%). Each bar represents SX-7, SX-8, SX-9, Harpertown, Nehalem-EP, and Nehalem-EX respectively from left to right

**NEC SX Series Vector Computers. Fig. 7** Single-core performance of Lattice-Boltzmann CFD program. (Left) Cell update ratio (in Million updates per second) (Right) Measured performance (in GFLOPS)

theoretical peak performance for all the six programs. In addition, the execution efficiency (peak performance ratio) is more than 40% for many application programs on the SX Series, which is significantly higher than the commodity scalar processors. The actual performance varies depending on such factors as the memory access frequency, which depends on the ratio of the CPU-memory bandwidth and the floating-point operation capability.

Figure 7 shows the performance of a Lattice Boltzmann (LB) CFD program measured with a single CPU on different models of the SX Series for various numbers of fluid cells. The LB method emerges from a highly simplified gas-kinetic description. It represents the behavior of fluid by the translational movement

and the collision of virtual particles. The left axis indicates the fluid cell update rate (per second), while the right one represents the measured performance (in GFLOPS). Taking into account the maximum theoretical performance of each CPU (SX-9: 102.4 GFLOPS, SX-8R: 32 GFLOPS, SX-8: 16 GFLOPS), the computational efficiency (peak performance ratio) is proven to be high (35–60%) for a wide range of the number of fluid cells, thus surpassing the efficiency on conventional scalar computers [1].

### Concluding Remarks

While the commodity-chip-based parallelism is getting pervasive, complex control mechanisms and massive

hardware resources are necessary for realizing high performance with the current scalar architecture, spurring the widening gap between the theoretical peak performance of a processor and the performance for real scientific application programs [2, 3]. The vector mechanism is a possible solution to such an issue; it employs a highly developed single instruction multiple data stream (SIMD) approach because of a larger number of arithmetic operations handled by one instruction, which is further enhanced with multiple pipelines. It provides an easy way to express the concurrency needed to take advantages of the memory bandwidth with more tolerance about the memory systems' latency than scalar designs, facilitating the realization of high performance needed for scientific computing.

## Bibliographic Notes and Further Reading

The architectural aspects of the SX Series are described in [4–6]. The fundamental descriptions about vector processors (or SIMD approach) and the general trend of the performance of high-performance computers are available, for example, in [2, 3]. There are several papers that focus on the computing performance of the SX Series concerning real scientific application programs (References [1, 7]). As for more comprehensive performance evaluations of the SX-9, for example, reference [8] is suggestive. In relation to such benchmarks,

the descriptions of the referenced scalar computers can be found in [9, 10]. The elaborate descriptions of the HPC Challenge benchmark and its awards are available in [11, 12]. It is also useful to refer to the overview of the Earth Simulator featuring the vector-processing capabilities that inherit from the SX Series for deeper understanding of the NEC vector supercomputers (references [13, 14]).

## NESL

GUY BLELLOCH

Carnegie Mellon University, Pittsburgh, PA, USA

## Definition

NESL is a strongly typed functional programming language designed in the early 1990s to make it easy to program and analyze parallel algorithms. It is loosely based on the ML class of languages and supports parallelism through operations on sequences. Its main features are nested data-parallelism, deterministic parallelism, and a built-in cost model for analyzing the asymptotic performance of algorithms.

## Discussion

### Introduction

NESL is a high-level parallel programming language with an emphasis on concisely and clearly expressing parallel algorithms and the ability to run them on a variety of sequential, parallel, and vector machines [1–4]. It is a strongly typed call-by-value (strict) functional language loosely based on the ML language [5]. The language uses sequences as a primitive parallel data type, and parallelism is achieved exclusively through operations on these sequences. As such it is a data-parallel, or collection-oriented language [6]. The main features of NESL are:

1. The support of *nested parallelism*. NESL fully supports nested sequences, and the ability to apply any user-defined function over the elements of a sequence, even if the function is itself parallel and the elements of the sequence are themselves sequences. Such functionality is important for expressing parallel divide-and-conquer algorithms as well as irregular nested parallel loops. The support for nested parallelism differentiates it from most other data-parallel languages such as C\* [7], High Performance Fortran [8], and ZPL [9]. NESL was the first data-parallel language for which the implementation supported nested parallelism. More recently Data Parallel Haskell [10] also supports nested data parallelism.

2. The support of *deterministic parallelism*. Since NESL has no side effects and hence no race conditions, its semantics is sequential and deterministic [3]. In particular a program with the same input will always return the same output independently of how it is run. Input and output and other nonfunctional features are only allowed at top-level and cannot be called in parallel (there are some well-specified exceptions, such as the random number generator). The philosophy behind NESL is that it is much easier to design, analyze, and prove the correctness of algorithms if the semantics is deterministic. Deterministic parallelism is also supported by other purely functional parallel languages such as ID [11], Sisal [12], and Data Parallel Haskell [10], and has been topic of recent interest [13].
3. The support for a *cost semantics* and corresponding *provable implementation bounds* that maps costs derived by the semantics onto asymptotic runtime on specific machines [3]. The semantics define two costs, *work* and *depth*, for the evaluation of every expression, and simple composition rules for composing these costs across parallel and sequential constructs. The work corresponds to the sequential running time (the total number of instructions executed during the evaluation) and is composed by adding costs across constructs. The depth (sometimes referred to as the critical path or span) corresponds to the longest chain of dependencies and is derived by taking the maximum of costs when composing in parallel and adding costs when composing sequentially. The notions of work and depth have since been used in other languages such as Cilk [14].

NESL has been implemented on a variety of architectures, including both SIMD and MIMD machines, with both shared and distributed memory. The released compiler generates a portable intermediate code called VCODE [15], which runs on vector machines, distributed memory machines, and shared memory machines [2, 16]. The implementation supplies an interactive read-eval-print loop.

### Parallel Operations on Sequences

NESL supports parallelism through operations on sequences, which are specified using square brackets. For example,

```
[2, 1, 9, -3]
```

is a sequence of four integers. In NESL, all elements of a sequence must be of the same type, and all sequences must be of finite length. Parallelism on sequences can be achieved in two ways: the ability to apply any function concurrently over each element of a sequence, and a set of built-in parallel functions that operate on sequences. The application of a function over a sequence is achieved using set-like notation similar to *set-formers* in SETL [17] and *list-comprehensions* in Miranda [18] and Haskell [19]. For example, the expression

```
{negate(a) : a in [3, -4, -9, 5]};
⇒ [-3, 4, 9, -5] : [int]
```

negates each element of the sequence  $[3, -4, -9, 5]$ . This construct can be read as “in parallel for each  $a$  in the sequence  $\{3, -4, -9, 5\}$ , negate  $a$ .” The symbol  $\Rightarrow$  points to the result of the expression, and the expression  $[int]$  specifies the type of the result: a sequence of integers. The semantics of the notation differs from that of SETL, Miranda, or Haskell in that the operation is defined to be applied in parallel. This notation is referred to as the *apply-to-each* construct and each subcall on a sequence element as an *instance*. As with set-comprehensions, the apply-to-each construct also provides the ability to subselect elements of a sequence: the expression

```
{negate(a) : a in [3, -4, -9, 5] | a < 4};
⇒ [-3, 4, 9] : [int]
```

can be read as, “in parallel for each  $a$  in the sequence  $\{3, 4, 9, 1\}$  such that  $a$  is less than 4, negate  $a$ .” The elements that remain maintain their order relative to each other. It is also possible to iterate over multiple sequences. The expression

```
{a + b : a in [3, -4, -9, 5]
 ; b in [1, 2, 3, 4]};
⇒ [4, -2, -6, 9] : [int]
```

adds the two sequences elementwise. In NESL, any function, whether primitive or user defined, can be applied to each element of a sequence. So, for example, one can define a factorial function

```
function factorial(i) =
 if (i == 1) then 1
 else i*factorial(i-1);
```

```
⇒ factorial : int -> int
```

and then apply it over the elements of a sequence

```
{factorial(x) : x in [3, 1, 7]};
⇒ [6, 1, 5040] : [int]
```

In this example, the `function name(arguments) = body;` construct is used to define `factorial`. The function is of type `int -> int`, indicating a function that maps integers to integers. The type is inferred by the compiler.

In addition to the apply-to-each construct, a second way to take advantage of parallelism in NESL is through a set of sequence functions. The sequence functions operate on whole sequences and all have relatively simple parallel implementations. For example, the function `sum` sums the elements of a sequence.

```
sum([2, 1, -3, 11, 5]);
⇒ 16 : int
```

Since addition is associative, this can be implemented on a parallel machine in logarithmic time using a tree. NESL supports many other built-in functions on sequences, including scans, permuting a sequence, appending sequences, extracting subsequences, and inserting into a sequence.

## Nested Parallelism

In NESL, the elements of a sequence can be any valid data item, including sequences. This rule permits the nesting of sequences to an arbitrary depth. A nested sequence can be written as

```
[[2, 1], [7, 3, 0], [4]]
```

This sequence has type: `[[int]]` (a sequence of sequences of integers). Given nested sequences and the rule that any function can be applied in parallel over the elements of a sequence, NESL necessarily supplies the ability to apply a parallel function multiple times in parallel; this is referred to as *nested parallelism*. For example, one can apply the parallel sequence function `sum` over a nested sequence:

```
{sum(v) : v in [[2, 1], [7, 3, 0], [4]]};
⇒ [3, 10, 4] : [int]
```

In this expression there is parallelism both within each sum, since the sequence function has a parallel implementation, and across the three instances of sum, since the apply-to-each construct is defined such that all instances can run in parallel.

NESL supplies a handful of functions for moving between levels of nesting. These include flatten, which takes a nested sequence and flattens it by one level, for example,

```
flatten([[2, 1], [7, 3, 0], [4]]);
⇒ [2, 1, 7, 3, 0, 4] : [int]
```

and collect that takes a flat sequence of pairs and collects elements with an equal first value together into a nested sequence, for example,

```
collect([(3, 7), (0, 1), (3, 9), (1, 11),
 (0, 6), (3, 5)])
⇒ [(0, [1, 6]), (1, [11]), (3, [7, 9, 5])]
 : [[int, [int]]]
```

As an example of nested parallelism, consider a parallel variation of quicksort (see Fig. 1). When applied to a sequence  $s$ , this version splits the values into three subsets (the elements lesser, equal, and greater than the pivot) and calls itself recursively on the lesser and greater subsets. To execute the two recursive calls, the lesser and greater sequences are concatenated into a nested sequence and qsort is applied over the two elements of the nested sequences in parallel. The final line extracts the two results of the recursive calls and appends them together with the equal elements in the correct order.

The recursive invocation of qsort generates a tree of calls that looks something like the tree shown in Fig. 2. In this diagram, taking advantage of parallelism within each block as well as across the blocks is critical

```
function qsort(a) =
 if (#a < 2) then a
 else
 let pivot = a[#a/2];
 lesser = {e in a| e < pivot};
 equal = {e in a| e == pivot};
 greater = {e in a| e > pivot};
 result = {qsort(v): v in [lesser,greater]}
 in result[0] ++ equal ++ result[1];
```

NESL. Fig. 1 An implementation of quicksort

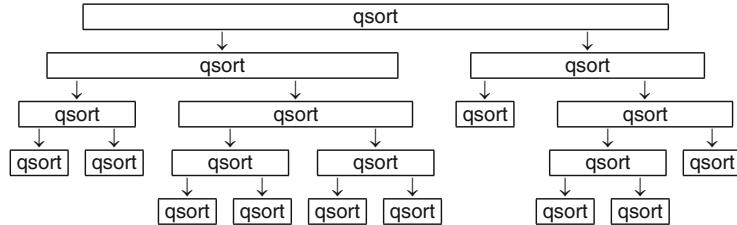

to getting a fast parallel algorithm. If one were to only take advantage of the parallelism within each quicksort to subselect the two sets (the parallelism within each block), the algorithm would do well near the root and badly near the leaves (there are  $n$  leaves which would be processed serially). Conversely, if one were only to take advantage of the parallelism available by running the invocations of quicksort in parallel (the parallelism between blocks but not within a block), the algorithm would do well at the leaves and badly at the root (it would take  $O(n)$  time to process the root). In both cases the parallel “depth” is  $O(n)$  rather than the ideal  $O(\lg n)$  that can be achieved using both forms of parallelism, as described below.

## The Cost Semantics

There are two costs associated with all computations in NESL.

1. **Work:** the total work done by the computation, that is to say, the amount of time that the computation would take if executed on a serial random access machine.
2. **Depth:** this represents the parallel depth of the computation, that is to say, the amount of time the computation would take on a machine with an unbounded number of processors. The depth cost of all the sequence functions supplied by NESL is constant.

The idea of using work and depth for analyzing the asymptotic behavior of parallel algorithms dates back at least to the work on Boolean circuit models, where work (typically referred to as size) is the number of circuit elements, and depth is the longest path in an acyclic circuit [20]. The power of using work and depth was demonstrated by Brent [21] who showed that any circuit of size (work)  $W$  and depth  $D$  can be simulated on a  $P$  processor parallel random access machine [22] (PRAM) in at most  $W/P + D$  steps. One should note that this bound is near optimal since in general the simulation must require at least  $\max\{W/P, D\}$  steps – that is, at least  $D$  steps to follow the chain of dependencies in the circuit, and at least  $W/P$  steps to simulate each of the  $W$  operations. Work and depth costs were also used in the (VRAM) model [23], a strictly flat data-parallel model.

**NESL Fig. 2** The quicksort algorithm. Just using parallelism within each block yields a parallel running time at least as great as the number of blocks ( $O(n)$ ). Just using parallelism from running the blocks in parallel yields a parallel running time at least as great as the largest block ( $O(n)$ ). By using both forms of parallelism, the parallel running time can be reduced to the depth of the tree (expected  $O(\lg n)$  in the Nesl cost model)

NESL introduced the idea of including the costs into the semantics of the language to give a well-defined abstract cost model. The precise definition is given in terms of a profiling operational semantics [3]. The costs are combined using simple combining rules. Expressions are combined in the standard way – for both work and depth, the cost of an expression is the sum of the costs of the arguments plus the cost of the call itself. For example, the cost of the computation:

```
sum(dist(7, n) * #a
```

( $\text{dist}(a, n)$  creates a sequence of  $n$  as) can be calculated as:

|            | Work   | Depth  |
|------------|--------|--------|
| dist       | $n$    | 1      |
| sum        | $n$    | 1      |
| # (length) | 1      | 1      |
| *          | 1      | 1      |
| Total      | $O(n)$ | $O(1)$ |

The apply-to-each construct is combined in the following way. The work is the sum of the work of the instantiations, and the depth is the maximum over the depths of the instantiations. Specifically, let the work required by an expression  $\text{exp}$  applied to some data  $a$  be  $W(\text{exp}(a))$ , and the depth required be

$D(\text{exp}(a))$ , then these combining rules can be written as

$$\begin{aligned} W(\{e1(a) : a \in e2(b)\}) &= W(e2(b)) \\ &\quad + \text{sum}(\{W(e1(a)) : a \in e2(b)\}) \end{aligned} \quad (1)$$

$$\begin{aligned} D(\{e1(a) : a \in e2(b)\}) &= D(e2(b)) \\ &\quad + \text{max\_val}(\{D(e1(a)) : a \in e2(b)\}) \end{aligned} \quad (2)$$

where  $\text{sum}$  and  $\text{max\_val}$  just take the sum and maximum of a sequence, respectively.

As an example, the cost of the computation:

```
{[0:i] : i in [0:n]}
```

( $[0:n]$  creates the sequence  $[0, 1, \dots, n-1]$ ) can be calculated as:

|                       | Work                   | Depth                  |
|-----------------------|------------------------|------------------------|
| $[0:n]$               | $n$                    | 1                      |
| <b>Parallel Calls</b> |                        |                        |
| $[0:i]$               | $\sum_{i=0}^{j < n} i$ | $\max_{i=0}^{j < n} 1$ |
| Total                 | $O(n^2)$               | $O(1)$                 |

Once the work ( $W$ ) and depth ( $D$ ) costs have been calculated in this way, the formula

$$T = O(W/P + D \lg P) \quad (3)$$

places an upper bound on the asymptotic running time of an algorithm on the CRCW PRAM model ( $P$  is the number of processors) [3]. The  $\lg P$  term shows up because of the cost of allocating tasks to processors, and the cost of implementing the  $\text{sum}$  and  $\text{scan}$  operations. On the scan-PRAM [24], where it is assumed that the scan operations are no more expensive than

references to the shared memory (they both require  $O(\lg P)$  on a machine with bounded degree circuits), the equation is:

$$T = O(W/P + D) \quad (4)$$

As an example of how the work and depth costs can be used, consider the `qsort` algorithm described in Fig. 1. To calculate the work one can just use the runtime from the standard sequential analysis (e.g., [25]). Assuming a random selected pivot, this gives  $O(n \log n)$  work with high probability. To calculate the depth one needs to analyze the depth of the recursion tree, but it is not hard to show that with high probability the tree has depth  $O(\log n)$ . All the sequence operations that are used (subselection and appending) are defined to have constant depth. The overall depth is therefore  $O(\log n)$ . This gives a running time on a PRAM of:

$$\begin{aligned} T(n) &= O\left(\frac{n \lg n}{p} + \lg^2 n\right) \quad \text{PRAM} \\ &= O\left(\frac{n \lg n}{p} + \lg n\right) \quad \text{scan-PRAM} \end{aligned}$$

To analyze quicksort by trying to map it onto a  $P$  processor PRAM or other  $P$  processor parallel model is quite complicated. The overall goal of NESL is therefore not only to simplify expressing an algorithm such as quicksort, but also to be able to reasonably easily analyze the asymptotic performance of the algorithm based directly on the code.

## Implementation

The released compiler for NESL translates the language to VCODE [15], a portable intermediate language. The compiler uses a technique called *flattening nested parallelism* [26] to translate NESL into the simpler flat data-parallel model supplied by VCODE. VCODE is a small stack-based language with about 100 functions all of which operate on sequences of atomic values (scalars are implemented as sequences of length 1). A VCODE interpreter was implemented for running VCODE on vector machines such as the Cray C90 and J90, on distributed memory machines based on an MPI back end, and on any serial machine with a C compiler [2]. The interactive NESL environment runs within Common Lisp and can be used to run VCODE on remote machines. This allows the user to run the environment, including the compiler, on a local workstation while executing interactive calls to NESL programs on the remote parallel machines.

Another approach to implementing NESL is to use various scheduling techniques such as work stealing [27] or parallel depth first scheduling [28].

## Bibliographic Notes and Further Reading

The original version of NESL was released in 2002 [29]. It was influenced by SETL [17], CM-Lisp [30], ID [11], and Miranda [18] among other languages. An extensive set of documentation and examples is available online (Web search, NESL). A reasonable set of examples of using NESL for algorithm design and analysis is given in a paper on programming parallel algorithms [4]. The technique of using flattening nested parallelism used in the released implementation is given in [26], and further formalized in [31]. A description of the NESL implementation and experimental results are summarized in [2]. The cost model is described informally in the manual [1] and more formally in a paper on the semantics and provable implementation [3]. Other languages that are similar to NESL in some ways include Cilk [14] (supports nested parallelism and costs based on work and depth – although they refer to them as  $T_0$  and  $T_\infty$ ) and Data-Parallel Haskell [10] (supports nested parallelism in a functional language).

## NetCDF I/O Library, Parallel

ROBERT LATHAM

Argonne National Laboratory, Argonne, IL, USA

### Synonyms

[High-level I/O library](#); [Pnetcdf](#)

### Definition

The serial netCDF library has long provided scientists with a portable, self-describing file format and a straightforward programming interface based on multidimensional arrays of typed variables (more detail in the History section). Parallel-NetCDF provides an API for parallel access to traditionally formatted netCDF files. Parallel-NetCDF both produces and consumes

files compatible with serial netCDF, while providing a programming interface similar, though not identical, to netCDF. Parallel-netCDF API modifications provide a more appropriate interface when expressing parallel I/O.

## Discussion

Parallel-NetCDF is one of a family of libraries built to meet the needs of computational scientists, as opposed to lower-level I/O libraries that deal more with the details of underlying storage. Before going into more detail about Parallel-NetCDF, let us see how it fits in the bigger picture of scientific computing and application I/O.

### Parallel-NetCDF and the I/O Software Stack

Today's leading computing platforms contain hundreds of thousands of processors. In order to efficiently utilize these computers, applications use simplifying abstractions provided by tools and libraries. MPI libraries provide a standard programming interface for parallel computation on a wide array of hardware. Math libraries such as BLAS hide the details of CPU-specific optimizations. These lower-level math and communication libraries contribute to an overall software stack built to allow developers to focus on the science behind their applications.

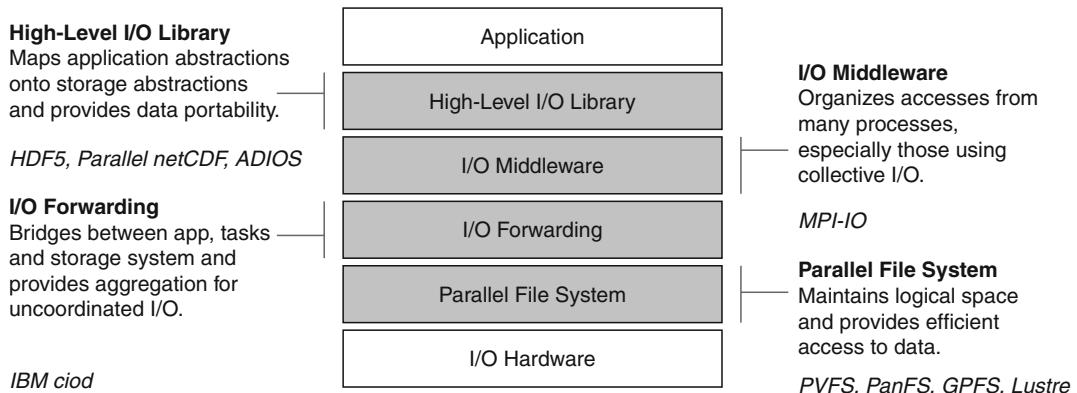

I/O performance on high-end computing platforms follows a similar story. Performance comes from aggregating many storage devices. In fact, CPU performance has consistently improved at a rate much faster than that of storage devices. This discrepancy makes the need for parallel I/O across multiple devices even more acute. Yet as the number of devices involved in I/O grows, coordinating I/O across those devices becomes more of a challenge. In the same way that communication and math libraries assist the parallel computation side of scientific simulations, an "I/O software stack" assists data management.

The large number of storage devices mentioned above forms the foundation of the software stack. Several additional layers provide abstractions to help make the task of extracting maximum performance accessible to applications programmers. The programming API and data model that Parallel-NetCDF presents to the scientific programmer are conceptually closer to the tasks common to scientific applications

and hide many lower-level details. A discussion of the lower levels of the software stack, though hidden by Parallel-NetCDF, will provide a better appreciation of Parallel-NetCDF's role at the upper level.

- Storage systems contain thousands of individual devices to increase the potential bandwidth. The *parallel file system* manages those separate devices and collects them into a single logical unit. The file system does lack some important features: typically file systems have no mechanism for coordinated I/O, and the data model is still fairly low level for computational scientists to use directly.
- The *I/O forwarding* layer typically exists only on the largest computer systems. Applications do not interact with this layer directly. Rather, this layer simplifies the scalability challenge: a large number of compute nodes communicate with a smaller number of I/O forwarding nodes, and these nodes in turn talk to the file system.
- The *middleware*, or *MPI-IO* [6], layer introduces more sophisticated algorithms tailored to parallel computing. This layer coordinates I/O among a group of processes, introducing collective I/O to the stack. MPI datatypes allow applications to describe arbitrary I/O access patterns. Applications can use the MPI-IO layer directly, but the programming model is still rather low level and not a perfect fit to the needs of common applications. MPI-IO libraries, however, provide an excellent foundation for higher-level libraries such as Parallel-NetCDF.

Parallel-NetCDF sits atop these lower-level abstractions; it belongs to the *high-level I/O library* layer. Libraries in this layer introduce concepts such as multidimensional arrays of typed data, which are better suited to scientific applications. For example, a climate code can represent temperature in the atmosphere with a three-dimensional array – latitude, longitude, and altitude – containing the number of degrees Celsius. In addition to array storage, applications can also provide descriptive information in the form of attributes on variables, dimensions, or the dataset itself. These libraries also define the layout of data on disk. These annotated, self-describing file formats make exchanging data with colleagues now and in the future much easier.

**NetCDF I/O Library, Parallel.** Fig. 1 The I/O software stack. Parallel-NetCDF sits at the top, allowing applications to express data manipulations more abstractly while lower levels deal with coordination among multiple processes and maximize performance of storage devices

## History

The netCDF library has long provided a straightforward programming API and file format for serial applications. In the summer of 2002, Argonne National Laboratory and Northwestern University started a joint effort to build a parallel I/O library while keeping the best parts of netCDF.

Parallel programs had been using netCDF for some time, though the serial library forced programmers to use serial approaches when writing out netCDF datasets. In one approach, each process writes out its own data set. This “N-to-N” model can put significant strains on both the file system and any postprocessing tools, especially since large systems today can have hundreds of thousands of processes. Another approach sends all data to a master I/O process, and that process in turn writes out the dataset. This “send-to-master” technique imposes an obvious bottleneck because all data must be funneled through a single process.

Without changing the existing netCDF file format, Parallel-NetCDF introduced a new programming API. This parallel-oriented API is not identical to serial netCDF, but is comfortable to anyone familiar with the existing serial netCDF API. The Parallel-NetCDF API allows computational scientists to write out datasets in parallel: all processes can participate in an “N-to-1” operation, producing a single dataset while leveraging a host of parallel I/O optimizations. The Parallel-NetCDF API and File Format section contains examples and more discussion of the Parallel-NetCDF API.

Parallel-NetCDF has become an important tool for high-performance I/O in the climate and weather domains. These domains have long-established netCDF-based workflows, using netCDF datasets for archiving, analysis, and data exchange. Since Parallel-NetCDF retains the same file format as netCDF, researchers in climate and weather can make changes to their simulation codes while leaving other components of their workflow the same. Parallel-NetCDF is useful in other domains as well: the programming API and file format make it possible to deliver good parallel I/O performance without having to master all of MPI-IO.

N

## The Parallel-NetCDF API and File Format

Discussions about Parallel-NetCDF need to cover two main points: the programming model and the on-disk data format. The API simplifies many MPI-IO concepts while retaining several key optimizations. The on-disk format affects I/O performance, but it also matters when exchanging data with collaborations and colleagues.

If applications were to use MPI-IO directly, the “basic type” they would build on would be a linear stream of bytes. In contrast, Parallel-NetCDF offers a more application-friendly model based on multidimensional arrays of typed data. Operations on these arrays could be as simple as reading the entire array, or more complicated such as having each process write a subcube representing a chunk of the Earth’s atmosphere. In addition to operations for manipulating data, the API contains routines to annotate the data in the file or the

file itself. Such annotations may include timestamps, machine information, experiment or workflow information, or other provenance information to better understand how an application produced the data in this file. The Standard Interface section goes into more detail about the programming interface as well as how Parallel-NetCDF interacts with the underlying MPI-IO library.

In addition to the programming interface, the file format plays a major role in how useful Parallel-NetCDF can be to application groups. Parallel-NetCDF applications create a self-describing, portable file with support for embedded metadata. API routines allow programs to query the contents of data files without any prior knowledge of the contents. The structure of the datasets extends to the representation of bytes on disk: even if a dataset is moved to a different machine, the library will still be able to understand that file. The IBM Blue Gene/P system, for example, has a 32-bit, big-endian architecture, while the Cray XT5 has a 64-bit little-endian architecture. Despite these differences, files created on one can be read on the other.

[Figure 2](#) depicts a simple Parallel-NetCDF application. A climate code wants to create a checkpoint file to store some key pieces of information. Atmospheric temperature is stored as a three-dimensional array of double-precision floating point values. Barometric pressure at the Earth's surface requires only two

dimensions and only single-precision floating points. Further, the application wants to ensure that future consumers of this dataset know which units these variables use. It therefore stores this information as an attribute on each variable. On disk, the dataset contains a small header describing the size and type of both variables and any attributes, followed by the actual data for the variables. This fairly simple file format comes with some restrictions, but the trade-off results in efficient file accesses for parallel I/O.

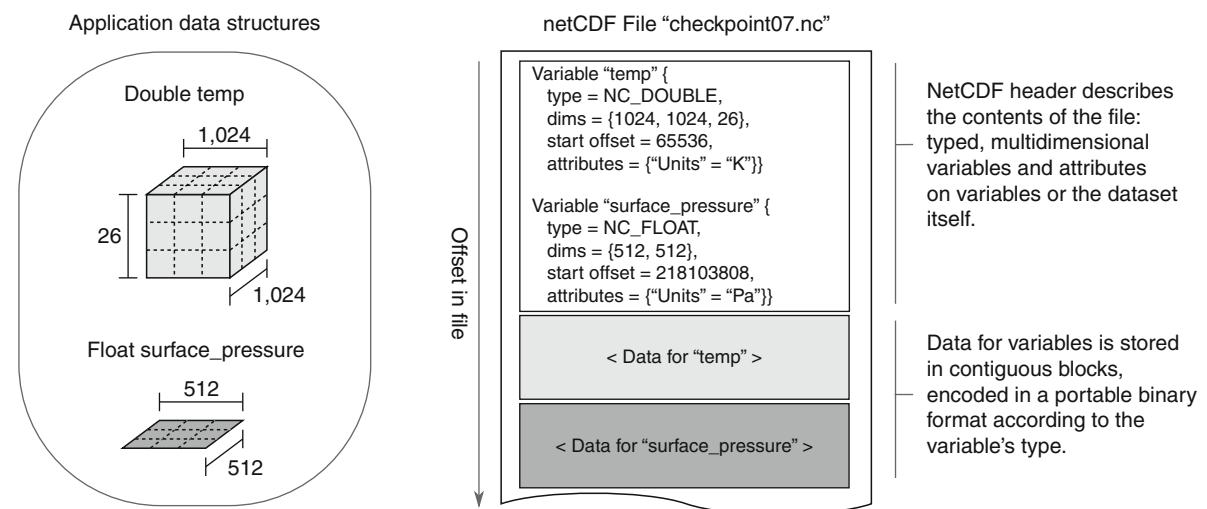

Parallel-NetCDF uses the same file format as netCDF, making it easier for application groups to adopt Parallel-NetCDF. A programmer can change the computationally intensive simulation code to use Parallel-NetCDF while the other components of the workflow (e.g., visualization, analysis, archiving) can continue to use serial netCDF.

### Annotated Examples

Parallel-NetCDF shares many netCDF concepts but uses a slightly different API. The following simple example programs should make the differences clear.

### Standard Interface

[Figure 3](#) contains a full, correct Parallel-NetCDF program to create a simple dataset and write data into that dataset in parallel. This program, though brief, demonstrates many key features of the library.

**NetCDF I/O Library, Parallel. Fig. 2** Left: how an application views netCDF objects. Right: how netCDF and Parallel-NetCDF store those objects on disk

```

1 #include <mpi.h>
2 #include <pnetcdf.h>
3
4 int main(int argc, char **argv) {
5 int ncid, nprocs, rank, dimid, varid1, varid2, ndims=1;
6 MPI_Offset start, count=1;
7 char buf[13] = "Hello World/n";
8
9 MPI_Init(&argc, &argv);
10 ncmpi_create(MPI_COMM_WORLD, "demo.nc",
11 NC_WRITE|NC_64BIT_OFFSET, MPI_INFO_NULL, &ncid);
12
13 MPI_Comm_rank(MPI_COMM_WORLD, &rank);
14 MPI_Comm_size(MPI_COMM_WORLD, &nprocs);
15
16 ncmpi_def_dim(ncid, "d1", nprocs, &dimid);
17 ncmpi_def_var(ncid, "v1", NC_INT, ndims, &dimid, &varid1);
18 ncmpi_def_var(ncid, "v2", NC_INT, ndims, &dimid, &varid2);
19 ncmpi_put_att_text(ncid, NC_GLOBAL, "string", 13, buf);
20
21 ncmpi_enddef(ncid);
22
23 start = rank;
24 ncmpi_put_vara_int_all(ncid, varid1, &start, &count, &rank);
25 ncmpi_put_vara_int_all(ncid, varid2, &start, &count, &rank);
26
27 ncmpi_close(ncid);
28 MPI_Finalize();
29 return 0;
30 }

```

**NetCDF I/O Library, Parallel.** Fig. 3 Basic Parallel-NetCDF program using the standard interface. Each process collectively writes its MPI rank into two variables. For brevity, error checking/handling has been omitted

Because Parallel-NetCDF relies on MPI-IO, the program must include the mpi.h header file (line 1) and initialize (line 9) and finalize (line 28) the MPI library.

The ncmpi\_create routine (line 10) adds two arguments to netCDF's creation function: an MPI communicator and an MPI Info object. These two arguments do expose a bit of the underlying MPI library, but they give the programmer some flexibility and the ability to tune operations if needed. In this example, the communicator is just MPI\_COMM\_WORLD, or all processes in this MPI program. In some situations, though, the application may wish to have only a subset of processes participate in a dataset operation. The Info object in this example is empty, but the Tuning Parallel-NetCDF section will cover some situations where the object is used.

Parallel-NetCDF, like netCDF, has a *bimodal* interface: when creating a dataset, an application starts in *define mode*, where it must first describe what variables it will write, the size and type of those variables, and any attributes. This example defines a single dimension (line 16) and assigns that dimension to two variables (lines 17 and 18).

Datasets can contain a great deal of metadata. Both variables and dimensions have human-readable labels. In addition to those labels, attributes may be defined and placed on dimensions, variables, or the dataset itself. Line 19 places an attribute on the entire dataset.

In the example, line 21 calls ncmpi\_enddef to switch from define mode to *data mode*. By asking the programmer to predefine variables and attributes, the library can allocate space with little overhead. Reentering define mode can potentially trigger an expensive rewriting of the dataset. For a large class of problems, however, one knows ahead of time which information will be written out.

Lines 24-25 do the actual work of storing information into the dataset. Parallel-NetCDF provides one set of functions for uncoordinated *independent I/O* and another parallel set for coordinated *collective I/O*. This example uses the collective version (as shown by the \_all suffix). Every MPI process participates in these writes, each writing out its MPI rank. In a traditional serial netCDF program, each rank would send data to a master process, and this process would in turn write out the information. This “send-to-master” model

quickly becomes untenable, however, as the number of MPI processes increases and as the amount of memory available to each MPI process gets smaller.

The collective Parallel-NetCDF routines in turn call collective MPI-IO routines. MPI-IO collective routines can use powerful optimizations such as two-phase I/O [4] or data shipping [3]. It is possible to use independent I/O with Parallel-NetCDF, but the opportunities for optimization are greatly limited in that case.

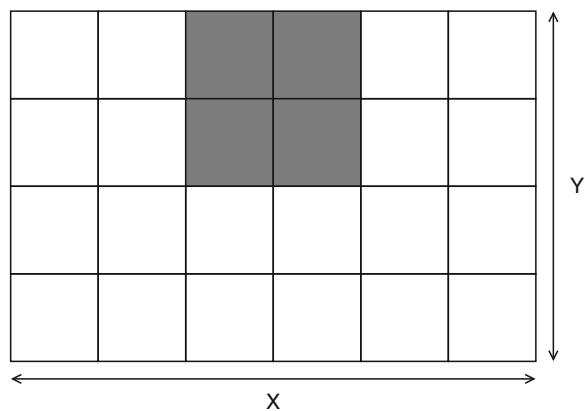

Once executed, this example will produce a file “demo.nc.” This dataset will contain two variables, as can be verified with either netCDF or Parallel-NetCDF utilities.

The Parallel-NetCDF standard interface shares much in common with the serial netCDF interface. The function name explicitly states whether the

operation is a read or write (`_put` or `_get`), the type of access (e.g., `_var`, `_vara`), and the type (e.g., `_int`, `_float`, `_double`). For example, from the name alone a programmer knows that the function `ncmpi_put_vara_int` writes integers into a subarray.

#### A more realistic example

This simple example, operating on a one-dimensional array, may not give the most insight into all the work going on behind the scenes. Figure 4 depicts a two-dimensional array of which this example program wants to only write a smaller subarray. Perhaps this array represents one frame of a movie and a parallel program renders portions of each frame.

**NetCDF I/O Library, Parallel. Fig. 4** Writing a subarray of a two-dimensional array

```

1 ...
2 #define NDIMS 2
3 int dims[NDIMS], varid1, ndims=NDIMS;
4 MPI_Offset start[NDIMS], count[NDIMS];
5
6 ncmpi_def_dim(ncfile, "y", 4, &(dims[0]));
7 ncmpi_def_dim(ncfile, "x", 6, &(dims[1]));
8
9 ncmpi_def_var(ncfile, "frame", NC_DOUBLE, ndims, dims, &varid1);
10
11 ncmpi_enddef(ncfile);
12
13 start[0] = 0; start[1] = 4;
14 count[0] = 2; count[1] = 2;
15 ncmpi_put_vara_double_all(ncfile, varid1, start, count, data);
16 ...

```

**NetCDF I/O Library, Parallel. Fig. 5** Writing the selected portion of the above array

Figure 5 contains the Parallel-NetCDF code needed to write the indicated region. First, the program must

describe the entire variable: lines 6, 7, and 9 describe the overall shape of the variable and the type of data it will contain. Lines 13 and 14 set up the shape of the desired selection or subregion of the variable and pass these arguments as parameters to the call at line 15.

These few lines of Parallel-NetCDF code trigger a lot of activity behind the scenes. Even though the desired region is logically contiguous, when the array is stored on disk, this selection will end up scattered across the file in a noncontiguous access pattern. Fortunately for Parallel-NetCDF, MPI-IO makes it easy to describe these accesses with a file view.

Storage systems yield the best performance with a few large, contiguous accesses. The MPI-IO library will

apply several optimizations to transform a noncontiguous access into one more likely to give good bandwidth. The Parallel-NetCDF call in this example is collective, which means that the lower MPI-IO layer can in turn use collective I/O optimizations: the MPI-IO library can communicate with the other processes participating in this I/O call and rearrange the requests. To the file system, this subarray access will end up looking like a more performance-friendly contiguous request.

While this discussion glosses over many of the details, the important point is that a few Parallel-NetCDF functions convey a great deal of information to the lower levels of the I/O stack. Applications using Parallel-NetCDF thus get the benefits of a self-describing portable file format and a relatively straightforward API while still achieving performance without requiring the application programmers to master MPI-IO.

### The Flexible Interface

Parallel-NetCDF provides an additional set of routines to allow for even more freedom in describing an application's data model. In Fig. 6, a write operation from Fig. 3 is converted to the Flexible Data Mode interface. This interface allows an application to use MPI datatypes to describe how information is laid out in memory.

The datatype in this example is simple (MPI\_INT), but a more complicated MPI datatype might, for example, write out all the data in a multidimensional array while skipping over the "ghost cells." Ghost cells, copies of data belonging to other MPI processes, are used to optimize communication in nearest-neighbor simulations and do not actually need to be written to disk. In many cases, the Flexible Data Mode interface permits

an application to avoid an additional buffer copy before making a Parallel-NetCDF call.

### Nonblocking Interface

Parallel-NetCDF further extends the traditional netCDF API through the introduction of nonblocking I/O routines. Programmers familiar with MPI nonblocking communication routines will note strong similarities between MPI nonblocking routines and those in Parallel-NetCDF. A program posts one or more operations and then waits for completion of those operations.

In Fig. 7, the example from Fig. 3 has been modified yet again, this time to use Parallel-NetCDF nonblocking operations. Throughout the I/O software stack, more information about I/O activity results in more opportunities for optimization. In this example, even though the calls operate on separate variables, those variables are still in the same dataset and appear to the MPI-IO layer as parts of a single file. Parallel-NetCDF can take these nonblocking requests and optimize them into a single, larger I/O operation [1].

Parallel-NetCDF can optimize these nonblocking requests in this way because the library makes no guarantees about when work will occur (sometimes called "make progress" in the MPI context). It may appear to the program that I/O work happens in the background when calling these nonblocking routines. Actually, when the operation is posted (lines 4 and 6), no work happens. Instead, the library defers all work until the application makes an additional "wait for completion" function call (line 9). Once Parallel-NetCDF has a list of all the outstanding operations, it can then construct a single I/O request encompassing all operations. Typically, storage systems perform better with larger

```

1 /* function prototype */
2 int ncmpi_put_vara_all(int ncid, int varid,
3 /* start and count describe access in file */
4 const MPI_Offset start[], const MPI_Offset count[],
5 /* 'buf' 'bufcount' and 'datatype'
6 /* describe data in memory */
7 const void *buf, MPI_Offset bufcount, MPI_Datatype datatype);
8
9 ...
10 start = rank;
11 ncmpi_put_vara_all(ncfile, varid1, &start, &count,
12 &rank, count, MPI_INT);
13 ...

```

NetCDF I/O Library, Parallel. Fig. 6 Prototype for and usage of one of the Flexible Data Mode routines

```

1 int requests[2], statuses[2], data[2];
2 ...
3 data[0] = rank + 1000;
4 data[1] = rank + 10000;
5 ncmpi_iwrite_vara_int(ncfile, varid1, &start, &count,
6 &(data[0]), &(requests[0]));
7 ncmpi_iwrite_vara_int(ncfile, varid2, &start, &count,
8 &(data[1]), &(requests[1]));
9 ncmpi_wait_all(ncfile, 2, requests, statuses);

```

**NetCDF I/O Library, Parallel. Fig. 7** The “implicit” nonblocking interface: no progress occurs in the background, but operations can be batched together when completed

I/O requests, so coalescing operations in this way can yield good performance improvements.

## Tuning Parallel-NetCDF

Extracting good performance out of Parallel-NetCDF comes down largely on following a handful of best practices: perform collective I/O to a small number of files. Doing so provides the most information to the lower I/O software stack layers, and allows for those layers to make as many optimizations as possible. For even more fine-tuning, the library does provide some additional tuning mechanisms for applications. For the most part, these tuning knobs help tweak parameters for layers farther down the software stack. The MPI Info parameter passed to the create and open calls can direct the optimizations the underlying MPI-IO library chooses to make. For example, on Lustre file systems file locks are exceedingly expensive. By setting the MPI Info hint `romio_ds_write` to “`disable`”, the ROMIO implementation of the MPI-IO library, the most common implementation on systems with Lustre installed, will avoid using locks. Knowing more about the characteristics of the storage system and the application workload will make the selection of appropriate hints easier and more productive. The available MPI-IO tuning parameters vary based on the MPI-IO implementation and file system used. Users should consult their MPI-IO library’s documentation.

Often, the most effective way for a computational scientist to improve the I/O performance of a program is to enlist the aid of the Parallel-NetCDF community (see the Bibliographic Notes and Further Reading section). If the scientist can remove the simulation and science aspects of the program, leaving only the representative data structures, the resulting “I/O kernel” becomes a

valuable resource for exploring all tuning options available. I/O kernels leave no doubt as to what the scientist requires from the Parallel-NetCDF library and storage system. Because these small programs have few if any dependencies on additional libraries, they can become part of the library’s correctness and performance tests, ensuring that modifications and improvements made to Parallel-NetCDF also benefit applications.

A discussion about tuning Parallel-NetCDF would not be complete without a few words concerning record variables. In Parallel-NetCDF and netCDF, variables can have an unlimited dimension. Often, variables that change over time use this feature: each iteration of the simulation can append data along the unlimited “time” dimension. When more than one variable contains an unlimited dimension, those variables are stored on disk in an interleaved fashion. The writing and reading of data interleaved in this way will often yield poor performance. Programmers must weigh the flexibility of record variable storage against the cost of performance. With an I/O kernel, Parallel-NetCDF experts can likely find a set of tuning parameters to mitigate some of the performance loss, and the project will be looking at more sophisticated ways of dealing with record variables in the future.

## Conclusion

The Parallel-NetCDF library provides a more natural programming interface for high-performance storage systems. By implementing parallel I/O concepts in terms of multidimensional arrays, many computational science simulations are able to naturally express their data structures.

Parallel-NetCDF provides a further benefit in that it encapsulates a great deal of I/O expertise. Computer scientists working on high-performance storage may not know a great deal about weather, climate, combustion,

or other scientific domains but know much about how to get the best performance out of storage devices, the file system, and MPI-IO. Application scientists in turn specialize in modeling phenomena, developing numerical methods, and exploring other topics more relevant to computational science. Parallel-NetCDF and other high-level I/O libraries provide a middle ground where scientists and storage experts can come together to maximize productivity.

## Related Work

The HDF5 library [5] was the first high-level I/O library to be built on top of MPI-IO. HDF5 provides a large and flexible API. For example, HDF5 applications do not need to enter a define mode to describe the variables and dimensions. HDF5 writes all metadata for the file on an as-needed basis. The trade-off for this flexibility is some additional overhead if the application is creating many new variables or other metadata-intensive workloads. HDF5 has the further benefit of allowing variables to grow without bound in any dimension. The HDF5 library allocates space for variables on demand. Consider the storage of a sparse matrix: only those values actually present in the matrix would be stored on disk. When multiple processes are updating variables in this way, however, this on-demand space allocation can result in some performance and consistency challenges. HDF5 currently forces all parallel metadata updates through rank 0, though the group is working on more sophisticated techniques.

More recently, the serial netCDF developers released netCDF-4 [7], a library with the netCDF programming API on top of the HDF5 file format. This project brought several HDF5 features to netCDF, including parallel I/O support, support for variables with multiple unlimited dimensions, and support for much larger variables. While introducing a new file format, it still can operate on older netCDF datasets. The netCDF-4 API does not have some of the more sophisticated Parallel-NetCDF features like the Flexible Mode interface or the Non-blocking interface.

## Network Interfaces

HOLGER FRÖNING

University of Heidelberg, Heidelberg, Germany

### Synonyms

NI (Network Interface); NIC (Network Interface Controller or Network Interface Card); Network adapter

### Definition

A network interface – or network interface controller, network interface card, network adapter – is a hardware component that is designed to allow computers to access an interconnection network for communication and synchronization purposes. Therefore, a network interface typically provides two different kinds of interfaces, one toward the computer (host) side and one toward the network side. The network interface translates the protocol of the host interface to the network protocol and vice versa, and translates between the different physical media. From the network's point of view, network interfaces are the end points of the network, as here the network packets are injected into, respectively retrieved from the network. As all end points of a network must be uniquely addressable, each network interface is assigned a unique number. The major task of a network interface is to insert packets into the network on the sending node, and to receive them from the network on the target node. The accomplishment

of this task, however, is highly dependant on the network interface architecture. In particular, the network interface architecture defines which subtasks are to be performed by software layers and which are performed by hardware modules.

## Discussion

### Introduction

The main task of a network interface is to provide a computer access to an interconnection network in a performant, transparent, and safe manner [1]. A well-designed network interface is performant by providing a high bandwidth and low latency. Similarly, it is transparent because it only adds minimal overhead to the performance properties of the network, which are again bandwidth and latency. A safe network interface should prevent erroneous processes from disabling the network or reducing the network's performance. Typically, a well-designed network interface is unobtrusive. Opposed to this, a badly designed network interface will turn into a bottleneck, preventing a client from leveraging the network's full performance.

Considering the Open System Interconnection Reference Model (OSI Reference Model) [2], which divides the task of communication into seven layers, the main task of a basic network interface is to handle the lowest two layers. These are the Physical Layer (PHY) and Data Link Layer (DDL). In the Data Link Layer in particular the Media Access Control (MAC) is handled by the network interface. However, more sophisticated network interfaces can also inherit task from upper layers. Then CPU off-loading takes place, and tasks are handled by the network interface instead of a software instance running on a CPU.

Implementing only the PHY and MAC layer on a network interface is typically true for indirect networks [3]. Here, central switches are used to connect an arbitrary number of network nodes, and routing only takes place in these switches. In a direct network the switching resources are distributed over the network nodes; thus, each network interface additionally includes the switching and routing modules. The network degree defines the number of links per node, and packets are routed among these links (forwarding of packets) and the host interface (injection and retrieval of packets). Therefore, a network interface for a direct network implements beside the PHY and MAC layer

also the Network Layer, which is responsible for switching and routing. Considering for instance a case in which the network (and the network interface) also provides Quality of Service (QoS), the network interface has also to implement parts of the Transport Layer.

## Basic Architecture

Network interfaces can be classified on how messages (or more generally: packets) are injected and retrieved from the network – which is the basic and unique task of all network interfaces. The most basic approach uses one register located on the network device, the so-called register-based interface. A process running on a Central Processing Unit (CPU) generates the message by consecutively writing into this registers: as messages are usually separated into header, payload, and tail part, these three parts are written word after word into the device register. The network interface collects the data written and assembles a message out of this information. The message is forwarded over the network to the destination, where a process can receive the message by reading it word after word from a device register. This approach requires a fixed message format in terms of header, payload, and tail size, which restricts the use of it. A solution to overcome this is to use a set of registers instead, where the different registers serve for different message parts.

In the register-based interface, the CPU (i.e., a process running on the CPU) is writing data into a register, respectively, reading data from a register, for each word of the message. This Programmed I/O (PIO) is a viable solution for small size messages [4]. For larger messages the CPU is occupied for a long time by copying data to and from the network. A solution to off-load this task from the CPU to the network interface is Direct Memory Access (DMA). Here, the CPU describes the message to be sent – including header and tail information and location of the data payload in the main memory – in a descriptor. Only this descriptor is transferred by the CPU to the network interface, typically using PIO. Using the information contained in this descriptor, the network interface is able to independently send or receive a message. In the case of sending it accesses the main memory to fetch the data payload and assembles a message. In the case of receiving it writes the data payload to the main memory location

specified in the receive descriptor. As such a descriptor-based network interface is working asynchronously, the CPU has to be explicitly informed if a task has been completed.

The descriptor-based approach implicates a higher overhead compared to the register-based approach: the descriptor must be constructed, it must be handed over to the network interface, and – as an indirection stage – the network interface must access the main memory to fetch or store the payload. Because for small payloads this overhead is a large fraction of the communication time, the descriptor-based approach is typically used for large payloads. In this case, the overhead is small compared to the complete communication time. Additionally, communication and computation can overlap because the CPU is not actively handling messages.

## Notifications

Notifications are an important part of the communication architecture, as they trigger certain operations in the CPU or network interface. Basically, for every action the CPU has to inform the network interface and vice versa. This is typically done using explicit notifications. An exception are device registers, because accessing these on-device structures can result in side effects which equal an explicit notification.

Basic notifications are possible using device registers, where the CPU can read out the current state of the network interface, for example, if a message in a register set has been consumed or if a new message has been received and is available in a register set. Similarly, the network interface uses side effects to get notified of new requests in the register sets.

However, side effects cannot be applied to the CPU because here no side effects exist. The usual solution to notify a CPU is either an interrupt that is asserted by the network interface, or to ensure that a CPU is periodically checking certain memory or register locations for changes (polling). While the polling method offers the lowest latency possible it consumes a lot of CPU time. On the other hand, interrupts do not consume CPU time when no event is present, but the latency of the notification is much higher due to the interrupt handling which has to be done by the Operating System (OS).

## Queues

While the basic architecture presented above is sufficient in principle, it is desirable to allow more outstanding send or receive requests for an improved decoupling between CPU and network interface. The register (set) – either being used for the message itself or for a descriptor – allows only one outstanding request: the CPU writes the information into the register set, and then waits until this data has been consumed by the network interface. Only then the register (set) can be used for the next request.

The solution for this problem are queues, which are used as interface between CPU and network interface. They provide a decoupling between CPU and network interface. By storing either a message or a descriptor as an entry in a queue, as many requests as queue entries exist can be outstanding. For sending a packet, the CPU inserts a new entry in the appropriate queue and the network interface consumes it. For receiving, the queue is used vice versa. Queues can be located in an arbitrary space – for instance main memory, on-chip memory of the network interface, or DRAM on the network interface card. For the send queue, it has to be ensured that the network interface is informed about new entries in the queues. This is in particular true for queues located in main memory, while for on-device queues side effects can eventually be leveraged. For the receive queue the CPU has to be notified about new entries. The only exception is a polling approach with guaranteed change of data in a queue entry.

Queues are applicable for all interactions between CPU and network interface, including notifications. Several approaches do exist where these queues are located. So-called memory-less network interfaces use queues in main memory, thus they do not require on-card memory. The reason is that main memory is one of the cheapest memories available, whereas on-card or on-chip memory is more expensive. In addition, main memory is also more scalable.

## Advanced Architecture

The network interface is typically a single instance located in between highly parallelized environments. On the host side the degree of parallelism is increasing due to the multi-core trend [5]. More and more CPU cores are integrated into CPU sockets and – in the worst case – all of them want to communicate using

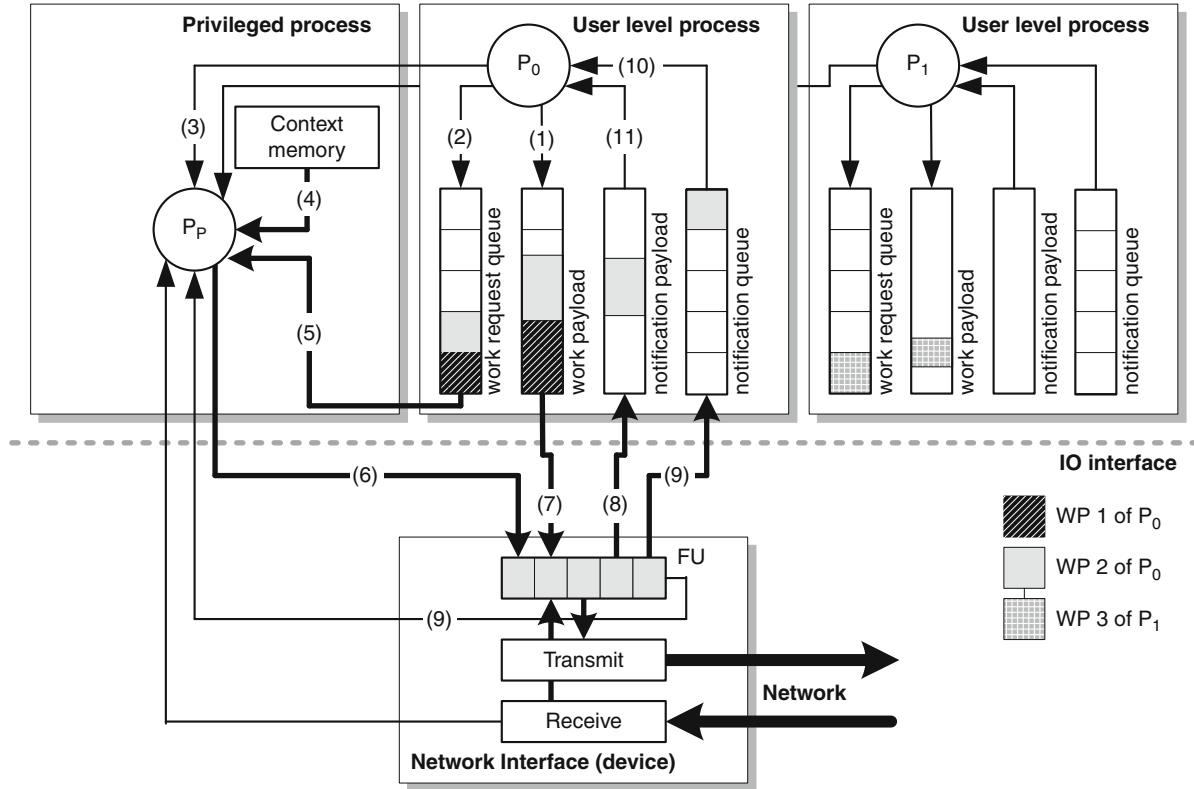

the network interface. The resurgence of interest in Virtual Machine (VM) environments [6, 7] is increasing the number of running processes potentially accessing the network. On the network side, a large number of remote network nodes are potentially accessing local resources over the local network interface. Only a network interface that adds only minimal overhead allows a performant network connection and does not turn into a bottleneck.

Many network interfaces rely on the OS to check requests and multiplex the network interface between competing processes. Only if requests are not erroneous they are forwarded to the network interface where they can be processed safely. Such network interfaces are typically of very low complexity. However, the involvement of the OS requires system calls (or inter process communication, IPC), which results in an increase of overhead, in particular CPU time and latency.

An example work flow for a multiplexed access is shown in Fig. 1. For each process, work packets and notifications are held in exclusive data structures located in main memory. A privileged process supervises the network access and multiplexes the network device among the competing user-level processes. For this purpose, each user process notifies the privileged process and the network device updates its status to the privileged process. If the network device is unoccupied, the privileged process can schedule a new work request from one of the user processes or a receive request to the network device. For a Virtual Machine environment, the privileged process is typically part of the Hypervisor, as a guest OS does not have access to hardware.

**User-level communication** [8] avoids the involvement of the OS (OS bypass) and allows user level processes to directly communicate with the device. In this case, however, it is up to the network interface to check requests for errors. Only then a safe operation is guaranteed and erroneous packets cannot disable the network or reduce its performance. Because the OS is bypassed, no multiplexing between processes can take place. This multiplexing must now be performed by the device, either in a time sliced manner, using module replication [9] or device virtualization.

**Device virtualization** [10] is an approach that virtualizes the network interface in way, that an arbitrary number of processes can use the network interface directly and without involvement of the OS. This

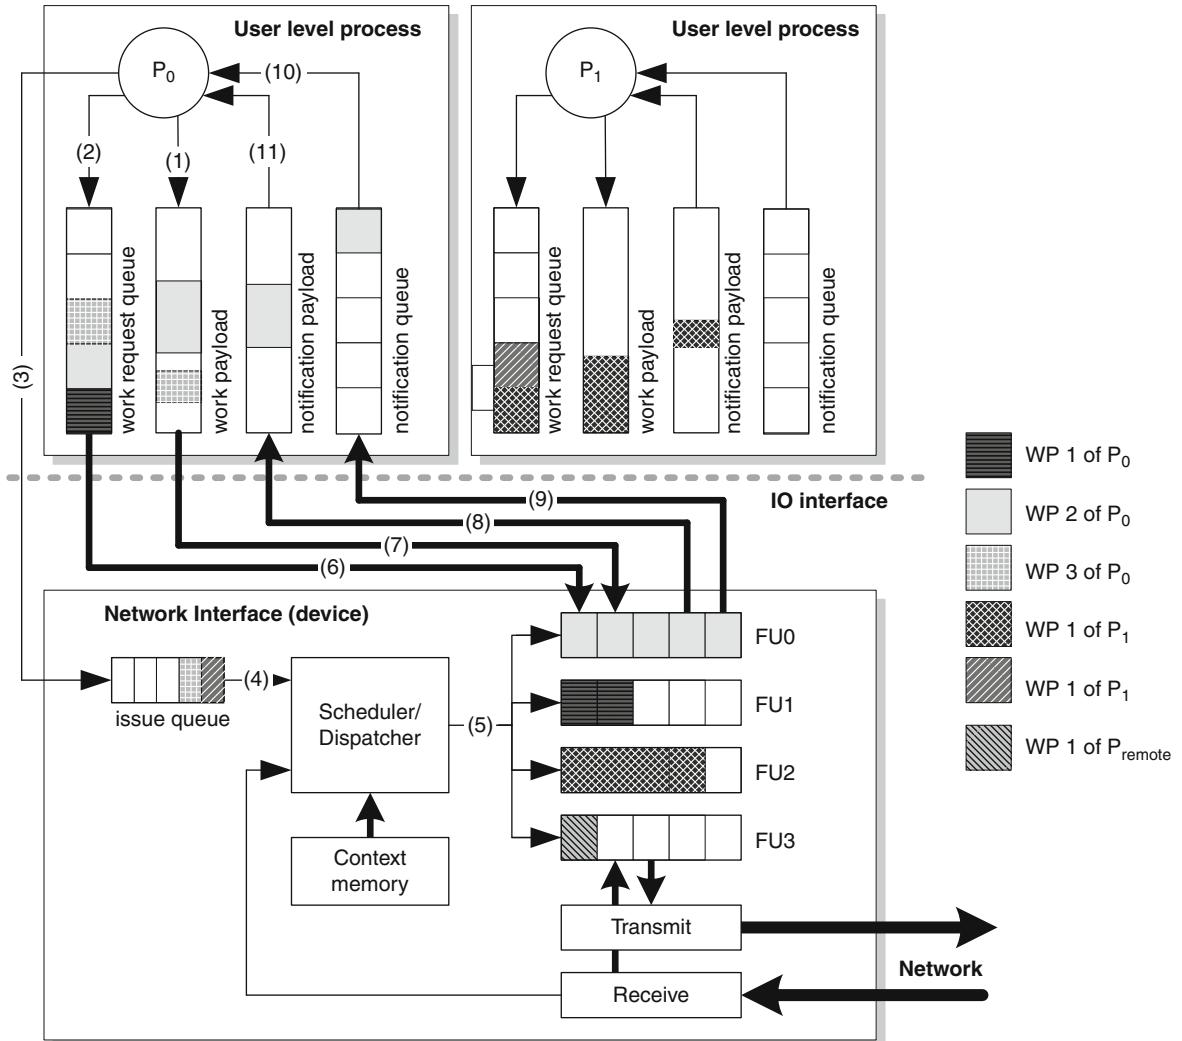

**Network Interfaces. Fig. 1 Work flow for multiplexed access.** Several processes are accessing the device by storing an optional payload (1) and a work request (2) in the appropriate exclusive data structures. Once a process has prepared such a work packet (WP), it notifies the supervising process or software instance using IPC or system calls (3). In the case of an unoccupied network device, the privileged process selects one user process and fetches the corresponding context information (4). It reads the work request entry from the queue (5) and checks it for correctness. It then forwards it to the network device's functional unit (FU) (6). The work request is enriched with information from the context, so the FU receives all information needed for processing. Also, if referenced it fetches the payload from the main memory data structure (7). It performs the processing (i.e., generation of a network packet) and then optionally writes back a notification (9), either with or without an associated payload (8). It also notifies the privileged process that it is free to receive a new work request (9). The user process consumes the notification (10), which optionally includes a reference to the payload (11)

typically relies on a context-switching approach, where a number of contexts are held on the device and upon an incoming request the corresponding context is used to configure the device for this process.

The work flow for a virtualized network interface is shown in Fig. 2: two processes are accessing a device for work processing, while an incoming packet from a remote process also requires processing. The interface between processes and device is here implemented by exclusive queues in main memory, only the issue queue on the device is shared. The combination of exclusive queue sets with only the issue queue being shared allows

bypassing any kind of privileged software instance. On the network interface, the scheduling/dispatching unit selects work packets either from local processes (i.e., from the issue queue) or from remote processes by incoming packets. It configures an unoccupied functional unit with the appropriate context, which can then process the work request.

Generally, a network interface must behave according to the properties of the whole network. For instance, if a network ensures reliability – that is, it guarantees that packets once injected are delivered without errors within finite time – the network interface must

**Network Interfaces. Fig. 2 Work flow for a virtualized device [12].** Several processes are accessing the device by storing optional payloads (1) and work requests (2) in appropriate exclusive data structures located in main memory. Once a process has prepared such a work packet (WP), it notifies the device by enqueueing an entry in the issue queue (3), which is consumed by the scheduler/dispatcher unit (4). This unit then configures a free functional unit (FU) for this process (5). The configured FU fetches the work request and optionally the payload. It performs the processing (i.e., generation of a network packet) and then optionally writes back a notification (9), either with or without an associated payload (8). The user process consumes the notification (10), which optionally includes a reference to the payload (11)

also ensure this. Similar applies for in-order delivery of packets: if packets are not allowed to bypass within the network, the same applies for the network interface. Other examples are Quality of Service or congestion management techniques. The latter is of particular interest, as many congestion management techniques use throttling of the injection rate to avoid or reduce congestions [11].

Considering the requirements above, the implementation of a high-performance network interface requires advanced architectural concepts. In particular, with regard to the highly parallelized environment a parallelization of the network interface's functional units seems appropriate. Concepts from modern processor architectures can be leveraged [12], for instance superscalar functional units, Simultaneous

Multi-Threading (SMT) [13] or Chip Multi-Processing (CMP) [5].

## Programming Paradigm

Architecture and functional behavior of a network interface are in particular dependent on the used programming paradigm.

Conceptually, there are several paradigms how communication and synchronization takes place in such a parallel computing system. The first paradigm is based on the exchange of messages, and this exchange is based on SEND and RECEIVE operations. For the purpose of communication or synchronization, or both, one process embeds the data as payload into a message and sends out this message to a remote process, which receives the message and unpacks the payload. The receiver decides where the payload is stored. Note that it is not possible to read remote locations directly, instead a message has to be sent in order to trigger a SEND operation with the data from the desired location. As both on the sending and receiving node processes are actively involved, this is also known as two-sided communication. The second paradigm is also based on the exchange of messages, but here PUT/GET operations are used. Here, the sender specifies where the data has to be stored, respectively read from. Thus, no receiving process is actively involved and one-sided communication takes place. Usually, notifications are used to inform target processes of completed operations. The last paradigm does not rely on the exchange of messages; instead, a global address space is set up. Each network node contributes to this global address space by allowing direct remote access to parts of its local memory. For communication and synchronization purposes, LOAD and STORE instructions on remote memory locations are used. Compared to the exchange of messages this approach is considered to be more intuitive for programmers, as it is similar to the multi-threaded programming paradigm used for multi-core architectures.

Depending on the used programming paradigm – either message passing or shared memory – a network interface must provide the appropriate functionality. A message passing network interface allows a process to send and receive messages, which includes for instance routing calculation (for source-path routed networks) and payload assembly (for descriptor-based interfaces).

Note that each operation – either send, receive, put, or get – is process dependent, because an appropriate set of queues or registers must be selected. Thus, support for multiple processes has to be implemented separately, for instance by hardware replication or by device virtualization. Opposed to this, a shared memory network interface (or “shared memory mapper”) has to perform an address translation from source local address to global address, and from global address to target local address. The destination is typically determined using parts of the global address. Then the operation is forwarded to the target node, where it is either completed or an appropriate response is sent back to the source node. As neither a LOAD nor a STORE instruction is process dependent, virtualization is provided inherently.

## Bibliographic Notes and Further Reading

An introduction to network interfaces covering the basics of different network interface types is provided by Dally and Towles in [1].

Practical examples for network interfaces can be separated into message passing and shared memory network interfaces: a well-documented example for a message-passing IO-attached network interface is Myrinet [14], which uses a network processor for protocol handling. Other examples for message passing network interfaces include Quadrics [15] and Infiniband [16]. Various other do exist, but due to commercial reasons they are mostly fairly documented. Further approaches to virtualize a network interface are described in [7, 17, 18].

Compared to the vast amount of message-passing-based networks, the number of shared memory networks is rather small. One of the first shared memory research projects is the Stanford DASH/FLASH [19, 21]. Examples for commercial projects implementing a global coherency include the SGI Origin [21] and SGI Altix [22]. A research project targeting a shared memory system with globally noncoherent but locally coherent memory is described by Yalamanchili et al. in [23]. Similar to this, the HyperTransport High Node Count specification [24] allows performing memory transactions on remote nodes, thereby forming a non-coherent shared memory system.

## Network Obliviousness

KIERAN T. HERLEY

University College Cork, Cork, Ireland

### Synonyms

Architecture independence

### Definition

A parallel algorithm is network-oblivious if it is formulated in a manner that is completely independent of any machine-specific parameters (such as the number of

processors and communication characteristics) of any parallel machine that might ultimately be employed to execute it. The objective is to design algorithms which, although oblivious to machine parameters, nonetheless exhibit good performance across a range of parallel machines with differing computing and communication characteristics.

## Discussion

A central issue in the study of parallel algorithms is the search for a model of computation that strikes a balance between the three desirable qualities of *usability*, the suitability of the model to provide a simple, expressive, and convenient basis for the design and development of algorithms; *effectiveness*, its ability to capture enough of the essence of specific parallel machines to ensure that the algorithms produced are likely to perform well on such machines; and *portability*, the quality that allows an algorithm to execute with good performance across a range of machines with differing computing and communication characteristics.

The large and varied menagerie of existing models for parallel computation attests to the lack of a universal consensus on a model that blends all three qualities in satisfactory way. The fact, for example, that many texts on the subject of parallel algorithms, such as that of Leighton[8], are organized by machine architecture (mesh algorithms, hypercube algorithms, and so on), demonstrates that, in many cases at least, the most efficient algorithms are highly architecture-specific, essentially pointing to a conflict between effectiveness and portability.

The well-known PRAM (Parallel Random Access Memory) model is admirably usable, but is often criticized for its lack of effectiveness. Since the model does not explicitly model communication costs, it does not discourage profligacy with regard to communication, with the result that PRAM algorithms often perform poorly when related to real parallel machines.

Valiant's BSP (Bulk Synchronous Parallel) model [9] arguably strikes a better balance between usability and effectiveness. But, while it shields the algorithm designer from the finer details of the communication fabric of the machine being modeled, the model does force the algorithm designer to tune his algorithm specifically to a number of machine characteristics,

namely the number of processors and the bandwidth-latency parameters that BSP uses to model communication costs. In addition, BSP assumes a symmetric model of communication that takes no account of the fact that for machines involving a large number of processors, communication between "nearby" processors is likely to be less costly than that between more distant ones.

A natural question is whether it is possible to devise a framework that balances usability on the one hand with effectiveness and portability on the other. First, the model should allow algorithms to be formulated in a manner that frees the algorithm designer from any consideration of machine characteristics such as the number of processors, the interconnection structure, and the communication capabilities of the machine ultimately used to execute it. Second, the model should ensure that the algorithms produced exhibit good performance across a range of different machines with widely varying characteristics.

Somewhat surprisingly, at least for certain problems and certain classes of machine architectures, the answer to the question posed above is yes.

The results sketched in the remainder of this article consider only machine architectures that can be modeled by processor networks. In this model, a set of processor-memory nodes are interconnected by means of a set of channels that link pairs of nodes, and nodes may exchange messages directly only with their immediate neighbors.

Algorithms will be described in terms of a high-level model that takes no account of the number of processors or the specific interconnection structure. In that sense the algorithm is *network-oblivious* in the same spirit as the cache-oblivious algorithms studied by Frigo et al. [6]. It will be shown that network-oblivious algorithms can be devised for a variety of problems that while formulated to be completely independent of any machine characteristics, exhibit good (often optimal) performance for a wide range of machine architectures of widely varying characteristics.

## Cache-Oblivious Algorithms

The term "*network-oblivious*" echoes the concept of *cache-oblivious* algorithms in the sequential computing setting. Since the two concepts share certain ideas, the cache obliviousness concept is summarized briefly in this section.

It has long been recognized that the interplay between the execution of a sequential algorithm and the cache(s) on the underlying machine can have a significant effect on performance, yet the familiar RAM model traditionally used to formulate and evaluate sequential algorithms completely ignores all caching effects.

The cache-oblivious algorithm-design framework, formulated by Frigo et al. [6], allows the algorithm designer to formulate his algorithm within the familiar RAM framework, but the algorithm's performance is evaluated using to an idealized cache model that captures the amount of cache activity that the algorithm entails.

Informally, the model assumes a processor connected to a single-level cache of capacity  $Z$  words, partitioned into lines of  $L \leq \sqrt{Z}$  words each. The cache is in turn connected to the main memory, also partitioned into lines. A cache miss occurs whenever a request is issued for a word  $w$  that is not present in the cache. In this case, the line including  $w$  is copied from memory into the cache, replacing another line to make room. Algorithm performance is evaluated in terms of the work involved (i.e., the number of processor steps, as for the RAM model) and also of the number of cache misses.

It should be stressed that the algorithm designer must formulate his algorithm in a manner that is completely independent of the cache parameters  $Z$  and  $L$ . The objective is for the algorithm to have optimal or near-optimal performance regardless of the cache characteristics of the machine ultimately used to execute it.

To illustrate the idea, consider the problem of multiplying two square  $\sqrt{n} \times \sqrt{n}$  matrices  $A$  and  $B$  that are stored in row major order in memory. The following identity, based on a partition of the matrices into quadrants of size  $\sqrt{n}/2 \times \sqrt{n}/2$ , suggests a simple divide-and-conquer algorithm:

$$\begin{aligned} & \begin{pmatrix} A_{0,0} & A_{0,1} \\ A_{1,0} & A_{1,1} \end{pmatrix} \begin{pmatrix} B_{0,0} & B_{0,1} \\ B_{1,0} & B_{1,1} \end{pmatrix} \\ &= \begin{pmatrix} C_{0,0} = A_{0,0}B_{0,0} + A_{0,1}B_{1,0} & C_{0,1} = A_{0,0}B_{0,1} + A_{0,1}B_{1,1} \\ C_{1,0} = A_{1,0}B_{0,0} + A_{1,1}B_{1,0} & C_{1,1} = A_{1,0}B_{0,1} + A_{1,1}B_{1,1} \end{pmatrix} \end{aligned} \quad (1)$$

The idea being that the eight  $\sqrt{n}/2 \times \sqrt{n}/2$ -sized subproblems  $A_{0,0}B_{0,0}, A_{0,1}B_{1,0}, \dots, A_{1,1}B_{1,1}$  that feature on the right-hand side of Eq. 1 are completed recursively, and then the results are combined as indicated to form the product  $A \cdot B$ .

Although this simple algorithm is not explicitly tuned to cache parameters  $Z$  and  $L$ , it turns out that it uses the cache optimally. No algorithm for this problem, including those specifically tuned to the cache parameters, can have an asymptotically better performance in terms of the work or number of cache misses. In other words, the algorithm, though completely oblivious to the cache characteristics, is competitive with those formulated in a cache-aware manner. Moreover, this algorithm is also optimal (under certain conditions) in relation to machines with multiple levels of caches.

The above algorithm exhibits a certain “self-tuning” quality. The recursive divide-and-conquer structure, entailing a series of subproblems of geometrically decreasing sizes  $\sqrt{n}, \sqrt{n}/2, \dots$ , implicitly exposes some spatial/temporal locality within the computation that the caching mechanism exploits to yield good performance. Once the subproblem size is sufficiently small that all the data related to it can fit in the cache, the subproblem can be completed without triggering any further cache misses.

Efficient cache-oblivious algorithms are also known for a variety of other problems such as matrix transposition, FFT (Fast Fourier Transform), sorting, among others. In most cases, the algorithm has the form a divide-and-conquer algorithm with highly regular structure. Some negative results are also known. Frigo et al. have also shown that algorithms that are efficient in the cache-oblivious sense often also exhibit good performance when executed on real machines.

## A Model for Network Obliviousness

To explore the concept of network obliviousness, Bilardi et al. [3] introduced the following framework for the formulation and evaluation of parallel algorithms. Algorithms are formulated in terms of a *specification model* and their quality assessed with respect to an *evaluation model*. The objective is that the framework provided by the pair of models offers a space for algorithm design and development that is conceptually simple, expressive

and easy to use, yet it gently constrains design in a manner that fosters the development of algorithms that are effective and portable.

The specification model, denoted  $M(n)$ , is an abstract machine embodying  $n$  numbered nodes  $P_0, \dots, P_{n-1}$ , each equipped with a processor and a private memory module. The computation consists of a sequence of supersteps in which each node may first complete some local computation involving data held within the node and then transmit messages to one or more other nodes. An  $i$ -superstep is a superstep in which nodes are constrained to send/receive messages only to/from nodes whose node number shares the same  $i$  most significant bits.

Note that the numbering of nodes induces a natural decomposition of the nodes of  $M(n)$ : the  $n/2^i$  nodes that share the same  $i$  most significant bits form a cluster, referred to as an  $i$ -cluster, and each  $i$ -cluster contains two  $(i+1)$ -clusters, each containing two  $(i+2)$ -clusters and so on. The  $\log n$ -clusters are individual nodes.

It must be stressed that  $n$  is an algorithmic parameter, typically related to the size of the problem instance (e.g., matrix size in the case of a matrix algorithm) and not intended to reflect the number of processors of the machine ultimately used to execute the algorithm.

The evaluation model, denoted  $M(p, B)$ , incorporates two parameters:  $p$  denoting the number of processing elements (each consisting of a processor plus local memory and referred to subsequently simply as a “processor” for brevity) and  $B$  the block size. The model shares the same clustering structure as  $M(n)$  and as well as a superstep-based mode of algorithm execution. In the case of the  $M(p, B)$  model, however, messages are aggregated into blocks of size  $B$  for transmission at the end of each superstep.

Consider the problem of matrix multiplication on the  $M(n)$  model. Suppose that two  $\sqrt{n} \times \sqrt{n}$  matrices  $A$  and  $B$  are distributed in row-major fashion among the nodes of  $M(n)$ . The product  $C = A \cdot B$  may be computed in a manner akin to that employed in the cache-oblivious setting seen earlier. Let  $P(i, j)$  denote the node that holds entries  $A[i, j]$  and  $B[i, j]$  (and ultimately also  $C[i, j]$ ).

- Partition the nodes of  $M(n)$  into eight clusters of size  $n/8$ . Distribute the elements of matrices  $A$  and  $B$ , so that each cluster has the matrix elements

required for one of the eight  $\sqrt{n}/2 \times \sqrt{n}/2$  subcomputations listed on the right-hand side of [Eq. 1](#).

- Recursively complete the eight subcomputations within the individual clusters.
- Distribute the elements of the results of the eight subcomputations so that  $P(i, j)$  receives the data it requires to compute  $C[i, j]$ .

Note that the algorithm is expressed purely in terms of the problem size parameter  $n$  and is completely oblivious to any machine characteristics.

Note that an algorithm  $\mathcal{A}$  for  $M(n)$  may be interpreted as an  $M(p, B)$  algorithm  $\mathcal{A}'$  by assigning groups of  $n/p$  consecutive nodes of the former to each processor of the latter, whose role is to simulate the actions of the  $M(n)$  nodes assigned to it. For communication steps,  $i$ -supersteps where  $i \geq \log p$  are handled internally within the  $M(p, B)$  processors (as the nodes of each  $i$ -cluster of  $M(n)$  are mapped to a single  $M(p, B)$  processor). Supersteps where  $i < \log p$  are handled as processor–processor communication, but with messages bound for a common destination bundled together into blocks of size  $B$  prior to transmission.

The *communication complexity* of a superstep is defined to be the maximum, over all processors, of the number of message blocks transmitted/received. The communication complexity of an algorithm is the sum of the complexities of its constituent supersteps. It turns out that the communication complexity of the matrix-multiplication algorithm on  $M(p, B)$  is  $O(n/Bp^{2/3})$  (provided that  $B \leq n/p$ ).

An algorithm  $\mathcal{A}$  for  $M(n)$  is optimal if the communication complexity  $C$  for its simulation  $\mathcal{A}'$  on  $M(p, B)$  is optimal, i.e., every  $M(p, B)$  algorithm for the same problem has a communication complexity that is  $\Omega(C)$ .

The  $O(n/Bp^{2/3})$  communication complexity for the matrix multiplication algorithm is in fact optimal (subject to certain technical assumptions). So the algorithm, though not specifically tuned to number of processors, is optimal with respect to the  $M(p, B)$  model.

To explore the effectiveness and portability of the algorithm, consider the performance of this algorithm on a network of processors  $p$  with a two-dimensional  $\sqrt{p} \times \sqrt{p}$  mesh interconnection, in which each processor can exchange messages directly only with its immediate neighbors.

Step 1 of the algorithm involves a communication step for the  $n$  elements of matrix  $A$  in which each processor is the source of  $n/p$  elements and the destination of  $2(n/p)$  (since each matrix quadrant is replicated twice). This can be accomplished in  $O((n/p)\sqrt{p}) = O(n/\sqrt{p})$  time on the mesh. The same bound applies to the distribution of matrix  $B$  and the communication involved in Step 3. Overall the communication cost of the algorithm is captured by a recurrence of the form  $C(n, p) = C(n/4, p/8) + O(n/\sqrt{p})$ , which has a solution  $T(n, p) = O(n/p^{2/3})$ . (Note that once a cluster size of one is reached, subproblems can be completed internally with a processor and no further communication is required.)

It turns out that this  $O(n/p^{2/3})$  complexity is optimal for the matrix multiplication problem for the square mesh in the network of processors model. In fact the  $\Omega(n/p^{2/3})$  lower bound holds (subject to some technical restrictions) even for the  $M(p, 1)$  model that takes no account of the nonconstant cost of communication between distant processors in a network of processors such as the mesh.

Thus the algorithm, developed in a manner that is completely oblivious to the structure and communication cost of the target architecture (in this case the two-dimensional mesh), is nonetheless optimal with respect to that architecture. Intuitively, the optimality of the algorithm stems from communication locality implicit in the hierarchical decomposition into subproblems of geometrically decreasing size and the mapping of these subproblems to smaller and smaller clusters (submeshes) in a way that exploits the lower communication costs within smaller submeshes.

It turns out that this phenomenon of efficient network-oblivious algorithms yielding efficient algorithms when executed on specific machine architectures is not unique to matrix multiplication or to the two-dimensional mesh architecture. The phenomenon extends to a variety of algorithmic problems and a range of different network architectures as well.

Optimal network-oblivious algorithms are also known for matrix transposition, FFT and sorting, for example. In each case, the optimality in the network-oblivious framework guarantees good performance when executed on a  $\sqrt{p} \times \sqrt{p}$  mesh. Efficient network-oblivious algorithms have also been explored for a

variety of other problems such as prefix sum, various dynamic programming algorithms, some variants of Gaussian elimination, among others.

Furthermore, the effectiveness of optimal network-oblivious algorithms applies to a wide class of network architectures, loosely speaking ones that exhibit a hierarchical structure in their pattern of interconnections and in their communication costs. Bilardi et al. [2] used the DBSP model (Decomposable BSP), a hierarchical variant of the well-known BSP model, to address the issues of effectiveness and portability of network-oblivious algorithms.

The DBSP model shares both the superstep-based structure of algorithm execution and hierarchical clustering structure of the  $M(n)$  and  $M(p, B)$  models, but has a more refined model for the costs of communication that better captures the communication characteristics of various network architectures. Specifically, it captures a notion of proximity: that communication with “nearby” processors should be cheaper than with those that are more distant. An  $i$ -superstep, in which processors may transmit messages to other processors within the same  $i$ -cluster, has a cost of  $\lceil \delta/B_i \rceil g_i$ , where the parameters  $g_i$  and  $B_i$  model the bandwidth-latency characteristics of communication within an  $i$ -cluster and  $\delta$  denotes the maximum number of words transmitted/received by any processor during the superstep.

The hierarchical nature of both the processor clustering and cost model for communication allows the DBSP model, for suitable choices of parameters  $(g_0, g_1, \dots, g_{\log p - 1})$  and  $(B_0, B_1, \dots, B_{\log p - 1})$ , to model a wide variety of architectures, such as meshes of various dimensions as well as fat trees. For example, a  $d$ -dimensional mesh architecture can be modeled by a  $p$ -processor DBSP with  $g_i = (p/2^i)^{1/d}$  and  $B_i = (p/2^i)^{1/d}$ . It should be noted that meshes of various dimensions are a common choice for interconnection on modern parallel machines. It can be shown that, under some reasonable assumptions on the pattern of communication embodied within the algorithm, an optimal network-oblivious algorithm yields an optimal DBSP algorithm and so optimal network-oblivious algorithms translate into efficient algorithms on architectures modeled by the DBSP, such as multidimensional arrays.

## Future Directions

To broaden the range of problems analyzed within the network-oblivious framework is an obvious line of further enquiry. An investigation of how near-optimal network-oblivious algorithms perform on various architectures as well as negative results (that certain problems do not admit optimal network-oblivious algorithms) might be valuable in casting light on what algorithm characteristics foster or frustrate network obliviousness. Clearly, further work that broadens the space of architectures to which these results apply would also be worthwhile. Work that extends these ideas into other settings, such as the multicore work referred to below, also looks promising.

Distributed switched networks; Hypercube; Interconnection networks; K-ary n-cube; Mesh; Network Architecture; Ring; Router-based networks; Torus

### Definition

A direct network is a network for interconnecting a set of nodes in such a way that no external switching components are required. These nodes are themselves usually programmable computers. A switch is an integral part of the nodes, so that the node itself can be directly connected to a set of neighbor nodes. Non-neighbor nodes can be reached through multiple hops in the network. The integration of the switch with the node implies that there is a set of network topologies associated with direct networks that is distinct from the set of topologies associated with indirect networks.

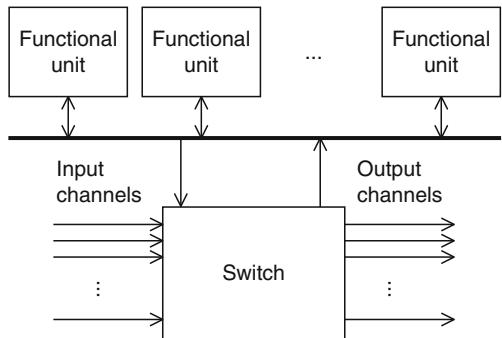

## Discussion

### Introduction

The preferred way to connect a small set of compute nodes to each other is to attach them all to a shared medium Bus. The main limitation of this approach lies in scalability. As the number of attached nodes increases, the total aggregate bandwidth of the Bus remains constant; thus, the Bus becomes a bottleneck.

A popular way to get around this scalability problem is to integrate switching capabilities into the compute nodes. This will allow a compute node to be directly connected to a subset of the other nodes in the system. Nodes that are directly connected to each other are generally referred to as *neighbors*.

A generic architecture of a node is depicted in Fig. 1. The Functional units depicted will typically be processors or memory, but other type units, such as graphic

**Networks, Direct.** Fig. 1 A generic architecture of a node for direct networks

processors or specialized vector processors are thinkable. Sometimes output channels and input channels are paired into bidirectional channels. In these cases, the channel interfaces denote the endpoint of bidirectional links. Still, the architectural layout of the node remains the same regardless of whether the links are unidirectional or bidirectional.

The direct network is constructed from a set of such nodes by repetitively coupling output channels of one node with input channels of another node until a topology of connected nodes has been built. There are many interconnection patterns that can be used in doing this, and each of them results in a defined class of topologies. The most well known classes of topologies are defined in a later section.

It is common to refer to the topologies generally used for direct networks as “direct network topologies,” and this chapter will follow the same convention. Although this wording hardly ever leads to misunderstandings, it is a bit inaccurate. All the topologies that can be applied for direct networks can equally well be the basis of the design of indirect networks (The opposite is, however, not always the case. Although it is possible to construct, e.g., a multistage network from switches that are integrated with nodes, the routing limitation of multistage networks makes it hard to obtain a fully connected and deadlock-free routing strategy for these cases.). Indeed, at the time of writing, there is a trend in industry to build switches as separate units, and in accordance with some communication standard, e.g., InfiniBand. Even if these switches are not integrated with a compute node, they are used to build systems with both direct-and indirect-network topologies.

Direct networks provide very good flexibility, both with respect to scalability and topology. The extension of a system with additional nodes is in many cases cost effective, as the needed extension in communication infrastructure is embedded in the node itself, and because the necessary connection points in the existing system are provided by the nodes already in the system.

## Topologies

*The network topology defines the interconnection pattern among nodes.*

The usual way of modeling network topologies is as a graph  $G(N, C)$  where the vertices, denoted by  $N$ , represent the set of processing nodes, and the edges  $C$  represent the set of links. The links may be defined to be unidirectional or bidirectional, based on the properties of the technology under study. In some cases it is necessary to model a bidirectional link of some technology as a pair of unidirectional links. In particular, this is necessary for the analysis of deadlock properties of routing algorithms.

In the study of topologies, there is a set of notions that are central. These stem partly from the requirements that the topology places on the nodes, and partly on the properties of the topology itself. *Node Degree* is a notion from the first category. This is the (minimal) number of external input and output channels that the topology requires of each node. Another example is *Forwarding Logic*. Topologies that are of a regular structure can be supported by a specialized logic for efficient and simple forwarding of packets tailored for that particular topology.

*Network diameter* is a direct property of the topology itself. It is the maximal length of the minimal path between any pair of nodes measured in number of intermediate nodes that have to be traversed. Much early research on topologies focused on solutions that minimized the diameter. The introduction of *Cut Through Switching* in the early 1980s did, however, make packet latency in a network to a large extent independent of the number of hops.

*Bisection Bandwidth* is a notion that captures the ability of a topology to handle bandwidth requirements. It is defined as the minimum aggregate bandwidth of a set of links that when they are removed divide the network in two equal-sized halves. Although this notion is important, its relevance is not independent of the

application that the network should support. The main strength of some direct-network topologies is that they support very well some applications that require communication only with neighboring nodes. In such a scenario, the bandwidth of a single link is important, but the aggregate bandwidth across the bisection is of less importance.

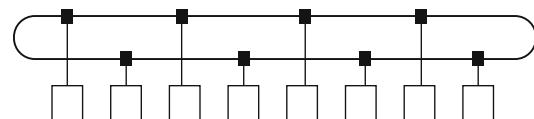

## Rings

The simplest extendible direct network topology is the ring (Fig. 2). The ring may be unidirectional or bidirectional. For rings, the nodes only need one input and one output channel. The forwarding logic can be made quite simple, in that every node compares the address of each packet passing by. If the address matches the node's own address, the packet is delivered to the internal parts of node itself. Otherwise, it is forwarded to the next node in the ring. Some technologies, like SCI, are tailor-made for ring structures, and thus take advantage of easy forwarding and low-node degree.

The bisection bandwidth and the network diameter of rings are generally considered as the weak points of these structures. The network diameter grows linearly with the number of nodes, and the bisection bandwidth remains constant whatever the size of the ring. This severely limits the size of the systems built as a single ring. Systems of rings can, however, be constructed to improve on this weakness. The most prominent example of this is the Torus-class of topologies. These are discussed below.

## Meshes

The  $n$ -dimensional mesh topology can be explained by imagining an  $n$ -dimensional grid, with a node in each cross-point. Each node has one bidirectional link connecting it to each of its closest neighbors in each dimension. This means that the nodes have at most  $2n$

**Networks, Direct. Fig. 2** This is an example of a ring with eight nodes. Note that the nodes on each side of the ring are interleaved, so that the length of the cable between each pair of nodes becomes uniform

neighbors, thus the switching element of the nodes must have at least  $2n$  ports to support an  $n$ -dimensional mesh. Note also that the nodes that are placed at the extreme of a dimension will have fewer than  $2n$  neighbors. The nodes that are at the extreme of all dimensions will have exactly  $n$  neighbors.

A more formal definition is as follows: An  $n$ -dimensional mesh has  $k_0 \times k_1 \times \dots \times k_{n-1}$  nodes, with  $k_i$  nodes along each dimension  $i$ . Let  $k_i$  be the *radix* of dimension  $i$ . Each node  $X$  in the topology is uniquely identified with a tuple of  $n$  coordinates identifying its position in the grid. If a node  $X$  in the topology is identified by  $\{x_0, x_1, \dots, x_{n-1}\}$ , then for all  $i$ ,  $0 \leq x_i < k_i$ . Two nodes are neighbors, and thus are directly connected to each other through a link, if and only if their identifying tuples of coordinates are identical in all places, except for exactly one coordinate  $i$  where they differ with exactly one (Fig. 3).

The bisection bandwidth of a mesh equals the link speed multiplied with the product of the number of nodes in each dimension and divided by the number of nodes in the dimension with the highest number of nodes. This means that when the radix of the dimensions is balanced,  $M$  is the number of nodes and  $n$  is the number of dimensions, the bisection bandwidth of a mesh grows with  $M$  divided by the  $n$ 'th root of  $M$ . The diameter of the mesh is the radix of the dimensions multiplied with the  $n$ 'th root of  $M$ .

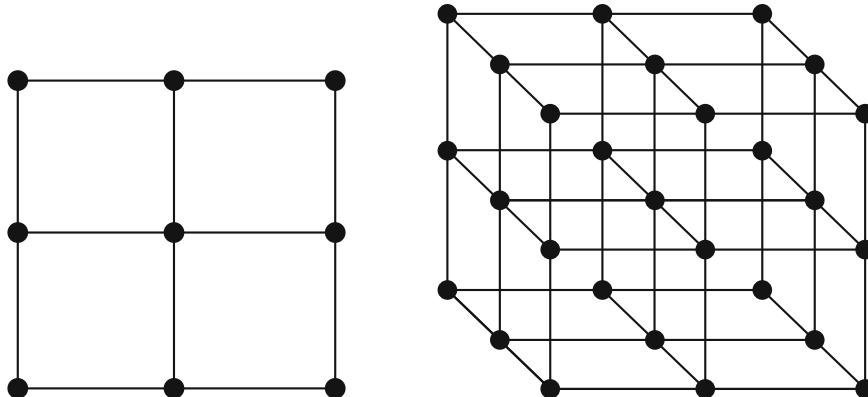

If specialized forwarding logic for meshes is implemented in a node, this generally means that the addressing scheme is based on the  $n$ -tuple that identifies the position of each node in the mesh. Typically then, each

forwarding step consists of moving the packet one step closer to its destination along one dimension. This is done by first identifying one digit in the  $n$ -tuple where there is a mismatch between the destination address of the packet and the address of the node that currently handles it. In the dimension identified by the digit, the packet is forwarded in the direction that decreases the mismatch. When all mismatches have been nullified, the packet has reached its destination.

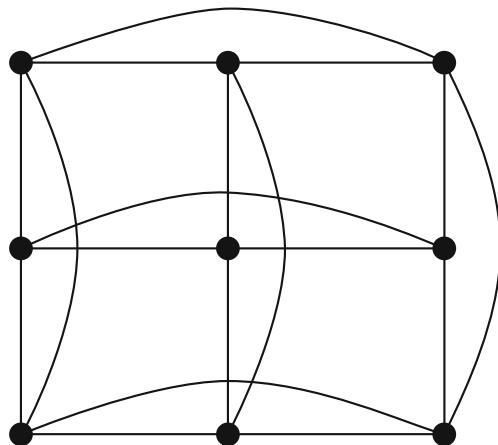

## Torus

Torus topologies are extensions of meshes with additional links. In the same way as for meshes, one can describe the placements of the nodes by referring to cross-points in a grid, and in the same way as for meshes, the nodes can be identified by tuples defining their placement in each of the  $n$  dimensions of the grid. The only topological difference is that there are additional links in a torus compared to a mesh. These links connect the first and the last node in a dimension, so that each sequence of nodes along each dimension forms a ring (*Some authors will define a torus such that the extra links are not there when the size of the dimension is two. Following that definition, the definition of torus and meshes coincide for this case. Our later discussion of bisection bandwidth for tori would not be valid for dimension-size of two under that definition.*) (Fig. 4).

The implication of this is that in a torus, each node has exactly the same number of neighbors, equaling twice the number of dimensions in the torus. It also means that the bisection bandwidth of the torus is

**Networks, Direct. Fig. 3** A two-dimensional and a three-dimensional mesh

**Networks, Direct.** Fig. 4 Example of a 2-dimensional torus

two times that of the mesh. The diameter of the torus approaches half that of the mesh when the network is large (*There is a subtlety in that the diameter of each ring in the torus is calculated differently depending on whether the number of nodes in the ring is odd or even. The effect of this subtlety approaches zero when the rings grow large.*). Specialized forwarding logic is possible for tori in the same way as for meshes. The notion of distance will, however, need to be more involved to capture the possibility for following the shortest path along wraparound links.

## Hypercube

The hypercube can be defined in several ways. One way is to define it as a mesh where the radix of each dimension is exactly two. The following recursive definition is more formal:

- A single node is a hypercube.
- Two identical hypercubes, where each isomorphic pair of nodes from the two hypercubes has a link between them, is a hypercube.

The construction of hypercubes from this definition is illustrated in Fig. 5.

Since hypercubes are a special case of meshes, the discussion of port requirements in the nodes, of forwarding logic in the nodes, the diameter, and the bisection bandwidth follows from the discussion above.

Still, it is worth reflecting over the implication of limiting the radix to two. First, it means that the only way to extend the network is to add another dimension.

This means that for each node that has been designed, the number of ports implemented in the node limits the size of the network that can be built. On the other hand, the bisection bandwidth grows linearly with the number of nodes, meaning that the bisection bandwidth per node remains constant. Furthermore, the diameter of the network equals the number of dimensions in the system, giving a diameter that is logarithmic to the number of nodes in the system.

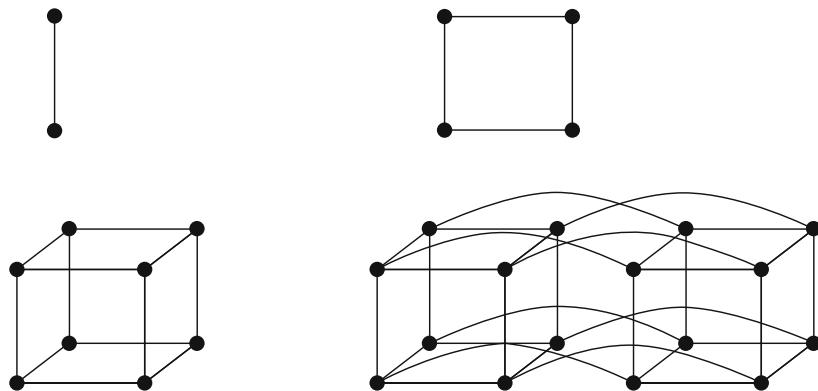

## Other Topologies

In addition to rings, meshes, tori, and hypercubes, a plethora of topologies have been defined in the literature. Most of these additional topologies were designed with the goal of minimizing the network diameter for a given number of nodes and/or a given node degree. With the introduction of pipelined switching techniques, like wormhole routing and Virtual Cut Through, end to end packet network latency is close to independent of network diameter. None of these topologies are therefore likely to be implemented. For a short introduction to some of these topologies, we refer to Sect. Popular Network Topologies of [1].

## Routing Functions

The routing functions in use for these topologies are quite similar to each other. At the base there is shortest path routing that follows one dimension at a time. Basically, the set of dimensions are ordered in a sequence, and the dimensions are traversed in this order. For meshes and hypercubes, this guarantees deadlock-free routing. For rings and tori, however, the cyclic structures in the topologies creates additional challenges, as shortest path routing will create cycles of dependencies between the buffers and the channels, and thus there is a danger of deadlock. In these cases, the solution is to introduce virtual channels, such that the cycle of dependencies between the different resources in the network is broken. More information on this is given in the entry on routing in this encyclopedia.

As the size of the networks grows, the importance of the system to remain in operation regardless of whether some of the nodes fail becomes important. Several routing strategies that cope with faulty nodes in direct network have been proposed, but very few of them have so far been implemented. More information on this can be found in the entry on fault-tolerant networks.

**Networks, Direct.** **Fig. 5** This is an illustration of the development of hypercubes from the recursive definition. Top left is a one-dimensional hypercube consisting of two nodes connected together. Top right is a two-dimensional hypercube, bottom left a three-dimensional hypercube, and bottom right is a four dimensional hypercube

### Direct Networks Today

For smaller networks, the choice of topology is relatively easy. Most solutions will work. Presently, one-dimensional meshes (or daisy chains) are typically used for HyperTransport, and simple rings are used for SCI and interconnecting the processing elements in the Cell Processor and the Intel Larrabee. The discussion does not really get involved until the system size increases to interconnect more than 10–12 nodes.

The properties of Hypercubes with respect to diameter and bisection bandwidth are very appealing. Still, real machines have to be built in the three available dimensions. This has limited the use of Hypercubes to medium-sized systems. For the recent systems that have been built with thousands of nodes, the preferred direct network topology has therefore been a three-dimensional torus.

When looking at the Top 500 list of supercomputers in the world, one finds both direct topologies, and indirect topologies – typically multistage networks. It is a well-established fact that for arbitrary traffic, multistage networks give superior price/performance compared to the direct topologies. Still, tori and meshes appear in the list. The reason for this is that many of the computational problems that run on such computers analyze physical systems in a three-dimensional world. A torus topology allows the physical world to be divided into three-dimensional cubes of equal size, and let these cubes be mapped isomorphically onto the compute nodes in the system. Since the physical influence between these cubes are between

neighbors, the communication in the computer system will mainly go between neighboring nodes, and thus the locality in the torus/mesh topology fits ideally with communication needs. Therefore, the current trend is that for multi-purpose installations, multistage topologies are used. For installations that are specialized to run a limited set of applications modeling the physical world, tori or meshes are still the topology of choice.

### Future Directions

There are few new developments in network topologies after the turn of the millennium. Still, the recent changes in technology have revitalized the field somewhat. The development in processor technology has made it possible to put many compute cores onto one chip. This has spawned the need for an on-chip interconnection network. Because of its square layout in two dimensions (or three when one considers different metal layers) have made meshes and tori look as obvious candidates for such networks.

The quest for simple integration of different components onto the same chip seems to indicate that the integration of switching capacity and functionality onto the same logical unit will increase. From this observation it is a reasonable guess that direct topologies will be preferred. There are, however, several reasons why our knowledge of direct network topologies will have to be extended to support on-chip networks.

The first reason is that the different functional units that are to be integrated onto the same chip will in many

cases not be uniform. They will have different characteristics, and different need for footprint on the chip. For that reason, it is not at all obvious that the on-chip network will be regularly structured in the same way as tori and meshes are. The second reason is that the traffic requirements will not be uniform either. On-chip networks will frequently be used in single application scenarios. The quest for minimizing power and area utilization will make designers deviate from regular structures whenever the communication needs will allow it.

Finally there are currently initiatives working in the direction of streamlining on-chip, on-board, and between-board communication. These initiatives may result in common addressing solutions. Still, the different requirements of these domains will most likely mean that there will be different network topologies in each of them. Efficient co-working of several networks with different topologies is therefore likely be a topic addressed in the future.

## Bibliographic Notes and Further Reading

There have are several sources to the state of the art in direct networks. The two most important books on interconnection networks both contain good overviews [1, 2]. Furthermore, there is a treatment of topologies for interconnection networks in an appendix of the book by Hennessy and Patterson [3].

Direct networks were used on some of the earliest parallel computers [7, 8]. Later, in particular inspired by the Caltech Cosmic Cube [9], there were a series of approaches using hypercube-like structures [10, 11].

William Dally did much seminal work on direct networks in the late 1980s. The one publication most relevant to the discussion on topology here was [4], where he made the case for low dimensional, high radix networks to have better scalability properties than the high dimensional hypercubes. Other important contributions were done together with Charles Seitz on mechanisms for deadlock-free routing on tori [5, 6]. From this point, two and three-dimensional meshes and tori have been the direct network of choice [12, 13]. A recent example that demonstrates the lingering relevance of these topologies is the Red Sky machine at Sandia National Labs. This machine was delivered in November 2009 and made number 10 on the Top 500 list then. Its interconnection network is a three-dimensional torus.

## Networks, Fault-Tolerant

MARÍA ENGRACIA GÓMEZ REQUENA  
Universidad Politécnica de Valencia, Valencia, Spain

### Synonyms

[Reliable networks](#)

### Definition

A fault-tolerant network is a network that can provide full connectivity among all the processing nodes connected to the network without losing any messages despite the presence of faults in the network elements.

### Discussion

#### Introduction

Large parallel computers with thousands of nodes have been and are being built as can be seen in the top 500 list [1]. In such systems, the high number of components significantly increases the probability of failure. Each individual component can fail with a certain probability and, thus, the probability of failure of the entire system increases dramatically as the number of components increases. In addition, the failure probability of each individual component increases as transistor integration density increases. Hence, in these systems, it is critical to keep the system running even in the presence of faults. Moreover, faults in the interconnection network may isolate a large fraction of the machine, containing healthy processing nodes. Therefore, fault-tolerant mechanisms for the interconnection network are critical design issues for large parallel computers. Fault-tolerance in an interconnection network refers to the availability of the network to function in the presence of component faults.

However, techniques used to implement fault-tolerance in the interconnection network are often at

the expense of considerable performance degradation, which is not desirable. A good fault-tolerance mechanism should degrade network performance gradually with the number of faults. Also each fault-tolerance mechanism can tolerate a certain number of faults. Beyond this number, an additional fault may disconnect the network.

The solution adopted to tolerate faults in a given system depends on the types of faults that can occur and the assumed fault-model. The pattern of faults and expectations about the behavior of processors and switches in the presence of these faults determines the approaches to provide fault-tolerance. This information is gathered in the fault model.

#### Fault Models

In the design of fault-tolerant techniques for the interconnection network, a fault model is assumed. In what follows, the most commonly-used fault models are presented [2].

First, there are two main kinds of faults in the interconnection network: transient and permanent. Permanent faults remain in the system until it is repaired. On the other hand, transient faults are dynamic in nature as integrated circuit sizes continue to decrease and speeds continue to increase. As it can be read below, the approaches followed to deal with both fault types are completely different.

Another consideration is the level at which components are detected as faulty. Usually, detection mechanisms differentiate between switch faults and link faults since most types of faults will simply manifest as link or switch faults. In the case of a switch fault, all links incident on the faulty switch are also considered as faulty.

The fault model also specifies the area of the fault information available at each node to tolerate the faults. On one hand, there are techniques in which each node only has fault information about adjacent nodes. On the other hand, in other techniques, every node knows the fault status of every other node. The advantage of the latter techniques is that messages can be forwarded along the shortest feasible path in the presence of faults. However, in practice it is difficult to have global fault information in a timely manner. These techniques require storage and computation time which have a significant impact on performance, and the occurrence

of faults during update periods requires complex synchronization protocols. In case of local information, nodes only have fault information about adjacent nodes; so routing decisions are simpler and can be computed quickly, and updating the fault information about adjacent nodes can be performed in a very simple way. However, in this case, routing decisions are not optimal and messages may be routed to network zones with faults, leading to longer paths. In practice, fault-tolerant techniques are between purely local and purely global fault status information. Fault diagnosis deals with developing algorithms for getting and maintaining timely fault information about neighbor nodes.

On the other hand, depending on the actions performed after the fault detection, two different types of fault models can be defined: static or dynamic. In a static fault model, once a fault is detected, all the processes in the system are halted, the network is emptied, and a management application is run in order to deal with the faulty component. This application detects where the fault is and computes the information required by the nodes in order to tolerate the fault. This information is distributed by the management application and, then, the system is rebooted and the processes are resumed. This fault model needs to be combined with checkpointing techniques in order to be effective. Applying checkpointing minimizes the fault's impact on applications, because they are restarted from the latest checkpoint. In a dynamic fault model, once a new fault is found, actions are taken in order to appropriately handle the faulty component while the system keeps running. For instance, a source node that detects a faulty component through a path can switch to a different path that does not use the failed component.

### Transient and Permanent Faults

As commented above, faults can be classified as transient and permanent [3, 4].

Transient faults are usually due to electromagnetic interferences and alpha particle impacts and they are usually corrected by retransmitting the packet either at the link level or at the end-to-end level. A link level treatment is performed by encoding redundant information in the packet using an error control code (ECC). Simple parity is enough to detect a single error of a bit. However, most links use a cyclic-redundant check (CRC) of sufficient length in order to reduce the

probability of an error of several bits. The error check can be performed at different levels of granularity: flit or packet. When the sender transmits the packet or flit, it retains a copy until correct reception is notified by the receiver. The redundant information included in the packet or flit is checked when it is received. If the packet or flit pass the test, the receiver sends an acknowledgment indicating that it has been received correctly. Each packet or flit is tagged to facilitate its identification and this tag is used in the acknowledgment to identify the packet or flit. The acknowledgment also indicates the reception status, that is, received correctly or received in error. Upon receiving this acknowledgment, the transmitter discards its copy of the packet. If a packet is received in error, the sender retransmits it. In most cases, the error is transient and the packet is received correctly on the second attempt.

Transient faults can be also treated by end-to-end mechanisms that operate in a similar way to that of link-level retransmission, except that packets are retransmitted over the whole network path up to the final destination [4]. In this case, as in the link-level mechanism, the sender must store a copy of each packet pending of its correct reception. The destination sends an acknowledgement when the packet arrives correctly. It contains the tag assigned to the packet. In this case, due to having longer paths, a timer is usually used at the sender node for each sent packet. If the timer of a given packet expires before an acknowledgement of that packet arrives to the destination or if a negative acknowledgement is received, then the source resends the packet. However, two copies of the same packet can be received at the destination if the acknowledgement arrives at the source delayed after the timer has expired. This can be identified in an easy way since both packets have the same tag, and the second packet is discarded.

On the contrary, permanent faults are due to components that stop working within specifications and cannot be recovered by retransmitting packets with the help of some higher-layer software protocol. In order to tolerate this type of faults, an alternative physical path must exist in the network topology.

Three main groups of techniques are used to deal with permanent faults in the interconnection network: resource replication, network reconfiguration, and fault-tolerant routing.

## Replication

Replication provides tolerance to permanent faults by replicating network components. Those spare components are switched on in case of fault and the faulty components are switched off (or bypassed). As an example, the ServerNet interconnection network is designed with two identical switch fabrics. Only one of the switch fabrics is available at any given time. In case of fault in one of them, the other fabric is used.

This technique is used by a large amount of fault-tolerant proposals for MINs. They add either links between switches in the same stage, more links between stages, more switches per stage or extra stages to increase the number of alternative paths. In [14], a new topology that consists of two parallel fat-trees with crossover links between the switches in the same position in both networks is proposed. In this topology, when a packet encounters a fault in its path, it is forwarded through the crossover link to the other parallel fat-tree.

The main drawbacks of this approach are the high extra cost of spare components and the non-negligible probability of failure of the circuits required to switch to spare components.

This technique can also be implemented without using spare resources, leading to a degraded mode in the system operation after a fault. The IBM Blue Gene/L supercomputer, for instance, offers the ability to bypass faulty network resources while keeping its topology and routing algorithm. In case a fault is detected, all the nodes included in several midplane boards that contain the faulty node/link are bypassed to isolate the fault. In this way, the network topology remains the same and routing is not changed. The main drawback of this technique is the relatively large number of healthy resources (i.e., midplane node boards) that may be switched off after a fault.

## Network Reconfiguration

Network reconfiguration relies on the use of routing tables as the routing mechanism. It is a more general technique to deal with changes in the network topology due to failures or to some other cause. When a fault appears, the routing tables are reconfigured to be adapted to the new topology resulting after the network topology change. In order to perform the network reconfiguration, the fault-free portions of the topology

must first be discovered, then the new routing tables must be computed and finally they are distributed to the corresponding network components (i.e., switches and/or end node devices).

Network reconfiguration requires the use of programmable switches and/or network interfaces, depending on how routing is performed. It may also make use of generic routing algorithms (e.g., up\*/down\* routing) that can be configured for all the possible network topologies that may result after faults. This technique relieves the designer from having to supply alternative paths for each possible fault combination at design time and is extremely flexible because it allows tolerating faults while there is physical connectivity in the network. The drawbacks of this technique are that it uses generic routing algorithms that are valid for any topology, but these routing algorithms achieve poor performance when they are used in regular networks, and that programmable network components have higher cost and latency. Most standard and proprietary interconnection networks for clusters and SANs – including Myrinet, Quadrics, InfiniBand, Advanced Switching, and Fibre Channel – incorporate software for (re)configuring the network routing in accordance with the new topology.

Another issue related to network reconfiguration is whether the interconnection network supports hot swapping. That is, whether the interconnection network can continue operation while a new component is added to or removed from the network. Most networks allow for hot swapping which is usually supported by performing a dynamic network reconfiguration without stopping network traffic.

The main problem with network reconfiguration is guaranteeing deadlock-free routing while routing tables are updated in switches and/or end node devices, as more than one routing algorithm may be used in the network at the same time. Most WANs solve the possible deadlocks by dropping packets, but dynamic network reconfiguration is much more complex in lossless networks.

## Fault-Tolerant Routing

Fault-tolerant routing takes advantage of the multiple paths usually available in the network topology between each source-destination pair, in order to route packets through the fault-free paths. Adaptive routing is usually

used in this case. The faulty components are made unavailable to the adaptive routing algorithm and all the packets are routed using the remaining components. Nevertheless, it is also possible to achieve network fault-tolerance with deterministic routing by routing a packet in two or more phases and storing it at some intermediate nodes.

The main difficulty of these routing algorithms is guaranteeing that the routing algorithm will remain deadlock-free and livelock-free after the fault appears given that arbitrary fault patterns may occur.

The solution adopted to provide fault-tolerance depends on the type and pattern of the component faults and the network topology. In what follows, different routing algorithms for regular networks are presented and grouped depending on the type of the regular topology, that is, direct or indirect.

### Fault-Tolerant Routing in Direct Networks

A large number of fault-tolerant routing algorithms for multiprocessor systems have been proposed, especially for mesh and torus network topologies.

In multidimensional direct topologies, if the number of faulty components is less than the degree of a node, then the topology provides at least a physical path between each source-destination pair, and therefore the routing algorithm may communicate any two nodes of the system.

In direct networks, guaranteeing that the routing algorithm remains deadlock-free after the fault appears and when using the alternative paths to avoid the fault is especially difficult since the faults can comprise its regularity.

Some approaches used in direct networks use global status information of the network, whereas others use only local status information.

In case of local information, faulty components can be avoided by using a dimension orthogonal to the dimensions leading to the faulty components. Chien and Shin [5] propose such an algorithm for hypercubes. When all of the shortest paths to the destination from an intermediate node are blocked by faults, the message is transmitted using an extra dimension that is not in the minimal path. The algorithm is  $n-1$  fault-tolerant.

Another alternative approach is the use of randomization to produce probabilistically livelock-free,

non-minimal, fault-tolerant routing algorithms. The idea is to avoid repetitive sequence of link traversals in order to avoid livelocks. The Chaos router incorporates randomization. In this case, messages are normally routed along any profitable output port. When a message is stored in an input buffer for too long, blocked by busy or faulty output buffers, it is removed from the input buffer and stored in a local buffer that has a higher priority and allows routing through non-minimal paths.

The previously presented approaches assumed the availability of only information about neighboring links and switches. An approach to maintain global fault information is by encoding the node state. Lee and Hayes [6] introduce the concept of unsafe node. A non-faulty node is unsafe if it is adjacent to two or more faulty or unsafe nodes. Each node must know the state of its neighbors, so each node must transmit its state information to the neighboring nodes. The unsafe state indicates to the routing algorithm that going through another path is a better routing option, that is, going through a safe neighbor node.

When maximum flexibility must be ensured, routing algorithms based on graph search techniques are used. A message can be routed to traverse a set of links corresponding to a systematic search of all possible paths between a pair of nodes. The routing overhead is significant, but the probability of delivering messages is maximized. A main issue in this case is that of passing through a node more than once which results in an unnecessary overhead. Most approaches maintain information in the header to avoid passing through the same node several times.

The aforementioned fault-tolerant routing algorithms are defined for SAF or VCT switching. When wormhole switching is used, new challenges appear in the design of fault-tolerant routing algorithms. The use of small buffers makes that blocked messages span multiple nodes, hence the fault affects several nodes. In this case, the most common approach is to define fault regions and route packets avoiding those regions. Adjacent faulty links and faulty switches are joined into fault regions. The idea is not to introduce new dependencies in the routing algorithm in order to guarantee deadlock-freedom.

The difficulty of routing messages around faulty regions depends on the shape of the region. The fault tolerant routing algorithms usually impose constraints

to the regions. In particular, they usually assume that the fault regions are convex, since concave regions present more difficulties. Moreover, in some algorithms convex regions are further constrained to be block fault regions, that is, regions whose shape is rectangular. Given a set of faults in a direct network, rectangular fault regions can be constructed by marking some healthy nodes as faulty to fill out the entire region. In this case, the fault-tolerant routing algorithm usually needs additional resources as virtual channels to avoid deadlocks.

Assuming block fault regions, when a message encounters a block fault region, an alternative non-minimal path is followed by the message. The alternative path should not introduce new dependencies in the routing algorithm. A solution to avoid deadlocks in 2-D meshes was introduced by Chien and Kim [7] and is to use planar adaptive routing, which adds an additional virtual channel. The technique can also be applied to multidimensional meshes and tori. In the case of torus topologies, this solution requires six virtual channels for each physical link. Moreover, it presents problems when fault regions are adjacent or include nodes on the mesh boundary. Both situations are equivalent to the occurrence of a concave fault region. Ensuring that fault region remains convex will require marking more healthy nodes as faulty, which is not desirable.

One solution to reduce the number of healthy nodes that are included in the fault region is based on the idea of fault rings. A fault ring is the sequence of links and nodes that are adjacent to and surround a fault region. If the fault region is rectangular, then the fault ring is also rectangular. If a fault region includes boundary nodes, then a fault ring cannot be defined and a fault chain is used. This fault rings and fault chains are used to misroute messages that are blocked due to faults in their paths. Meshes with non-overlapping fault rings and with no fault chains require two virtual channels to avoid deadlocks. If there are overlapped fault regions or fault chains then four virtual channels are required.

Some fault-tolerant routing algorithms are able to work with non-convex fault regions. In particular, some of them assume that faults are covered by solid fault regions. A solid fault region in an  $n$ -dimensional mesh is a region where any 2-D cross section of the fault region produces a rectangular fault region. In this case, the concept of fault ring is used to route messages around

the fault region. In this case, four virtual channels are required to ensure deadlock-freedom.

In [15], the authors propose a new fault-tolerant routing methodology based on the use of intermediate nodes. In order to avoid faults, for some source-destination pairs, packets are first sent to an intermediate node and then from this node to the destination node. Deadlocks are avoided by moving packets to a different virtual channel when crossing the intermediate node. Fully adaptive routing is used along both subpaths. In order to increase the level of fault-tolerance intermediate nodes are used together with disabling adaptive routing and/or using misrouting on a per-packet basis. The methodology uses a static fault model but tolerates a reasonably large number of faults without disabling any healthy node and only requires an additional virtual channel.

The preceding fault-tolerant routing algorithms rely on the use of virtual channels; however, virtual channels affect the speed and complexity of the switches. Software-based fault-tolerant routing is an approach that is not based on the use of virtual channels. When a packet encounters a fault, it is ejected from the network and is later injected and routed through an alternative path. This mechanism is very flexible and supports many fault patterns, without requiring assuming healthy nodes as faulty nor requiring additional virtual channels. However, some packets may suffer high latencies due to the packet ejection and reinjection, and memory bandwidth at the node where the injection/reinjection is performed is consumed.

## Fault-Tolerant Routing in Indirect Networks

The fault-tolerant proposals can be classified depending on whether they are applicable to unidirectional or bidirectional MINs. In UMINs, if they use the minimal number of stages, there is a unique path for each source-destination pair. In BMINs, the topology provides several paths for each source-destination pair. In particular in BMINs topologies, if the number of faulty components is smaller than the arity of the switches, then the topology provides at least a path between each source-destination pair, and therefore the routing algorithm may communicate any pair of nodes. This is true except for switch and link failures of the first and last stages, where the nodes directly

attached to the faulty components get disconnected from the rest of the network. So defining deadlock-free fault-tolerant routing algorithms is easier in BMINs topologies.

Some fault-tolerant routing algorithms for UMINs are based on misrouting packets by routing them in multiple passes [8, 9]. The packets that would cross the faulty elements are routed through other nodes of the network. In this way packets can avoid the faults. The drawback of using such technique is that these algorithms rely on a static fault model, inject the packet into the network several times, provide non-minimal paths, and increase the average packet latency. This technique can also be applied in BMINs.

In MINs, there are also proposals of disabling healthy nodes or network elements with poor network connectivity with the aim of making the routing easier after the occurrence of the faults. This approach is followed in [10] where the authors propose to create a new, but equivalent, topology from the faulty one, thus preserving the routing algorithm at the cost of disabling some healthy nodes and network elements.

The previous proposals are based on a static fault-model. But there are other proposals that use a dynamic fault model. In particular, some proposals exploit the high number of alternative paths of BMINs to provide fault-tolerance, such as the proposal made in [11, 12]. In these papers, when a fault is detected, the network reconfigures the routing information at the switches or nodes, and paths that would use any of the faulty network elements are disabled. This provides a good fault-tolerance at almost no overhead in cost. There are several works that mix this proposal with replication of links to increase the number of routing options, increasing the cost of the network.

A more recent technique is based on misrouting the packets when they encounter a fault without ejecting the packet from the network [13] and without using additional hardware. The authors provide a wide analysis to ensure that the misrouted packets cannot form a deadlock.

### Definition

A multistage network is a network for interconnecting a set of nodes through a switching fabric. These nodes can either be programmable computers or memory blocks. The switching fabric consists of a set of switches interconnected to form a *topology* with defined connection points for the nodes. The switches are organized in stages. A switch may have zero, one or more connection points, thus differentiating *multistage* networks from *direct* networks where every switch must have at least one connection point and *indirect* networks in general which have a less strict switch organization.

### Discussion

#### Introduction

Multistage networks are an approximation to the ideal network in terms of *bisectional bandwidth*, communication latency, and the number of concurrently communicating pairs in the network. In order to best understand this it is helpful to view the multistage networks in terms of a telephone exchange system, which is where the concept first emerged.

An old-fashioned telephone switchboard had a number of input channels, output channels, and internal switching points (the leads used to connect to telephone lines). As long as the switchboard had enough internal switching points it was possible to connect any two free phone lines together and allow them to communicate. In that case the switchboard was *nonblocking*. However, without enough leads to connect to telephone lines two parties wishing to initiate a phone call might have had to wait until one of these leads were available before the call could be initiated. In that case the switchboard was *blocking*.

As the telephone network grew a single switchboard was not sufficient to connect all the endpoints without becoming prohibitively large. The solution was to create a network of the switchboards so that a telephone call might have to traverse multiple switchboards.

As the size of the switchboards and the number of switchboards increased the challenge became to maintain the nonblocking capabilities of the network to as large an extent as possible. This led to the advent of multistage networks (clos networks) which will be discussed below.

The concepts from the telephone network can be more or less directly transferred to computer networks, with the important addition of *packet switching* in addition to the *line/circuit switching* used by the telephone network. The rest of this chapter focuses on packet switched multistage networks, as they are the ones most commonly found in current computer systems.

Multistage networks are commonly found in tightly coupled networks such as networks used in computer clusters, within switches, or in single chips. Here the nonblocking concept is often modified to *statistically nonblocking* as discussed further down. It is in these domains that multistage networks have been most extensively studied.

#### Topologies

As for direct networks, the topology of a multistage network can be modelled as a graph  $G(V, C)$  where  $V$  is the set of switches and  $C$  is the set of links (unidirectional or bidirectional) interconnecting the switches. The processing nodes are usually not included in the model. In addition, a regular multistage network can be modelled as an  $N \times M$  network with  $N$  inputs and  $M$  outputs. It is not uncommon that  $M$  equals  $N$ .

Depending on the size of  $N$  and  $M$  there are practical limitations on how these can be interconnected in a topology. The ideal topology is the crossbar (discussed below), and for small  $N$  and  $M$  this is indeed a practical implementation. However, as  $N$  and  $M$  increase, implementing a crossbar becomes impractical. A common solution to this problem is to implement the network in multiple stages as a multistage network.

### Crossbar

The crossbar is perhaps the most ideal network topology. Given  $N$  nodes to be interconnected, an  $N \times N$  crossbar allows  $N$  one-to-one interconnections without contention, i.e., it is nonblocking. A node can send data to any other node that is not already receiving data without having to wait for capacity in the crossbar. This lack of contention allows the connection points in the crossbar to be implemented as very simple arbiters. The crossbar has very high bisectional bandwidth that scales linearly with the size of the crossbar, and because of its simplicity the time used to cross it is very low. A simple crossbar is visible in Fig. 1.

The high degree of connectivity of the crossbar makes it a quite expensive topology to implement. The cost of it is  $O(N^2)$ , indicating that it does not scale well beyond small sizes. Because of this, the crossbar is often used to interconnect the input and output ports of a switch itself, and the switches are again interconnected

to create larger networks to overcome the scaling problem of the crossbar. The largest single-chip crossbar switches in commercial production at the time of writing typically have around 36 ports.

### Multistage Networks

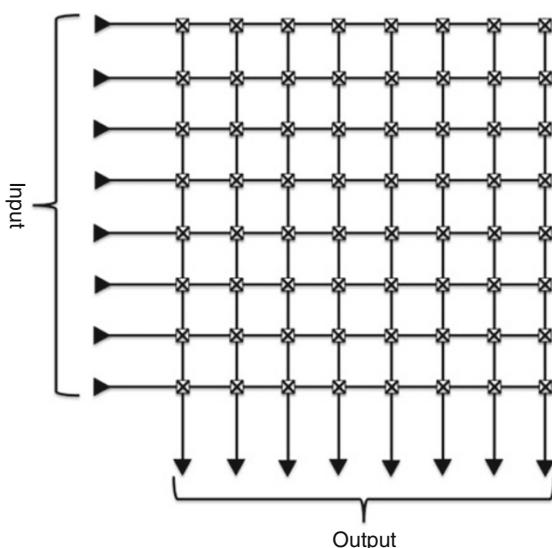

In order to solve the problem of scalability of the crossbar and still maintain its nonblocking properties, Charles Clos introduced nonblocking switching networks in 1952. While the work was originally intended for the telephone networks, the concept of nonblocking switching networks has, together with the crossbar, been transferred to the packet-switched computer networks domain. The types of networks he introduced are often called clos networks.

The basic idea behind clos networks is to connect switches in an odd number of switching stages, with one or more switches at each stage. This idea has been greatly extended since its inception, resulting in a class of networks called Multistage Networks. The common way of denoting a multistage network is by giving the number of stages in the network, the sizes of the switches that make up the stages, and the permutations that determine the interconnections between the stages.

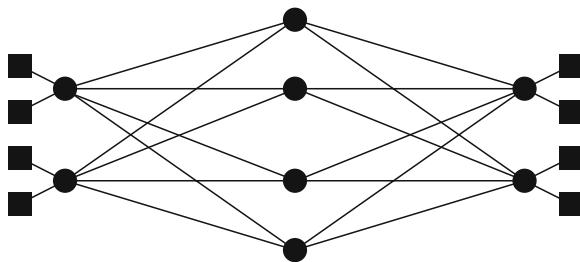

Going back to the original work by Clos, the minimum number of stages for a clos network is three; an input stage, an output stage, and a middle stage. The number of switches and the number of ports on each switch for the three different stages determines the number of nodes that can be connected and the communication properties of the network.

For the three stage networks, every switch at the input side of the multistage network has  $n_1$  input ports and  $m$  output ports. There are  $m$  middle stage switches with  $r_1$  input ports and  $r_2$  output ports. Finally, the output stage consists of  $r_2$  switches with  $m$  input ports and  $n_2$  output ports. It is the relationship between these variables that determines the blocking characteristics of the multistage network as discussed in the next section. Figure 2 shows a three-stage clos network with four middle-stage switches and  $n_1 = 2, m = 4, r_1 = r_2 = 2$ , and  $n_2 = 2$ .

The permutation defines how the switches are interconnected between the stages. This affects scheduling of the packets to cross the topology, and also any degree of redundancy that may be available for use for fault tolerance.

**Networks, Multistage.** Fig. 1 An 8 × 8 crossbar

**Networks, Multistage.** Fig. 2 A three stage clos network

For a fixed switch size (e.g.,  $2 \times 2$ ) increasing the number of inputs and outputs supported by the topology is achieved by increasing the size of the middle-stage switches. By recursively replacing the middle-stage switches with three-stage clos networks based on smaller switches, the large switches can be replaced by  $2 \times 2$  switches at the cost of increasing the number of stages in the network. Even though the number of stages in the network is increased this makes sense from a cost perspective because  $2 \times 2$  switches are quite inexpensive and fast. However, the overall latency of the network will in many cases increase.

### Blocking Characteristics

The switch sizes, the number of stages, and the number of switches at the middle stage also determine the blocking characteristics of the MIN. Pure clos networks are *strictly nonblocking*, i.e., regardless of any pre-existing paths set up through the network, it is always possible to find a path between two idle connection points. In terms of the parameters defined above it is required for the network to be strictly nonblocking that  $m \geq 2n - 1, n = n_1 = n_2$ . As the size (in terms of switches and switch sizes) of the middle stage decreases, the degree of blocking in the network increases. Some MINs are *rearrangeable* (e.g., Benes networks) where it is always possible to set up a connecting path between two idle nodes by moving pre-existing paths around in the network.

Other blocking characteristics also exist based on how and when pre-existing paths through the topology are moved around to accommodate further communication pairs.

### Unidirectional MINs

Multistage networks can either be unidirectional or bidirectional. This section considers the unidirectional topologies.

A unidirectional MIN consists of a series of two or more switching stages where packets always move from an injection point at the left side to an ejection point at the right side. To allow bidirectional communication between nodes each injection and ejection pairs are connected to a single node, usually by a short link to the ingress and a long link to the egress. MINs are usually designed in such a way that it is possible to move from any injection point to any ejection point in a single pass through the network.

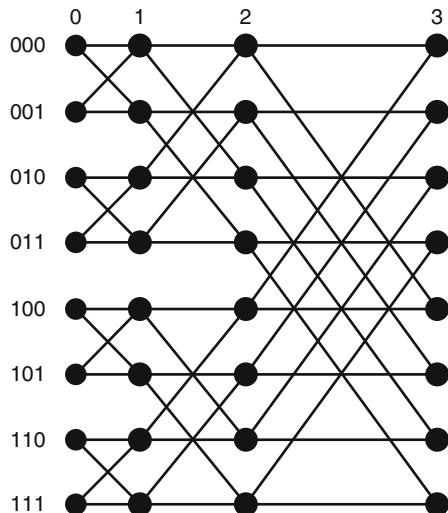

A large number of connectivity permutations (different ways of interconnecting switches at neighboring stages) have been proposed for unidirectional MINs. This includes the shuffle-exchange, the Butterfly, Baseline, Cube, Omega, and the Flip to name a few. All of the topologies mentioned here are isomorphic, or topologically equivalent. This means that any one topology can be converted to any of the other topologies simply by moving the switching elements and the endpoints up and down within their stages.

Aside from these a large number of other unidirectional MIN topologies also exist, such as the Benes network, which provides more than one path between each pair of nodes.

Each of the existing topologies represents a trade-off between implementation complexity, blocking versus nonblocking, the ability to route from a single source to multiple destinations in one pass through the topology, partition ability, fault tolerance, and the number of switching stages required to realize these properties.

An important characteristic of unidirectional multistage networks is that the path length to any destination is constant. This is an important characteristic with regards to scheduling packets as it helps to make the network very predictable.

**Butterfly** The Butterfly, or  $k$ -ary  $n$ -fly, is one of the most commonly mentioned topologies when discussing multistage networks.  $k$  and  $n$  represent the number of ports in each direction of every switch and the number of switching stages, respectively. The connection between any two switches at two neighbouring stages is defined

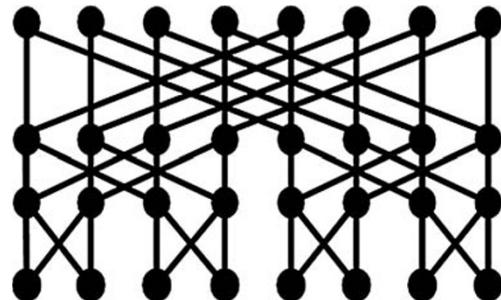

**Networks, Multistage. Fig. 3** A four stage butterfly

by the following function. The interconnection pattern is illustrated in [Fig. 3](#).

Let every outgoing switch port be identified by a  $n$ -digit number (tuple) where each digit  $x$  can have the values from 0 to  $k - 1$ ,  $\{x_{n-1}, x_{n-2}, \dots, x_0\}$ .  $\{x_{n-1}, x_{n-2}, \dots, x_1\}$  corresponds to the switch number and  $x_0$  is the port number on that switch. The connection from a port  $a_{i-1}$  at stage  $i-1$  (enumerated from 0 on the left) to a switch  $b_i = \{b_{n-1}, b_{n-2}, \dots, b_1\}$  at stage  $i$  is given by exchanging the first digit ( $x_0$ ) with the  $i$ 'th digit  $x_i$ . For instance, port 000, which is port 0 on switch 00 at stage 0, is connected to switch 00 at stage 1. Port 001, which is port 1 on switch 00 at stage 0, is connected to switch 01 at stage 1, and so on. In this manner, a Butterfly network of any size may be constructed.

### Bidirectional MINs

Unidirectional MINs are a very old development, and most modern-day systems use bidirectional channels. The bidirectional channels can be used to construct bidirectional multistage networks. These topologies have usually been derived from unidirectional MINs by “folding.” In simple terms, all end nodes are connected to only one side of the topology. In order to reach any other end node packets is moved to the right in the network until they reach a switch that is also reachable by the destination node. At this point the direction

**Networks, Multistage. Fig. 4** A common fat tree, a 2-ary 4-tree

reverses and the packet travels to the left, towards its destination.

The consequence is that, contrary to unidirectional MINs where all path lengths were equal, the path length from a specific source to different destinations may be different. In fact, the destinations can be grouped by locality with respect to a specific source, yielding a hierarchical representation of the distance of the destinations.

**Fat Tree** The most commonly used class of multistage networks are fat trees. The fat tree was introduced as a topology by C. Leiserson in 1985. In its original inception, the fat tree was presented as a tree topology with a single root (a tree topology is a multistage network). What made the topology unique was that the aggregate bandwidth of all links between any two tiers in the tree was constant. This was achieved through simply increasing the link bandwidth at every tier.

Increasing the link bandwidth and switch capacity is not a viable approach for large bandwidth systems, so fat trees are in practice most often implemented as folded clos topologies. Contrary to unidirectional networks, fat trees/folded clos networks are most often represented in a vertical manner instead of horizontal, with the end nodes connected to the bottom of the network. Depending on the exact interconnection pattern and the number of switches at the different tiers, the connections of a fat tree are often described as a  $k$ -ary  $n$ -tree or  $m$ -port  $n$ -tree, where  $m$  is the number of switch ports and  $k = m/2$ .  $n$  is the number of tiers in the tree. An example topology is depicted in [Fig. 4](#).

The fat tree is a very popular topology in modern supercomputers because of its universal nature. Averaged over all possible traffic patterns, the fat tree shows the best mean performance. This means that for general purpose computers designed to solve a multitude of different problems, the fat tree is well-suited. There exists, however, a number of specific problem domains such as physical simulations that are better handled by direct networks such as meshes or tori (see the Chap. Direct Networks).

## Routing Functions

Many of the multistage networks are *self routing*. This means that the path through the network to the destination is completely determined by the destination address. At each stage the output port is determined by the corresponding tuple in the destination address. This allows for very simple routing logic and helps to maintain the high performance of the networks.

Many direct networks must follow routing restrictions in order to guarantee deadlock freedom. This means that it is difficult to achieve the maximum theoretical performance from the topology. On the other hand, all the types of MINs described here support minimal deadlock-free routing without any limitations. This means that as long as a packet moves towards the destination, any output port can in principle be selected without risking deadlock.

For modern large-scale implementations, it is common to use routing tables since the systems often are built using commodity hardware that are routing table-based. So, even though any path is deadlock free, the exact path chosen for a given destination is determined by a specific *routing algorithm* in use, whether it is *adaptive* or *deterministic*, and in the latter case, the deterministic path that has been set up for the destination.

## Multistage Networks Today

Multistage networks are a very old research topic. Unidirectional MINs have been extensively studied in order to create topologies that support all desired properties for any given application. This interest has abated significantly in the last decade, mainly because the industrial forces have not shown enough interest in the developments in this field.

In contrast to this, the interest for bidirectional MINs, and specifically the fat tree, has grown in recent years. This is especially evident when looking at the list of the 500 fastest supercomputers in the world. The systems that are not specifically tailored towards applications that require tori-like structures are typically fat trees. This has led to a sustained research interest into how to most efficiently route traffic through the fat tree in a manner that achieves good balancing for a wide variety of traffic patterns.

Another challenge that is actively researched is the best way to efficiently utilize the large degree of redundancy in fat trees. This may be exploited either for increased performance through multipath routing or to achieve fault tolerance.

## Future Directions

Fat trees will continue to be an important topology for high-performance computing. As the number of ports supported by commodity off-the-shelf switching hardware increases, it becomes possible to build larger and larger fat trees without increasing the number of tiers of the topology. Alternatively, the increased switch sizes can be exploited to keep the same topology size and to reduce the number of tiers. This is equivalent to a reduction in latency, which is an important parameter in high-performance computing.

Another area where fat trees lend themselves well is in hierarchical communications schemes. A typical example of this is memory systems where a computing core is connected to different levels of cache. Each cache level is larger than the previous and is located further away. At the very end there are typically the RAM chips. By connecting the processing cores to one subset of the tree, and the memory modules to other subsets of the tree that are sequentially further and further away, the hierarchical nature of the memory is replicated to some degree. As the processing scale decreases and more and more memory fits onto a single chip, there might be a need for such approaches to allow scalability and flexibility in the memory management.

## Bibliographic Notes and Further Reading

The first presentation of multistage networks was done by Charles Clos [1]. There exists a huge number of publications on typical multistage networks, and a simple overview of the characteristics of clos networks is given in [4]. Other good introductions to the topic of multistage networks can be found in the books by Duato et al. [3] and Dally et al. [2].

The seminal paper on fat trees was published by Charles Leiserson [5]. This also spawned an extensive amount of work focusing on both reducing the redundancy to achieve cheap topologies with the same characteristics [9], and on utilizing the redundancy for fault tolerance [8] and high-performance. The fat tree structure is originally quite strict. This has been extended [10] to support a more flexible structure. This is important since most actual implementation of this topology deviates from the strict fat tree definition. The common multiple root definitions of fat trees are  $k$ -ary  $n$ -trees [7] and m-port n-trees [6].

## Non-Blocking Algorithms

DANNY HENDLER

Ben-Gurion University of the Negev, Beer-Sheva, Israel

## Synonyms

- Lock-free algorithms

## Definition

Non-blocking algorithms are shared-memory multiprocessor algorithms that can avoid race conditions and guarantee correctness without using mutual exclusion

locks. They are in general more resilient to asynchronous conditions than lock-based algorithms since they guarantee progress even if some of the threads participating in the algorithm are delayed for a long duration or even fail-stop. (The definition of the terms “non-blocking” and “lock-free” has changed in recent years, creating some terminology confusion. In the past, an algorithm was called “non-blocking” if it guaranteed global progress and “lock-free” if it did not rely on mutual exclusion locks. In recent years, most authors call an algorithm “lock-free” if it guarantees global progress and “non-blocking” if the delay of some threads cannot delay other threads indefinitely. This entry adopts the latter terminology since it is more widely used nowadays. Precise definitions are provided later in the sequel.)

## Discussion

### Introduction

To ensure correctness, shared-memory multiprocessor algorithms (also called *concurrent algorithms*) must employ inter-thread synchronization for precluding concurrency patterns that result in *race conditions* – situations in which correctness depends on the order in which steps by different threads are scheduled.

The traditional approach for inter-thread synchronization is to use *blocking* (lock-based) mechanisms, such as mutex locks, condition variables, and semaphores, for ensuring that conflicting critical sections of code do not execute concurrently. Synchronization based on only a small number of locks (*coarse-grained locks*), each protecting a large portion of data, may restrict parallelism too much and is not scalable. On the other hand, when numerous locks are being used (*fine-grained locks*), it becomes difficult to avoid correctness issues such as deadlocks, convoying, and priority inversion. Moreover, the failure of a thread that holds a lock may prevent other threads from making progress.

Non-blocking algorithms take a different approach and can ensure correctness without using locks. Non-blocking synchronization is more resilient to asynchrony conditions than blocking synchronization since thread delays or failures do not prevent other threads from making progress.

### Progress and Correctness Guarantees for Non-blocking Algorithms

Non-blocking algorithms can be characterized according to the type of progress they ensure. The key progress guarantees provided by non-blocking algorithms are the following:

1. *Wait-freedom* [15] ensures that a thread will always complete its operation in a finite number of its steps regardless of the progress of other threads. Wait-free algorithms thus guarantee the individual progress of any non-failed thread.
2. *Lock-freedom* [15] ensures that *some* thread will complete its operation after a finite number of steps is taken by the participating threads. Lock-free algorithms thus guarantee global progress, but individual threads may starve (they might never complete their operation).
3. *Obstruction-freedom* [21, 22] ensures that any thread that *runs in isolation* (i.e., it is the only thread taking steps) from some point on will complete its operation in a finite number of its steps. If no thread runs solo long enough, then obstruction-free algorithms may suffer from *live-lock*, where threads constantly interfere with one another and none of them completes its operation.

It is easily seen that wait-freedom implies lock-freedom which, in turn, implies obstruction-freedom. The converse implications are false: an obstruction-free algorithm is not necessarily lock-free, and the latter is not necessarily wait-free.

The *correctness* condition of a concurrent data structure specifies how to derive the semantics of concurrent implementations of the data structure from the semantics of the corresponding sequential data structure. This requires to disambiguate the expected results of concurrent operations on the data structure.

Two common ways to do so are *sequential consistency* [25] and *linearizability* [19]. Both require that the values returned by the operations appear to have been returned by a sequential execution of the same operations; sequential consistency only requires this order to be consistent with the order in which each individual thread invokes the operations, while linearizability further requires this order to be consistent with the real-time order of nonoverlapping operations.

The vast majority of the non-blocking synchronization literature considers linearizable (also called *atomic*) implementations.

## Base Objects and Primitive Operations

Concurrent algorithms in general, and non-blocking algorithms in particular, are used to implement *concurrent objects* such as concurrent counters, queues, hash-tables, and so on. Concurrent objects are typically implemented from simpler *base objects*. The simplest base objects in a given system are its memory locations. The system's hardware or operating system provide *primitive operations* that can be applied to memory locations.

The familiar atomic *read* and *write* primitive operations are assumed to be provided by all systems. In the shared-memory nomenclature, a memory location that supports the read and write operations only is called a *register*. It has been shown [15] that registers alone cannot support non-blocking implementations of even the most basic data structures, like queues and stacks. This and other evidence on the relative weakness of reads and writes have led much of the research on non-blocking algorithms to assume the existence of stronger primitive operations. The most notable of these is *compare and swap* (often denoted CAS), which takes three arguments: a memory address, an expected value, and a new value (Fig. 1). If the address stores the expected value, it is replaced with the new value; otherwise it is unchanged. The success or failure of this operation is then reported back to the program. It is crucial that this operation is executed *atomically*; thus an algorithm can read a datum from memory, modify it, and write it back only if no other thread modified it in the meantime. CAS can be used, together with reads and writes, to implement any object in a wait-free manner [15]. It has consequently become a synchronization primitive

```
compare-and-swap(w,expected,new)
 if(*w==expected)
 then
 *w=new,return success
 else
 return failure
fetch-and-add(w,Δ)
 curVal=*w
 *w=curVal+Δ
 return curVal
```

**Non-Blocking Algorithms. Fig. 1** The *compare and swap* and *fetch and add* primitive operations

of choice, and hardware support for it is provided in many multiprocessor architectures.

Another widely available primitive operation is the *fetch and add* primitive (denoted FAA), which takes two arguments: a memory address storing an integer value and an integer  $\Delta$ . The FAA operation atomically increases the integer stored at the argument address by  $\Delta$  and returns its previous value. The pseudo-code of the CAS and FAA primitive operations is shown below.

To exemplify the use of the CAS and FAA operations, consider the implementations of a concurrent *counter* object shown in Fig. 2. A counter supports a single operation *fetch-and-inc*, which atomically increments the counter value by 1 and returns its previous value. The *fetch-and-inc* operation can be trivially implemented in a wait-free manner by applying the FAA operation with  $\Delta = 1$ .

Using CAS, the *fetch-and-inc* operation can be implemented by reading the current counter value (this is the expected value), adding 1, and then using CAS for attempting to update the counter. If no other thread modifies the counter between the read and CAS operations, the CAS will succeed, and the counter will be updated. However, if a concurrent modification does occur, the CAS will fail, and the thread will repeatedly retry the update (by first reading the new value of the counter) until it is successful (if it ever is). This algorithm is not wait-free since other threads may keep incrementing the counter and make a specific thread repeatedly fail. It is lock-free since a failure of a CAS operation implies that a CAS operation by a different thread succeeded between when the expected value was read and the failing CAS was attempted.

N

## Theoretical Foundations

As shown above, the FAA operation can be used to implement a counter in a wait-free manner. Can a wait-free counter be implemented by using only read and write operations? Can the CAS operation be implemented in a wait-free manner by using only read, write, and FAA operations? It turns out that the answer to both these questions is negative. The foundations of the rich theory underlying non-blocking synchronization were laid down in 1991 by a seminal paper of Herlihy [15]. Quoting from [15]: “The fundamental problem of wait-free synchronization can be phrased as follows: given two concurrent objects X and Y, does there exist

```

class Counter {
 private int val=0
 int fetch-and-inc()
 return fetch-and-add(&val,1)
 }
}

class Counter {
 private int val=0,exp
 int fetch-and-inc()
 do
 {exp=val}
 until CAS(&val,exp,exp+1)=success
 }

```

**Non-Blocking Algorithms.** Fig. 2 Implementing a counter object from *fetch and add* and from *compare and swap*

```

class Consensus {//Code for thread $i \in \{0,1\}$
 private Counter c initially 0
 private register vals[0..1]
 boolean decide(Vv){
 vals[i]=v
 if c.fetch-and-inc()==0
 return v
 else
 return vals[1-i]
 }
}

```

**Non-Blocking Algorithms.** Fig. 3 A two-thread consensus implementation from counter objects and registers

a wait-free implementation of X by Y?" Herlihy introduced powerful techniques for obtaining the answers to such questions. These techniques are based on reductions to the consensus object.

A *consensus object* supports a single operation called *decide*, which every thread may call with its input at most once. The *decide* operation must satisfy the following requirements.

- *Agreement*: all terminating calls of *decide* (that is, all calls made by threads that do not fail while executing the *decide* operation) must return the same value. In other words, all threads agree on the same value.
- *Validity*: the common decision value is the input of some thread.

A *consensus number* is associated with each object type, specifying the maximum number of threads for which the object type can implement consensus in a wait-free manner. More specifically, if object type X has consensus number  $CN(X)$ , then a wait-free consensus object, shared by  $CN(X)$  or fewer threads, can be implemented by objects of type X and registers; however, a wait-free consensus object that is shared by more than  $CN(X)$  threads cannot be implemented by objects of type X and registers.

For instance, Herlihy proves [15] that the consensus number of a register is 1. This means that registers can (trivially) implement wait-free consensus for only a single thread but cannot be used to implement wait-free consensus for two or more threads. As shown in Fig. 3, a counter object can implement wait-free consensus for two threads. Herlihy proves also [15] that wait-free consensus shared by 3 or more threads cannot be implemented by any number of counter objects and registers. Thus, the consensus number of a counter is 2. It follows that a wait-free implementation of a counter from registers, shared by two threads or more, is impossible.

An object type X is called *universal* if any object can be implemented from instances of X and registers in a wait-free manner. Herlihy proves that an object is universal in a system of  $n$  threads if and only if it has consensus number at least  $n$ . The universality of consensus is established by presenting a *universal construction* algorithm (using consensus objects and registers) that can implement any object in a wait-free manner. Consensus is not the only universal object: Herlihy shows that the CAS object has consensus number  $\infty$ . It follows that CAS can be used, together with read and write, to implement any object (shared by any number of threads) in a wait-free manner. The CAS operation has consequently become a synchronization primitive of choice, and hardware support for it is provided in many multiprocessor architectures.

The concepts of consensus-numbers and universality imply that there is a hierarchy of objects (called the *wait-free hierarchy*), where objects are placed in hierarchy levels according to their consensus numbers, such that (1) an object at level  $l$  cannot implement objects at level  $m > l$ , shared by more than  $l$  threads, in a wait-free manner, and (2) an object at level  $l$  (together with registers) is universal in  $l$ -thread systems.

The table below presents the consensus numbers of several concurrent objects.

| Consensus number | Objects                                                        |
|------------------|----------------------------------------------------------------|
| 1                | Read/write registers                                           |
| 2                | Fetch and add, swap, test and set, stack, queue                |
| :                | :                                                              |
| m                | m-enqueues augmented queue                                     |
| :                | :                                                              |
| $\infty$         | Compare and swap, load-link/store-conditional, augmented queue |

CAS, the *load-link/store-conditional* pair of operations (a weak version of which is implemented on some IBM architectures), and the augmented queue object (a queue that supports a *peek* operation that returns the value of the first queue item, in addition to *enqueue* and *dequeue* operations) all have consensus number  $\infty$  and are therefore universal in any system. It is noteworthy that all levels of the hierarchy are populated (An *m-enqueues augmented queue* is an augmented queue that allows at most  $m$  enqueue operations and starts returning a  $\perp$  response after the  $(m + 1)$ 'st enqueue operation is applied to it [7]).

The impossibility and universality results presented in [15] and summarized above hold also for lock-free implementation but do not hold for obstruction-free implementations: there are obstruction-free implementations of any object from read and write operations only [22]. An objects hierarchy is called “robust” if objects at lower levels cannot be used to implement objects at higher levels. Jayanti [24] showed that the wait-free hierarchy is not robust if consensus numbers are defined so that implementations cannot use registers or can only use a single object of the lower type.

## Algorithms and Design Considerations

Non-blocking synchronization has been the focus of intense research in recent years, and numerous non-blocking algorithms have been published. A few such algorithms are described in the following, mainly for highlighting the design principles underlying them.

A register is called *safe* if a *read* operation that does not overlap a *write* operation returns the value

written by the most recent *write* operation (or the initial value if there are no preceding *write* operations) but may return any value if there is a concurrent *write* operation. A register is *single-writer single-reader* if it can only be used for unidirectional communication between two specific threads, one of which may write the register and the other may read it. A register is *multi-writer multi-reader* if multiple threads may read and write to it. Lamport [26, 27] defined various register types based on the number of threads that are permitted to read and write them and their correctness guarantees. A series of constructions established the rather surprising result that binary safe single-writer single-reader registers can be used to implement the much stronger atomic multi-writer multi-reader registers in a wait-free manner. (They are simply referred to as *atomic registers* in the rest of the text.)

The atomic *snapshot* object [2] allows a thread to take an instantaneous snapshot of an array of registers. It supports two operations: the *update* operation writes a value to the calling thread's register, and the *scan* operation returns an instantaneous snapshot, that is, a state of the array that existed at some point during the execution of the *scan* operation. The ability to obtain an instantaneous snapshot in a wait-free manner can simplify the design of non-blocking algorithms. Indeed, the snapshot object is used as a building block of non-blocking implementations of key objects such as *k-set consensus*, *approximate agreement*, and *renaming* (see [7], Chapter 16).

N

## Helping

A wait-free implementation of the snapshot object from atomic registers is given in [2]. In this implementation, *update* operations help *scan* operations by performing an embedded scan themselves and storing the resulting snapshot value along with the value they write. This is an example of a general design principle underlying many wait-free implementations, called *helping*: operations may need to assist other operations to prevent starvation. A helping mechanism is also used in Herlihy's universal wait-free construction [15], where each thread, before performing its own operation, chooses another thread and checks if it requires help; if it does, it first performs the other thread's operation and only then performs its own operation.

## The ABA Problem and Safe Memory Reclamation

Many non-blocking implementations of concurrent objects based on strong synchronization operations have been presented, including (but not limited to) counters, stacks, queues and double-ended queues, linked lists, sorting networks, hash tables, skip lists, priority queues, and renaming objects (See [18] for a comprehensive discussion of such implementations). Most of these implementations use *unary* atomic operations (i.e., operations that are applied to a single memory location) such as CAS, FAA or *test-and-set*, but some implementations are based on *multi-word* operations such as *double compare and swap*.

Since the CAS operation is available on most modern multiprocessor architectures, and because it can be used to implement any object in a wait-free (hence also lock-free) manner, CAS is used by many non-blocking algorithms. CAS-based algorithms often have to deal with a problem of CAS called the *ABA problem*. The ABA problem occurs when a thread  $t$  reads some value  $A$  from a memory address  $m$ , then some other threads change  $m$ 's value from  $A$  to a different value, say  $B$ , and back again to  $A$ , and finally  $t$  attempts to swap  $m$ 's value from  $A$  to some other value by using CAS; the CAS will then succeed. The correctness of the implementation may be compromised if it depends on the assumption that the CAS must fail if  $m$ 's value changes between the read and the CAS applied to it by  $t$ .

A simple solution to the ABA problem is to associate a reference counter with the application value and to increment it whenever the application value is modified by CAS. This requires packing the application value and reference counter within a single machine word, reducing the number of bits that can be used for storing application values. For some applications, and especially on 64-bit machines, this may be a satisfactory solution; for other applications, however, reducing the domain size of application values is infeasible.

The ABA problem is closely related to the problem of safe memory reclamation. A thread must not recycle (i.e., initialize and then re-use) a dynamic memory structure, even after it was logically removed from the data-structure, while other threads may still be holding references to this structure, which they may later use to access it. Violating this rule may compromise the implementation's correctness. Specifically, unsafe

memory reclamation may result in the ABA problem occurring for CAS operations that attempt to swap a pointer value; in such scenarios, the swap may succeed instead of failing and corrupt the implementation's data-structure.

General schemes for safe non-blocking memory reclamation exist [23, 29]. Michael [29] proposed a wait-free safe memory reclamation technique that uses *hazard pointers*. (The scheme described in [23] uses similar ideas.) Informally, an access to a dynamic memory structure is called *hazardous* if the structure may be concurrently recycled by other threads. With Michael's scheme, each thread owns some (typically small) number of hazard pointers. Before making a hazardous access to structure  $s$ , a thread  $t$  sets one of its currently unused hazard pointers to point to  $s$ ; then,  $t$  verifies (in some application-dependant manner) that  $s$  is still logically part of the algorithm's data-structure. If the verification succeeds,  $t$  can safely access  $s$  as the scheme now guarantees that  $s$  will not be recycled as long as  $t$ 's hazard pointer points to it. If the verification fails, implying that  $s$  is no longer part of the data-structure,  $t$  proceeds to handle this situation in an application-dependant manner. After a dynamic memory structure is logically removed from the data-structure, it is designated as a candidate for memory recycling but will only be recycled when no hazard pointers point to it.

## Memory Contention and Adaptive Algorithms

The number of steps performed by a thread in the course of performing an operation on the implemented data-structure is not the only factor that contributes to the time complexity of non-blocking algorithms. In practice, the performance of non-blocking algorithms is often limited by *memory contention* [12], the extent to which multiple threads access widely-shared memory locations simultaneously. The degradation in performance that is caused by contention is the result of limitations on the bandwidth of both memory and processor-to-memory interconnect.

Important properties of a non-blocking algorithm are therefore (1) the extent by which threads executing the algorithm may encounter memory contention as they execute their steps, and (2) whether the algorithm's step complexity is a function of the total number of processes that *may participate* in the execution or

a function of the number of threads that *actually participate* in the execution (as captured by the memory contention encountered by an operation).

There are several ways to measure contention during the interval of an operation  $op$ . The *total contention* [5] of an execution is the number of threads that ever took steps in the execution. The *interval contention* [3] of  $op$  is the number of threads whose operations are concurrent with  $op$ . The *point contention* [6] of  $op$  is the maximum number of operations *simultaneously* concurrent with  $op$ . Finally, the *step contention* [10] of  $op$  is the number of threads that take steps during  $op$ 's execution interval. An implementation is *adaptive* to (total, interval, point or step) contention if the step complexity of an operation is a function of the contention during the operation interval. By definition, algorithms with adaptive step complexity are wait-free. Yet another measure of contention is *hot-spot contention* [12], defined as the maximum number of threads simultaneously poised to access the same memory location.

Reducing memory contention and designing algorithms that are adaptive to different measures of contention has been the focus of the design of many non-blocking data structures. Some examples include: *Counting networks* [4, 20], which are highly concurrent wait-free implementation of a counter that eliminates sequential bottlenecks and reduce hot-spot contention; adaptive non-blocking implementations of *Collect* [1, 6, 9, 14], and adaptive wait-free implementations of *Renaming* [5].

## Non-blocking Algorithms: Pros and Cons

Non-blocking algorithms are one approach for implementing concurrent data-structures, but alternative approaches exist as well. In this section, the key alternative paradigms for concurrent multi-threaded programming are briefly described and the advantages and disadvantages of the non-blocking approach in comparison with these alternatives are discussed.

The traditional approach for inter-thread synchronization is to use mutual-exclusion locks. Fine-grained lock-based algorithms can be highly efficient but are error-prone and difficult to program. Coarse-grained lock-based algorithms, on the other hand, are much easier to program but, in general, are not scalable.

The key advantage of non-blocking synchronization in comparison to lock-based programming is its

resilience to asynchrony, since, in general, threads executing a non-blocking algorithm can make progress even when other threads are delayed or even fail. On the other hand, the design of wait-free and (to a lesser extent) lock-free algorithms is notoriously hard. Due to their design difficulty, obtaining efficient wait-free or lock-free implementation of basic data-structures is an active research topic in recent years.

Another disadvantage of wait-free and (to a lesser extent) lock-free algorithms is that they often incur high overhead in terms of time-complexity. As shown by Attiya et al. [8], there are problems for which the step-complexity of wait-free implementations is inherently higher than that of non-wait-free implementations. Wait-free and lock-free algorithms often use strong synchronization operations, such as CAS, that are slower than read and write operations, which also hurts their performance.

Designing obstruction-free algorithms, on the other hand, is easier and they have the potential of being faster in the lack of contention. However, obstruction-free algorithms may be susceptible to live-lock scenarios and require contention-management mechanisms for overcoming them.

*Transactional memory* (TM) [16, 31] is an emerging concurrent programming abstraction. Memory transactions allow a thread to execute a sequence of shared memory accesses whose effect is atomic: similarly to database transactions, a TM transaction either has no effect (if it fails) or appears to take effect instantaneously (if it succeeds). Some software transactional memory (STM) implementations are non-blocking, while others are lock-based. A key advantage of the TM programming abstraction is its simplicity: due to the atomicity provided by transactions, programmers can apply sequential reasoning and only need to consider executions that consist of transaction sequences for ensuring correctness.

On the other hand, since TM is a generic mechanism, it is likely that optimized direct non-blocking implementations of specific data-structures will be more efficient than TM-based implementation (assuming both implementations guarantee the same progress and correctness guarantees) but will be much harder to derive.

It is now accepted that no single programming methodology is a panacea for multi-threaded

programming. Instead, multiple approaches must be considered and possibly combined, depending on the application type and the target architecture.

## Further Reading

The textbooks by Attiya and Welch [7], Herlihy and Shavit [18], Lynch [28] and Taubenfeld [32] contain a wealth of information about Distributed Computing in general, and the theory and practice of non-blocking algorithms in particular.

Numerous lower bounds and impossibility results for both deterministic and randomized non-blocking algorithms, under various measures, were published over the last 20 years. One of the key developments of this very active area of research is the use of algebraic topology tools for proving impossibility results on the computability of wait-free decision tasks from read and write operations [11, 17, 30]. A detailed description of this research area is out of the scope of this entry, and the interested reader is referred to a comprehensive survey by Fich and Ruppert [13].

### Definition

NUMA is the acronym for Non-Uniform Memory Access. A NUMA cache is a cache memory in which the access time is not uniform but depends on the position of the referred block inside the cache. Among NUMA caches, it is possible to distinguish: (1) the NUCA (Non-Uniform Cache Access) architectures, in which the memory space is deeply sub-banked, and the access latency depends on which sub-bank is accessed; and (2) the shared and distributed cache of a tiled Chip Multiprocessor (CMP), in which the latency depends on which cache slice has to be accessed.

## Discussion

### Introduction

For the past decades, microprocessors' overall performance has been improved thanks to the continuous reduction of transistor size obtained in silicon fabrication technology. This scaling contributed in both (1) allowing designers to put on a chip more and more transistors, and thus to implement on the same die more and more complex microarchitectures, up to arrive to single Chip Multiprocessor (CMP) systems, and (2) increasing processors' clock frequencies.

As the memory bandwidth requirements of cores have increased as well, the increased number of on-chip transistors has also been used to integrate on the same die deeper and larger memory hierarchies. However, reducing feature sizes has also introduced the *wire-delay* problem: sizes of on-chip wires have been also reduced, resulting in larger delay for signals propagation [1]. In particular, considering a huge traditional on-chip cache, the wire delay and the increase of clock frequency lead to an increase of the latency experienced on each access. The bulk of access time involves signals' routing to and from cache banks and not the bank access themselves. Exploiting a non-uniform access time for on-chip caches is a viable solution to the wire-delay problem.

By allowing non-uniform access time also to cache memories, it is possible to design a cache composed by independently accessible banks, connected via a scalable connection fabrics, typically a Network-on-Chip (NoC) [2, 4, 5]. The overall cache access latency is proportional to the physical distance between the requesting unit and the accessed bank. This organization is called NUCA (Fig. 1b and c): banks close to the requesting unit can be accessed faster than a traditional monolithic cache. If the cache management policies succeed in keeping the most performance impacting blocks in such banks, the overall performance will be boosted. NUCA architectures have been proposed for both single-core [2, 3, 6, 7] and multi-core [4, 5, 8–13] environments.

Needs for scalability in CMP designs has lead to the design of CMP tiled systems that are composed by many identical nodes, called tiles. Each tile is composed by one cpu, its private cache levels, and the LLC. Nodes are typically connected through a NoC. In these systems,

the LLCs can be used as a globally shared cache, the LLC inside each node being a slice of the whole cache. Hence, the access time depends on respective position of the requesting node and of the memory slice involved in the access, and this results in a non uniform access time. Those systems results to be implicitly NUMA caches as a consequence of their tiled architecture, differently from NUCA architectures whose design explicitly focuses on the non-uniformity in access time in order to tolerate the wire-delay effects.

### NUMA Caches in the Single-Core Environment: NUCA

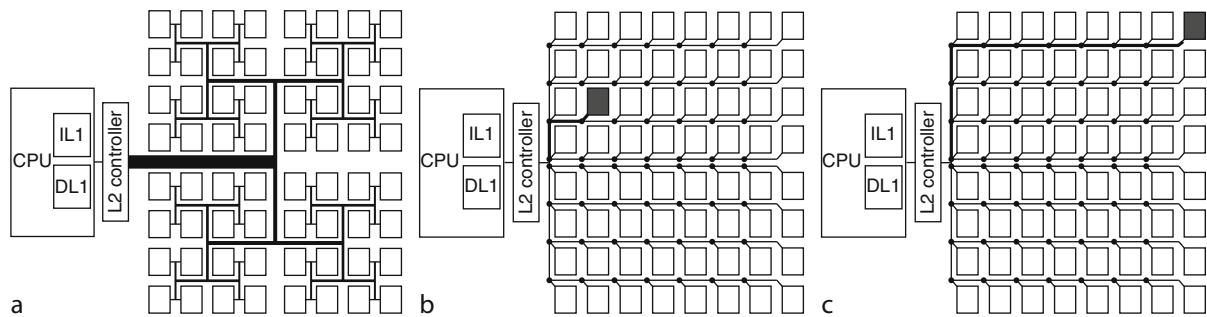

In a traditionally organized cache, each bank is connected to the controller via a fixed length path, usually organized according to the H-Tree model (Fig. 1a). Thus, in a wire delay-dominated context, the access latency of each bank is dominated by the constant length of the path followed by control and data signals, and it is independent from the physical position of the bank. This organization is referred as UCA (Uniform Cache Access) as its access time is *uniform*.

The basic idea of NUCA, first proposed by Kim et al. [2], is to design the cache so that banks are connected among them and with the controller via a connection fabric, typically a NoC. Figure 1b and c show a system equipped with a Level 2 NUCA, partitioned in 128 independent banks, connected with a partial 2-D mesh NoC.

The adoption of a NoC allows to access each bank independently from the others. In particular, in a NUCA, there is a different access latency for each bank depending on its physical distance from the controller. Being in a wire delay-dominated environment, the signal propagation delay dominates overall access latency. Hence banks that are closer to the controller (Fig. 1b) can be accessed faster than the others that are farther (Fig. 1c). As a consequence, the access time is *non-uniform* as it is proportional to the physical distance to be traversed by signals. This architectural design is complemented by data management policies that maintain critical blocks in faster banks. This allows better performance with respect to UCA architectures by obtaining a lower average cache access latency, thus hiding wire-delay effects.

### Data Management Policies: S-NUCA and D-NUCA

When designing a NUCA, one of the main choices is related to the *mapping rule* that dictates which bank can hold a given memory block. The simplest mapping rule is the *static mapping*: a block can exclusively reside in a single predetermined bank, basing on its memory address. A NUCA cache adopting the static mapping is called Static NUCA (S-NUCA). An alternative rule is the *dynamic mapping*: a block can be hosted in a set of banks, called *bankset*, and can be moved inside the bankset. A NUCA cache adopting the dynamic mapping is called Dynamic NUCA (D-NUCA) [2].

**NUMA Caches.** Fig. 1 Examples of systems adopting a traditional sub-banked UCA cache (a) and a NUCA cache (b and c). In all the designs the memory space is partitioned in 64 banks (white squares in the picture). UCA adopts the H-Tree connection model, while NUCA uses a network on chip made up of routers (black circles in the picture) and links. In this way, each bank is independently accessible from the others and the access latency of a block that is in a bank near the controller (b) is lower than access latency that is in a far bank (c), because the network path that must be traversed in order to reach the farther bank is longer

## S-NUCA

In an S-NUCA made up of  $N$  banks, the bank to be accessed is selected basing on the value of  $\log(N)$  bits of the address. Proposed policies for static mapping are *sequential mapping*, which uses the most significant bits of the index field of the physical address, and the *interleaved mapping*, which uses the low-order bits of the same field in order to distribute among different banks blocks that are memory contiguous, thus reducing bank contentions.

When searching for a block, the controller injects into the NoC, a request that will be delivered to the pertaining bank. If the block is present, i.e., the cache access results in a *hit*, the bank sends it to the controller. If the block is not present, i.e., there is a *miss*, the block is retrieved from the main memory, then is stored in the cache bank and, finally, is delivered to satisfy the request.

Despite the simple design and management policies, an S-NUCA usually exhibits lower average access latencies with respect to traditional UCA caches. However, as the data mapping doesn't take into account the data usage frequency, it may happen that more frequently used data are mapped in banks that are far from the controller, thus resulting in higher access latencies and poor performances.

## D-NUCA

In a D-NUCA, banks are grouped into banksets, and each block can be stored in any of the banks that belong

to the pertaining bankset: for example, in the systems of Fig. 1b and c, a bankset could be made up of all banks belonging to the same row. The bankset is chosen basing on the address of the block itself, using  $\log(\text{number of bankset})$  bits of the index field, adopting either the sequential or the interleaved mapping. Blocks can move from one bank to another of the same bankset thanks to the *block migration* mechanism. Migrating most frequently used data from farthest banks to closest banks allows to reduce the average access latency, and thus to achieve better performance with respect to S-NUCA.

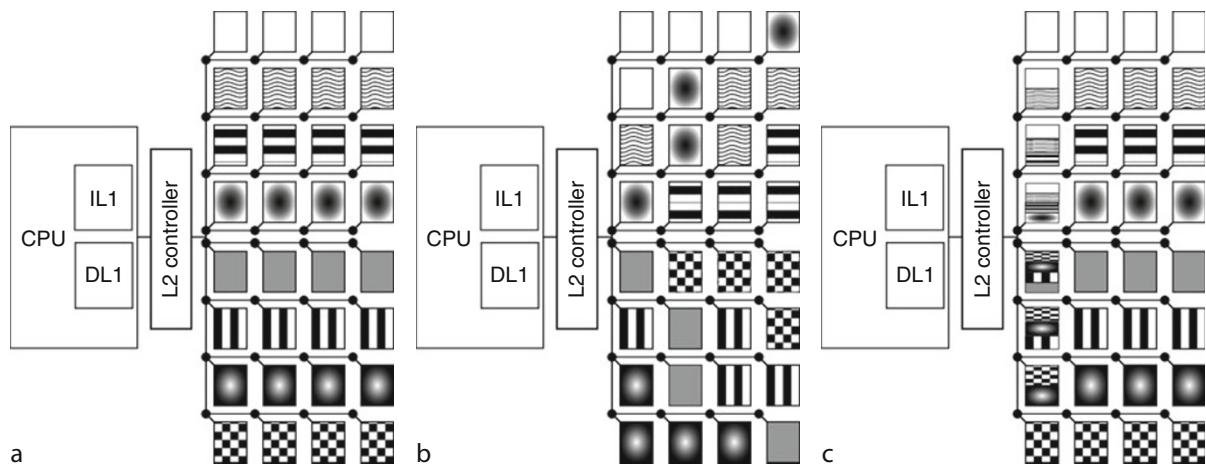

The three main topics in designing a D-NUCA are:

- *Bank Mapping*: how to map banksets to physical banks?
- *Data Search*: how the possible banks are searched to find a block?
- *Movement and replacement*: how and when the data should migrate? In which bank of the bankset a new block should be placed?

## Bank Mapping

The bank mapping policy of a D-NUCA dictates how to group the available physical banks into banksets. Many different policies can be adopted, each offering a different trade-off in terms of implementation complexity and fairness, among the various banksets, of the latency distribution. Proposed mapping policies are [2]: (1) *simple mapping*, (2) *fair mapping*, and (3) *shared mapping*.

The simple mapping (Fig. 2a) maps a bankset to all the banks belonging to the same row. Such policy is

NUMA Caches. Fig. 2 Three examples of bank mapping: simple mapping (a), fair mapping (b) and shared mapping (c)

simple to be implemented, but there are very different access latencies between banksets that are mapped to the central rows of the cache and those that are mapped in the other rows; to access them, a longer network path along the vertical direction must be traversed. In the fair mapping (Fig. 2b), this is avoided at the cost of additional complexity: the banks are allocated to banksets so that the average access times to all the banksets are equalized. In the shared mapping (Fig. 2c), the banksets share the banks closest to the controller so that a fast bank-access is provided to all the sets.

## Data Search

When the search is performed, all the banks of the bankset that can contain a referred block must be searched. The controller injects in the network a request that will be delivered to all the pertaining banks, and the block is searched inside each bank. If all the banks miss the searched block, then there is a *cache miss*, and the block must be retrieved by the next level in the memory hierarchy. Alternatively, one bank contains the searched block, there is a *cache hit*, and the block is sent to the controller.

Examples of proposed search policies for D-NUCA caches are *multicast search* and *incremental search* [2]. In the multicast search, the request is delivered in parallel to all the possible banks, and each of them starts the search as soon as possible. Figure 3 shows an example of memory operation in a D-NUCA adopting the simple mapping scheme and the multicast search. As opposite, in the incremental search, the banks of a set

are sequentially searched from the closest to the farthest. The delivery of the request to each bank is performed only if the previous bank has missed the block. In this way, the number of bank accesses and the associated energy consumption are reduced at the cost of an increase of the total latency.

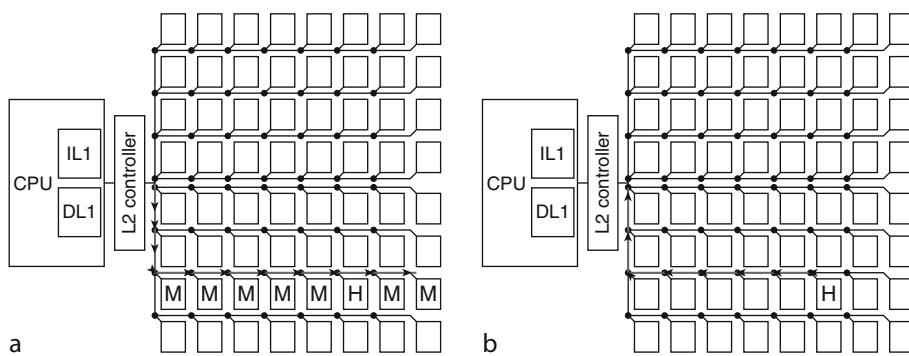

Other solutions have been proposed [5] mixing the two techniques: the banks of one bankset are divided in two or more groups; inside each group the multicast search is adopted, while the various groups are searched incrementally.

## Data Movement and Replacement

Basing on the locality principle, chances there are that, when a block is referred, it will be referred again in a short time. So, when a block is accessed, it makes sense to move it in another bank of the bankset that is closer to the controller. This movement is called *data promotion* [2].

An ideally desirable policy would be to use LRU ordering for the blocks in the banksets, with the closest bank holding the MRU block, second closest holding second most-recently used, etc. Maintaining this ordering would require a heavy block redistribution among banks on each access, with consequent impact on network traffic and energy consumption.

For this reason, more practical low-impact policies are employed usually based on *generational promotions* [2] of blocks basing on their access pattern. For example, in the D-NUCA cache of Fig. 1c on every hit, the accessed block is moved in the left direction by one

**NUMA Caches. Fig. 3** The multicast search operation in a D-NUCA adopting the simple mapping: the request first traverses the vertical links to the pertaining bankset, then traverses the horizontal links and routers where is replicated to reach all the banks of the bankset (**a**). The bank containing the block sends a reply to the controller (**b**) that follows the inverse path of the request message

bank. In this way, the next access to the same block will incur a lower latency. This migration policy is called *per-hit promotion*.

More generally, designing a generational data promotion, in the case of a D-NUCA, requires the definition of three elements: the *promotion trigger* (number of hits after which a promotion must be triggered), the *promotion distance* (number of banks that the promoting block must be advanced), and the *initial placement* of a newly loaded block after a cache miss.

Another important design decision involves what to do with the block that, in the new bank, is eventually occupying the line in which a promoting block must be inserted. Basic choices for this design issue are the *demotion* of the block in the bank previously hosting the promoted block or its *eviction* from the cache. Demotion requires more bank accesses and network traffic than eviction; however, the latter affects performance as it evicts blocks without taking into account their actual usefulness.

Different choices result in different power, network traffic, and performance trade-off; however, the majority of the proposed D-NUCA designs [4–7, 9, 10] adopt the per-hit promotion (i.e., one hit as promotion trigger and one bank as promotion distance) and the insertion of new blocks in the farther from the controller bank. Increasing the value of promotion trigger has been shown to affect performances too much as it limits the promotion of newly loaded data that, basing on the temporal locality principle, are likely to be requested at the next accesses. At the same time, increasing the promotion distance involves the rapid demotion of data that, because of the spatial locality principle, may be needed again in the next future. Using different insertion point for newly loaded data means evicting from the cache blocks that are still useful as they occupy banks that are close to the controller.

## NUMA Caches in the CMP Environment

The increase in the number of available on-chip transistors and the demand for increasing performance have driven the design of CMP systems that include more elaborating cores and a multilevel cache memory hierarchy in a single die. The adoption of a large on-chip multilevel cache allows to guarantee fast memory access to each core.

CMP caches are usually organized in two or more levels in which the Last-Level-Cache (LLC) can be shared among all on-chip cores, while all the other levels are private for each core. As the LLC is usually quite large, it is likely to be affected by the wire-delay problem. For this reason, a CMP system can adopt a shared NUMA cache as its LLC [4, 5, 9, 10].

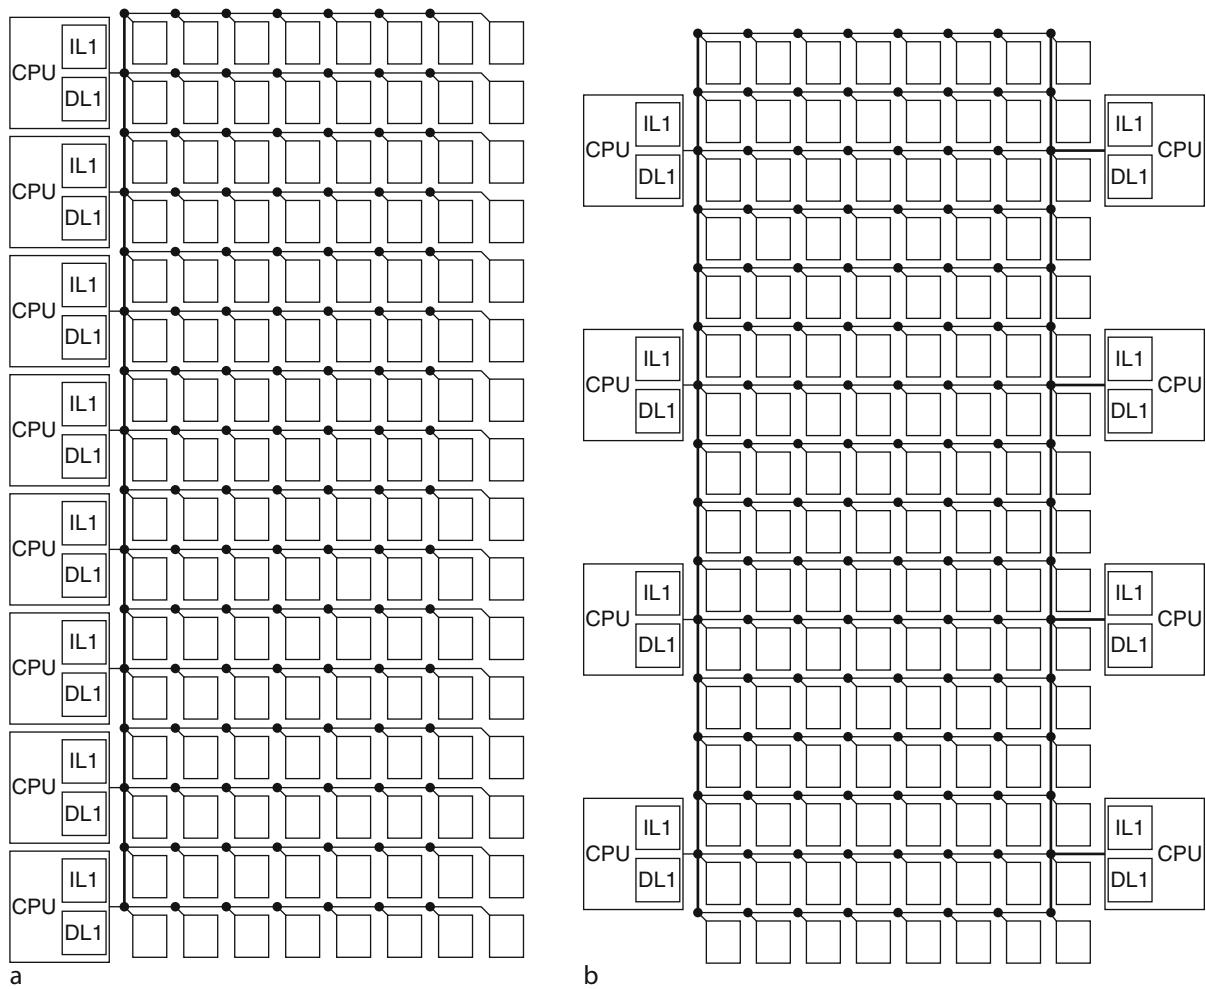

## System Topologies

Taking into account the respective position of cache banks and cpus, CMP systems can be classified in two main topology families: *dancehall* and *tiled*.

In the dancehall, the shared LLC is concentrated in an area of the chip, while cpus stay at one or more sides of the cache. In a dancehall architecture cpus and cache banks can be connected via a NoC (or other connection fabric), resulting in NUCA CMP designs [4, 5, 9, 10, 12] that are analogous to the single core systems previously discussed. Figure 4a shows an example of dancehall CMP in which cpus are plugged to the same side of the NUCA. Variations of this simple configuration have half of the cpus plugged at one side of the shared NUCA, and the others plugged to the opposite side (Fig. 4b), or all the cores distributed along all the sides of the banks matrix [5].

The tiled topology, as shown in Fig. 5, is composed by many identical nodes, called tiles. Each tile is composed by one cpu, its private cache levels, and a LLC that can be used as a private cache or as a local slice of a globally shared LLC [11–13]. In the last case, the access time to the shared LLC depends on the position of both the requesting node and the looked-up LLC slice. In particular, for a core, an access to a remote slice will result in a greater latency, with respect to an access to the local slice. This is due to network paths that depend on the physical distance from the local to the remote tile.

When designing a CMP system, choosing between dancehall and tiled introduces a trade-off in terms of performance and scalability. The three main components of the NUMA access time are: (1) the number of NoC hops to be traversed to reach the hosting bank, (2) the latency of each hop, and (3) the access time to the banks that stores the block. Hence, if the bank to be accessed is small and close to the requesting node, the access latency will be limited. If the interested bank is huge and far from the requesting node, the cost of the cache access will proportionally increase.

**NUMA Caches. Fig. 4** NUCA based CMP systems adopting the *dancehall* topology, with 8 cpus with private L1 caches, and a shared L2 NUCA cache composed by  $16 \times 8$  banks. All the cpus, together with their private caches, can be plugged at the same side of the NUCA **(a)**, or at two opposite sides **(b)**

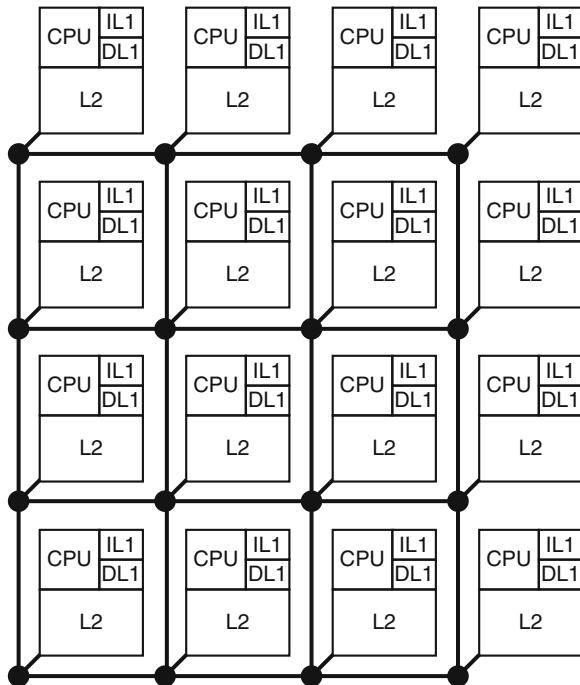

Adopting the *dancehall* topology results in a large number of small banks, each characterized by small response latencies. Moreover, NoC links, being designed to surround banks, are short. Thus they are characterized by a limited link traversal delay. Instead, in the tiled organization, there is a small number of greater and slower banks. Links are longer since they surround the entire tile, and consequently, their traversal delay is higher. Consequently, a request to any non-local slice traverses a small number of higher cost network hops.

Adopting a tiled topology will increase scalability at the cost of high cache access latency due to huge

cache slice and high network hop traversal cost. Instead, adopting a *dancehall* topology minimizes the latency of each hop, as well as the access time to each single bank, but presents a smaller degree of scalability than the tiled case.

### Coherency in CMP Systems Adopting NUMA Caches

In a CMP system, private cache levels must be kept coherent. Given that NUMA LLCs adopt a communication fabric which does not guarantee sequencing of coherence traffic (e.g., the NoC), a directory-based coherence protocol, similarly to the ones proposed for

**NUMA Caches. Fig. 5** A NUCA based CMP system adopting the *tiled* topology, with 16 cpus with private L1 cache, and a shared NUCA cache composed by 16 slices, one for each tile

classical DSM systems, must be adopted. The *directory* is a node of the system that tracks which of the private caches hold a copy of each block. In CMP systems with NUMA LLC, the directory can be *centralized* or *distributed*.

A centralized directory is a monolithic node of the system separated from the remaining nodes. This solution presents some scalability issues because all the nodes must access it to guarantee the correctness of memory operations. When the number of such nodes increases, then directory contentions increase as well, resulting in higher response time and thus affecting performance.

The distributed directory is typically implemented inside each NUMA cache bank. Directory information is stored near the TAG field of each cached block, using some specific status bits. As a consequence, directory accesses are distributed among all banks. When a *miss* in the last private level cache occurs, an unique access is used to retrieve both the block and the directory information.

## Mapping Policies

Also for the NUMA cache in CMP systems, the two possible mapping policies are static and dynamic. Due to the presence of many traffic sources, in both cases the NoC traffic increases proportionally to the number of cores per chip. At the same time, the contention of shared blocks introduces new design issues that are related to both mapping policy and topology.

### Static Mapping

Static mapping has been adopted in both *tiled* [11] and *dancehall* [9, 12] designs. The static mapping associates each memory address to a single cache bank, which is able to satisfy both read/write and coherence requests coming from any of the private next-level cache.

The path followed by request and coherence messages to reach the interested bank depends on the respective position of requestor and bank. If the bank is far from the requestor, the message has to traverse many network hops before reaching the bank. If the bank is close to the requestor, the network path will be short. As the bank to be accessed is chosen basing on the block address, the banks that a processor accesses depend on how the *working set* of the running process/thread is mapped on memory, i.e., which are the physical addresses that are accessed. So, if the running process/thread's *working set* is mapped to remote banks, then the cache access latency will be high; otherwise it will be small. Consequently, both topology aspects and memory mapping rules contribute in affecting or enhancing overall performance.

### Dynamic Mapping

Block migration can be used to improve performance also in CMP systems adopting a NUMA LLC. *Dancehall* [4, 5, 8, 10, 12] and *tiled* [11–13] designs have been proposed in which cache blocks are able to move among banks in order to reduce response latency.

As for the *dancehall* case, the design results in a D-NUCA similar to the single core case. Also in this context, the shared D-NUCA is usually considered as partitioned in many banksets, and cache blocks are able to migrate among banks belonging to the same bankset [4, 5, 9, 10]. For example, in the systems shown in Fig. 4a and b, banksets may be constituted by the rows of the NUCA bank matrix. If D-NUCA succeeds in bringing the most frequently accessed blocks near to the

referring cpu(s), overall performance will be boosted. However, the performance gain that could be obtained with migration comes with some design issues, as in a CMP there are many traffic sources that complicate the managing of the block migration process.

Blocks that are shared by two or more threads can be accessed by different nodes if the sharers are running on different cpus. This is not necessarily a disadvantage but depends on the overall system topology and process scheduling. By considering the system of Fig. 4a, as all the cpus are placed at the same D-NUCA side, all the blocks migrate toward the same direction because the faster way is the same for all cpus. Instead, in the system of Fig. 4b, the faster way for half of the cpus is the slowest for the others, and vice versa. If the sharers are running on cpus plugged at opposite D-NUCA sides, shared blocks will alternatively migrate in both directions, and none of the cpus will succeed in bringing such blocks in the respective faster way. This phenomenon is known as *ping-pong*, and if not properly managed, reduces the performance gain deriving from block migration.

Another design issue of D-NUCA CMP systems regards the *initial placement* of a new block after a cache miss (i.e., choosing which bank of each bankset will store incoming blocks). Considering the *dancehall* configuration of Fig. 4a, choosing the fastest way as the block entry point would interfere with most referred blocks, and similar considerations can be done as in the single core case. Instead, for the system shown in Fig. 4b, the farthest way for half of the cpus is the closest for the other half, so blocks loaded by half of the cpus would interfere with most frequently used blocks of the other half. Consequently, a possible trade-off could be choosing the *initial placement* in the central banks.

Alternative schemes, for both the *dancehall* and *tiled*, have been proposed [11, 12], in which blocks are initially placed near the first requestor and stays there until they are requested by a different cpu. In this case, the blocks migrate toward a bank (or a slice) that is determined according to its memory address basing on a static mapping policy. On subsequent requests, the block is not further moved. Dually, migration schemes have been proposed so that blocks are initially placed basing on their memory address and

subsequently migrated basing on the position of the referring cpu [13].

Dynamic block movement designs must face the *false miss* problem. This is a particular race condition that can occur when a subsequent access to a migrating block arrives when the block is still *on-the-fly*. A block migration involves two banks: the *source* and the *destination*. If the new request is received by the *source* after the block has been sent and by the *destination* before the migrating block has arrived, both the accesses will result in a miss; actually, the block is present in cache and must not be retrieved by the next level memory. This would cause two problems: (1) performance loss, because off-chip accesses are always more expensive than cache accesses; (2) the correctness of memory operations, as there would be two (or more) unmanaged copies of the same block. Techniques for resolving such problem have been proposed, for example, a directory holding all the cached block addresses can be accessed in order to recognize false misses [5], or a specific false miss avoidance algorithm can be designed [10].

## Research Directions

Promising lines of studies for NUMA caches are:

1. Power-consumption saving techniques. While being able to reduce wire-delay effects, NUCA caches still suffer of another typical problem of nanometers technologies: the static power consumptions due to the increase of leakage currents. Besides, due to the additional NoC traffic and bank access, D-NUCA exhibit an increase also in the dynamic power consumption [14]. Even if NUCA caches are made up of traditional cache banks, the direct adoption of well-known techniques like, for example, drowsy memories and decay cache lines, may not be effective particularly in D-NUCA because of the data movement that modify bank access pattern. An alternative proposed technique [16] exploits different usage of banks due to block migration to power-gate farther and less used banks, and has been introduced for both the single-core case and the CMP environment in which all the cpus are connected to the same cache side. However, when cpus are distributed around more NUCA sides due to the problems that arise in D-NUCA based CMP systems, the concept

of farthest banks is ambiguous and has to be redefined; thus the raw application of such technique is no longer possible.

2. Performance improvement via remapping policies. Memory remapping at compile time is traditionally used to improve cache memory performance, in particular for reducing conflict misses. In the context of NUCA caches, similar techniques can be used also for placing data block in banks (or banksets) that reduce their average access latency [16]. Typical samples of used metrics in mapping policies are the data usage frequency and their being shared or private. Remapping can be implemented also via hardware, for example, by designing specific protocols that dynamically change the hosting bank (in the case of S-NUCA, similarly to [12]) or bankset (in the case of D-NUCA).
3. Efficient block migration schemes are an open issue for CMP caches. Generational promotion schemes as in the case of single-core D-NUCA are effective in *dancehall* systems in which cores are all plugged at the same cache side. In all the other cases, such simple schemes are no longer effective due to the *ping-pong* problem that can arise on shared data. Alternative solutions are likely to take into account the position of cores that share a specific block in order to migrate it in a position that optimizes overall performance (similarly to [13]). Moreover, blocks replication could be evaluated as a viable solution to the *ping-pong* problem so that each copy can migrate toward a specific requestor [18]. Such scheme must take care of the need of each application. In fact, while the convenience of replicating Shared-Read-Only Blocks is obvious, there may be classes of applications, in which replicating also Shared-Read-Write blocks can contribute in improving performance.

## Bibliographic Notes and Further Reading

The first NUCA cache architecture was proposed in [2], and demonstrates that a dynamic NUCA structure achieves an IPC 1.5 times higher than a traditional Uniform Cache Architecture (UCA) when maintaining the same size and manufacturing technology. Leveraging on alternatives data mapping policies, NuRapid [4] and Triangular D-NUCA cache [6, 7] have been proposed as alternative designs for NUCA architectures in order to optimize the trade-off between area occupation and performance. An energy model for NUCA architecture is proposed in [14] together with an energy/performance trade-off evaluation for NUCAs and its comparisons with UCA. The Way Adaptable D-NUCA architecture is proposed in [16] shows that it is possible to dynamically adapt the cache size to the application needs, thus consistently reducing NUCA static power consumption while marginally affecting the performances. The impact of NoC elements parameters on NUCA performances have been analyzed in [17]. The same work proposes an alternative design for NUCA caches that relaxes the constraints imposed on network routers latency by clustering multiple banks around each router.

In the context of on-chip multiprocessors, the behavior of D-NUCA as shared L2 caches has been analyzed in [4, 5, 8]; these works evaluate the performance of different data mapping and migration policies. Topology studies for S-NUCA and D-NUCA, related to the dancehall configurations, can be found in [9, 10]. These works also propose a directory coherence protocol specifically suited for CMP NUCA environment and a solution to some design issue of block migration policies in D-NUCA-based CMP systems. The analysis in [11] is based on the tiled architecture and employs an optimized block placement and migration scheme, taking into account both block usage characteristic (Read-Only or Read-Write) and threads migration. In [12] is proposed a scheme called SP-NUCA in which private blocks are dynamically recognized and then stored in S-NUCA banks that are very close to the owner. The system proposed in [13] is based on a tiled architecture and implements a migration mechanism that places blocks in slices depending on the sharers' position.

## NVIDIA GPU

MICHAEL GARLAND

NVIDIA Corporation, Santa Clara, CA, USA

### Synonyms

[Graphics processing unit](#)

### Definition

NVIDIA's GPUs (Graphics Processing Units) are a family of microprocessors that provide a unified architecture for both visual and parallel computing. They generate and process complex 2-D and 3-D imagery, typically via application programming interfaces such as Microsoft's DirectX or OpenGL. NVIDIA's CUDA architecture provides a platform for executing massively parallel computations, written in standard languages such as C or Fortran, on these processors.

### Discussion

Graphics Processing Units, or GPUs, are massively parallel microprocessors. They are present in every workstation, game console, desktop computer, and laptop in use today. They are also increasingly common in mobile devices such as smartphones. The GPU is responsible for generating the 2-D and 3-D graphics required by modern applications, and it provides a platform for real-time image and video processing. These visual computing capabilities are typically accessed via standard application programming interfaces (APIs) such as OpenGL or Microsoft's DirectX. Modern NVIDIA GPUs also support the CUDA parallel programming architecture, and can be programmed directly in standard languages such as C and Fortran. This makes them a platform for parallel computing in general.

### Accelerating Computer Graphics

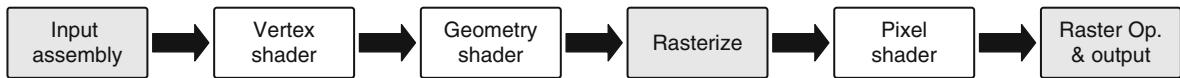

Historically, the GPU has evolved to meet the needs of applications that generate and process complex

computer graphics. To understand the design of a GPU processor, it is instructive to understand the graphical tasks that they have been designed to accelerate.

The real-time rendering of 3-D computer graphics is a computationally challenging task. Essentially all APIs designed for real-time rendering adopt a pipeline execution model. As an example, Fig. 1 shows a high-level block diagram of the Direct3D 10 pipeline [2]. Geometric primitives – typically points, lines, and polygons – are generated by the application and enter the graphics pipeline at the left. Primitives and their vertices are independently processed by the geometry and vertex shader stages, respectively. The rasterization stage converts each primitive into a set of pixel fragments, one for each pixel on the screen touched by the primitive. Each of these pixel fragments is processed in the pixel shader stage, and the results are composited into the framebuffer at the end of the pipeline.

The gray-colored stages of the pipeline are fixed-function components; their operation is restricted to a set of functionality defined in the relevant API standards. The others allow the application to provide custom procedures – typically referred to as “shaders” – that process individual primitives, vertices, and pixels. Shader programs are typically written in C-like domain-specific languages such as Cg [6], OpenGL's GL Shading Language (GLSL), or the DirectX High-Level Shading Language (HLSL).

The design and evolution of GPU processors has been influenced in a number of ways by the needs of interactive graphics. Foremost among these is the fact that graphics represents a workload with tremendous inherent parallelism. Even the simplest of 3-D scenes typically contain thousands of polygon primitives, and scenes containing a million or more primitives are not uncommon. At high-definition resolutions, a display device contains 2 million pixels. Rendering the scene involves processing each primitive, each vertex of every primitive, and each pixel touched by every primitive. The graphics pipeline model mandates that every primitive/vertex/pixel can be processed independently of every other primitive/vertex/pixel. Thus, at any one instant in time, a GPU may be given a workload with many millions of independent tasks, all of which could be processed in parallel given the necessary computational resources.

NVIDIA GPU. Fig. 1 Block diagram of the graphics pipeline execution model of Direct3D 10

Interactive computer graphics is also a fundamentally throughput-oriented problem. Applications typically render their scenes at a fixed frame rate, such as 30 frames per second. The amount of work that can be completed in 1/30 of a second is thus of primary importance, since this will largely determine the richness of the resulting visual experience. This has led GPU processors toward aggressive throughput-oriented designs; they are generally willing to sacrifice performance of a single task in order to increase total throughput over all tasks.

### Parallel Computing Architecture

Current GPUs, as illustrated in Fig. 2, are designed around a large array of parallel processors and various fixed-function units for tasks such as work distribution, rasterization, and image processing. The pipeline execution model of the graphics APIs is mapped onto the machine by circulating work through these processors. Shader programs provided by the application for the various programmable stages of the pipeline execute on the processor array and fixed function logic handles the scheduling of these tasks. This basic architecture has been used in all NVIDIA GPUs beginning with the G80 processor first released in the GeForce 8800 GTX in late 2006. This first-generation processor was later followed by the GT200 processor, which first introduced double precision floating point support. NVIDIA recently released its third major generation of unified processors, a GPU architecture code-named “Fermi.”

In addition to executing all shader programs for graphics applications, this parallel processor array can also be programmed directly. NVIDIA’s CUDA architecture provides a programming model and application interface for executing parallel programs – referred to as “kernels” – on the GPU. This programming model can be adapted to most typical sequential programming languages, and compilers for CUDA C, C++, and Fortran are currently available.

The programmer organizes a CUDA program into a sequential host program, intended to run on the CPU, and a collection of parallel kernels, that are

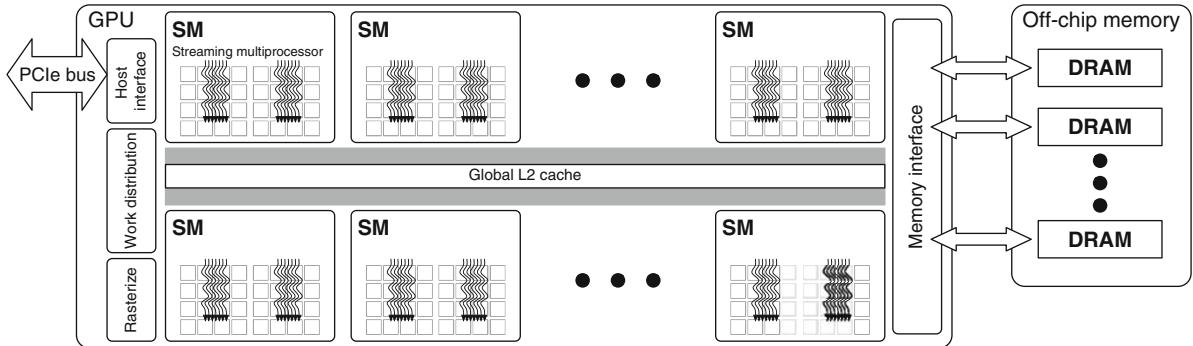

intended to run on the GPU. A single kernel is a blocked SPMD (Single Program Multiple Data) parallel computation. It consists of a collection of concurrent threads, all executing the same program. These threads are further grouped into thread blocks. When launching a kernel, the application specifies both the number of thread blocks and the number of threads per block to instantiate.

Figure 3 shows a simple example of a CUDA C program fragment for computing  $y \leftarrow \alpha x + y$  for a scalar  $\alpha$  and two  $n$ -vectors  $x$  and  $y$ . This is the so-called SAXPY kernel of the BLAS linear algebra library.

The `parallel_saxpy` routine is part of the host program, as indicated by the `_host_` attribute attached to its declaration. Given pointers to the  $x$  and  $y$  vectors allocated in the GPU memory, it invokes the parallel kernel. This code is designed to process each corresponding pair of elements with a single thread. Therefore, the host program selects a thread block size of 256 threads – an arbitrary choice in this case since there is no inter-thread communication – and determines the number of 256-thread blocks needed to create at least 1 thread per element. The function call-like `saxpy_kernel<<<B, T>>>()` actually launches the kernel with  $B$  blocks of  $T$  threads each.

The procedure `saxpy_kernel` is a kernel entry point, indicated by the `_global_` attribute. Although each thread may subsequently follow its own execution path, all threads of the kernel begin their execution at the beginning of this procedure. Thus, the kernel procedure itself is a standard sequential program describing the action of a single thread.

Individual threads within a kernel are differentiated by unique integer indices. The thread blocks of a kernel are numbered on a 1-D or 2-D grid. CUDA C exposes these indices through special variables visible within kernel functions: `blockIdx.x`, `blockIdx.y` give the index of the current block and `gridDim.x`, `gridDim.y` provide the number of blocks in each dimension. Similarly, each thread is given a unique index within its block. These indices may be one-, two-, or three-dimensional. A thread’s index is available via

NVIDIA GPU. Fig. 2 High-level structure of a modern discrete GPU

```

global__ void saxpy_kernel(int n, float a, const float *x, float *y)
{
 // Each thread processes 1 element, determined from the thread's index.
 int i = blockIdx.x*blockDim.x + threadIdx.x;

 if(i<n) y[i] = a*x[i] + y[i];
}

host__ void parallel_saxpy(int n, float a, const float *x, float *y)
{
 // Create kernel with 256-thread blocks.
 int blocksize = 256;

 // We will need [n/256] blocks to process n elements.
 int nblocks = ceil(n/blocksize);

 saxpy_kernel<<<nblocks, blocksize>>>(n, a, x, y);
}

```

NVIDIA GPU. Fig. 3 CUDA C implementation of  $y \leftarrow \alpha x + y$  given two  $n$ -element vector  $x$  and  $y$

the special variables `threadIdx.x`, `threadIdx.y`, and `threadIdx.z`, while the dimensions of a block are `blockDim.x`, `blockDim.y`, and `blockDim.z`.

The example shown in Fig. 3 uses only 1-D indexing; all other dimensions are ignored. It begins by computing a linear index  $i$  from the block and thread indices of the current thread. This assigns unique elements  $x_i$  and  $y_i$  to the thread. The conditional test that  $i < n$  is required since there will be more threads than elements when  $n$  is not a multiple of the block size, which is 256 in this case. Those threads that are within the bounds of the array conclude their computation by performing the element-wise update  $y_i \leftarrow \alpha x_i + y_i$ .

Figure 3 illustrates the basic mechanics of a CUDA program, but it also highlights an important qualitative difference between CPU and GPU programming. Typical CPUs tend to treat threads as heavyweight

objects of which there are relatively few. Concurrency runtimes like OpenMP and Intel's Threading Building Blocks typically create a persistent pool of worker threads proportional in size to the number of cores available. On current machines, this would typically imply a thread count of up to roughly 16, and these threads most likely persist over the application's entire lifetime. Their schedulers are then responsible for mapping tasks created by the application onto the available threads. In contrast, GPUs treat threads as extremely lightweight objects that may also have extremely brief lifetimes. Given two vectors of ten million elements, this single SAXPY kernel will launch, execute, and retire ten million threads. This significantly different viewpoint is largely a result of the GPU's graphics background. Graphics applications require GPUs to execute many millions of shader invocations per frame. Unlike CPUs,

which tend to assume that parallelism in their given workload is fairly scarce, GPUs assume that they are provided with workloads containing abundant parallelism.

### The Streaming Multiprocessor

The parallel processor array at the heart of the GPU is composed of a number of multithreaded Streaming Multiprocessors (SMs). When a kernel is launched on the GPU, the hardware work distributor enumerates its thread blocks and launches them on SMs as resources are available. If no SM can accommodate any additional blocks, the work distributor waits for some running block to retire, at which point it may launch a pending block on that SM. The SM is thus “streaming” in the sense that thread blocks “stream” through the multiprocessor: they launch, run, and then retire without being suspended and evicted to memory.

Each multiprocessor supports on the order of 1,000 coresident threads, with the precise number varying between processor generations. [Table 1](#) provides specific data for the three most recent generations of NVIDIA GPUs. The SM manages the creation, execution, and scheduling of its threads directly in hardware.

### Memory Organization

All threads running on the GPU have access to a global random-access memory. For discrete GPUs – those housed on PCIe cards – global memory is serviced by a high-bandwidth memory system that can deliver roughly 150 GB/s of bandwidth on the highest end cards. For GPUs in other form factors, such as GPUs integrated with the motherboard chipset, this memory may be the same system memory used by the CPU.

**NVIDIA GPU. Table 1** Capacity of each SM for three GPU generations

|                        | G8x/G9x | GT2xx  | “Fermi” |
|------------------------|---------|--------|---------|
| Scalar cores           | 8       | 8      | 32      |
| Registers (32-bit)     | 8192    | 16,384 | 32,768  |
| Coresident threads     | 768     | 1024   | 1536    |
| Shared memory (KB)     | 16      | 16     | 48/16   |
| L1 cache (KB)          | –       | –      | 16/48   |
| L2 cache (KB per chip) | –       | –      | 768     |

An SM is provisioned with a large register file so that every resident thread can be given its own dedicated register set. For example, the register file of a Fermi SM has 32,768 32-bit registers, for a total of 128 KB of register space. At its maximum occupancy level of 1,536 resident threads, the Fermi SM can allocate 21 registers to every thread. These registers provide primary storage for the local variables of the thread, with excess variables spilling to external memory.

In addition to the register file, which provides for private per-thread storage, the SM is also equipped with a small on-chip shared memory. This memory is high speed and low latency. It is allocated on a per-block basis, thus providing a space for sharing data among all the threads of a block and for intra-block communication.

The Fermi architecture augments this on-chip RAM with an L1/L2 cache hierarchy. Each SM maintains its own private L1 cache. The L1 shares a fixed 64 KB memory space with the shared memory RAM. This memory may be divided into either 16 KB L1 and 48 KB shared memory, or 48 KB L1 and 16 KB shared memory. The L2 cache is a global cache across all SMs and is 768 KB in size.

### Thread Synchronization

Parallel threads running on the GPU may synchronize with each other at one of three levels. At the highest level, there is an implicit barrier between successive kernels. By default, no thread of a given kernel may be launched until all threads of previously launched kernels have completed. For truly independent kernels, CUDA provides an additional mechanism to launch kernels in separate streams, thus specifying that they may be run concurrently.

The threads of a single thread block may synchronize with each other by calling a barrier function. This is a lightweight barrier that translates to a single SM instruction. It thus incurs essentially no overhead, except for the time required to physically wait for all threads to reach the barrier.

Individual threads may also perform atomic operations on memory addresses. These operations include, but are not limited to, atomic compare and swap, atomic increment/decrement, and atomic reduction for commutative operations such as addition, min/max,

and binary and/or/xor. Atomic operations may be performed in both global and on-chip shared memory.

### SIMT Execution

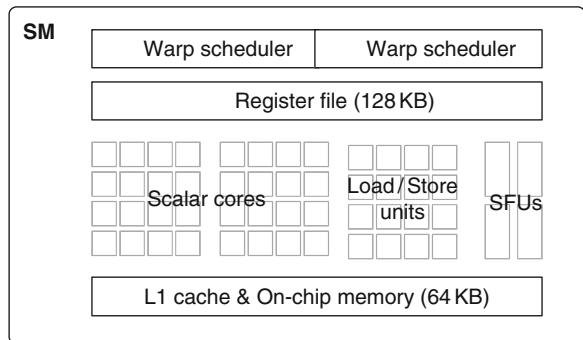

To manage its large population of threads efficiently, the SM employs a SIMT – Single Instruction, Multiple Thread – architecture. The threads of a given block are grouped into 32-thread units called “warps.” A warp of threads can execute a single instruction at a time across all its threads. Since each thread may follow its own independent path of execution, threads within a warp may potentially follow different code paths. The hardware automatically tracks and handles such execution divergence. When a warp of threads executes a divergent conditional, for instance, it will execute first one branch and then the other of the conditional. Threads of the warp will be activated only in the branch of the conditional which they chose to follow.

The SIMT architecture used by the GPU is an instance of the broader class of SIMD (Single Instruction, Multiple Data) architectures. However, it is qualitatively different from the vector SIMD extensions prevalent on other platforms. The action of each thread is described by a normal sequence of scalar instructions. When executing the same code path, these threads will automatically execute together and realize the benefits of SIMD execution. When they follow different paths, the execution of the program remains correct, although there is a performance loss proportional to the number of diverging paths. In contrast, a vector SIMD model embeds vector instructions directly in the instruction stream. They must be inserted explicitly, either directly by the programmer or by compiler autovectorization of loops.

Warps are the fundamental unit of scheduling in the SM. On each clock cycle, an SM warp scheduler is free to select from its available pool any runnable warp to issue an instruction. Runnable warps are simply those not waiting for some pending operation to complete. Thus, the scheduler interleaves the execution of separate warps at a very fine level. When there are multiple runnable warps, this has the effect of switching between warps at each instruction.

### Processing Elements

The SM contains a collection of processing elements that execute the instructions issued by running threads.

NVIDIA GPU. Fig. 4 Basic structure of a single streaming multiprocessor in a Fermi GPU

The precise configuration of these elements varies between GPU generations. Figure 4 sketches the configuration for a Fermi SM.

Each SM is built around 32 scalar cores. Each of these cores provides fully pipelined integer and floating point arithmetic units. The floating point units support IEEE 754-2008 single (32-bit) and double (64-bit) precision arithmetic based on the FMA (Fused Multiply Add) operation.

The scalar cores are grouped in two sets of 16, and each group is associated with a separate warp scheduler. Thus, two separate warps may be executing simultaneously. A 32-thread warp is executed on one set of 16 cores by running two half-warps of 16 threads each, back to back on the scalar cores. The scalar cores are augmented with a set of 16 Load/Store units, that handle address calculations and dispatch for memory transfers, and four Special Function Units (SFUs) that execute transcendental instructions such as sine, cosine, reciprocal, and square root.

N

### Throughput-Oriented Design

As observed above, one of the key characteristics of the workloads generated by interactive graphics applications is that they are fundamentally throughput oriented. The goal is to finish as many tasks as possible within the fixed time period of a single frame. Since the number of tasks that must be completed easily reaches into the tens of millions, the amount of time required to complete any particular task is essentially insignificant. For such workloads, the amount of available parallelism is obviously abundant. This abundance of parallelism, coupled with the throughput-oriented nature of the

problems it is typically targeted for, combines to drive a number of GPU architectural design decisions.

One major consequence of these assumptions is that the GPU relies extensively on multithreading to hide the latency of long-running operations. This is true even of relatively short latencies, such as the time required for instructions to make their way through the instruction pipeline, but it is particularly true for accesses to global memory. On all modern processors, the time that elapses between issuing a memory request to external DRAM and its completion is typically hundreds of clock cycles. No high-performance processor can afford to remain idle for such a length of time. Traditional processors, like CPU cores, which emphasize running a single sequential task as quickly as possible attempt to avoid long-latency memory operations through large, sophisticated on-chip caches. In contrast, GPUs largely rely on multithreading to hide this latency; it is perfectly acceptable for some threads to be blocked waiting for memory transactions to complete as long as many others are ready to run. NVIDIA GPUs prior to the Fermi architecture did not have any caches for load/store operations on external memory. Even the Fermi architecture, which employs a full cache hierarchy, still relies heavily on multithreading to hide latency.

Another consequence of the throughput-oriented design of GPUs is that they use relatively simple processor control schemes. Modern superscalar CPUs employ a variety of sophisticated techniques to accelerate sequential programs. These include out-of-order execution, branch prediction, and speculative execution. GPUs do not employ any of these techniques. The scalar cores of the SM are simple in-order pipelined processors. They perform neither branch prediction nor speculative execution. While this means that a single thread may take longer to run, simpler control logic translates into less chip area devoted to control. Hence, there is more area available for functional units which leads to higher total throughput for a fixed chip area.

The use of SIMD execution in the SM similarly increases total peak throughput by amortizing the cost of control over many functional units. This comes at the cost of lower performance on completely divergent tasks. However, in practice, a massively parallel computation that provides a pool of tens of thousands of concurrent tasks is likely to show a high degree of uniformity. Rather than 10,000 disparate tasks, it is generally

much more likely that there will be a fairly small number of task types, each of which provides ample uniformity for efficient SIMD execution.

## Bibliographic Notes and Further Reading

The physical design of early hardware systems for 3-D graphics acceleration, exemplified by the Silicon Graphics Reality Engine [1], tended to mimic the structure of the graphics pipeline execution model. The hardware itself was a feed-forward pipeline of fixed-function hardware units. Over time, graphics hardware evolved, introducing programmable units for vertex, pixel, and geometry processing.

Lindholm et al. [5] provide an overview of the original G80 chip architecture, and an NVIDIA whitepaper outlines the basic characteristics of the upcoming Fermi architecture [8]. Nickolls et al. [7] explain the basics of the CUDA programming model. More complete information can be found in the official CUDA Programming Guide [9] and a recently published book on parallel programming by Kirk and Hwu [4]. Owens et al. [10] survey the field of GPU computing and its historical development. Garland et al. [3] report on experiences with CUDA in a collection of real-world applications.

An extensive collection of documentation, training materials, examples applications, and the CUDA development environment itself is all available online at <http://www.nvidia.com/CUDA>.

### Synonyms

Computational chemistry; Quantum chemistry

### Definition

NWChem (Northwest Computational Chemistry Package) is DOE's premier massively parallel computational chemistry package. It is an open-source high-performance platform with extensive capabilities for large-scale quantum and classical atomistic simulations that can be applied to a broad range of application areas.

### Discussion

Computational atomistic modeling has emerged as a powerful approach for fundamental studies in chemistry, materials science, geosciences, and biology. It has the ability to provide detailed insights into complex phenomena and, over the years, has grown into a powerful tool not only to validate experiments, but also to predict new phenomena. In order to harness computational modeling to the fullest, superior computational tools are required that not only offer a broad spectrum of capabilities, but that are also capable of taking advantage of modern massively parallel computer architectures efficiently to solve real-world problems.

The NWChem program suite is an example along these lines. It offers a range of capabilities to perform first-principles electronic structure calculations on molecular and periodic systems, classical molecular dynamics simulations, and hybrid QM/MM simulations that permit one to combine quantum and classical methods within a calculation.

The code is designed to run on high-performance parallel supercomputers as well as conventional workstation clusters with the goal to provide scalable solutions for large-scale atomistic simulations. It has been ported to almost all high-performance computing platforms, workstations, PCs running LINUX, as well as clusters of desktop platforms or workgroup servers. The package is scalable, both in its ability to treat large problems efficiently and in its utilization of available parallel computing resources. The parallel framework for NWChem is provided by the Global Array (GA) toolkit developed at PNNL.

NWChem is developed and maintained by the Environmental Molecular Sciences Laboratory (EMSL) located at the Pacific Northwest National Laboratory (PNNL) in Washington State. The latest release (version 6.0) of the code is distributed under the terms of the Educational Community License (ECL) version 2.0.

### Overview

NWChem [46] provides a number of quantum mechanical or electronic structure approaches for computing various properties of molecules, finite clusters, and periodic systems [46]. These include self-consistent field (SCF) or Hartree–Fock (HF) theory, density functional theory (DFT) including support for a broad range of state-of-the-art exchange-correlation (xc) functionals, plane-wave-based DFT methods for Car–Parrinello molecular dynamics (CPMD) and band structure calculations of periodic systems, higher-order many body methods like second-order Moller–Plesset (MP) perturbation theories and a full range of coupled cluster (CC) theories, relativistic approximations (DKH, ZORA), excited state approaches like time-dependent density functional theory (TDDFT), and equation of motion coupled cluster (EOMCC) theories. Most of the above approaches can be used to perform geometry optimizations (structure minimization and transition state location), frequency calculations, and/or molecular response calculations either analytically or

numerically. Macromolecular simulations and free-energy computations can be performed using classical molecular dynamics with parameterized classical force fields. These methodologies may also be combined to perform multi-physics mixed quantum mechanics/molecular mechanics (QM/MM) simulations. Other capabilities include hybrid approaches like ONIOM, continuum solvation models like COSMO, electron transfer (ET), as well as interface to a number of other programs.

## Core Capabilities

Since an exhaustive discussion of all the capabilities is beyond the scope of this essay, only a brief overview of the core capabilities is provided here. The interested reader is referred to published review articles [1, 10, 19, 46, 48] for a complete description.

## Self-consistent Field and Density Functional Theories

The Hartree–Fock (HF) or self-consistent field (SCF) method is a single determinant-based theory [45] and is an essential in any computational chemistry suite. It forms the basis for higher level electronic structure theories like Moller–Plesset perturbation theory (MP), coupled cluster (CC) theory-and other post-HF approaches. Density functional theory (DFT) [21, 35, 37] provides an alternative route to the many-electron problem and offers an excellent balance between accuracy and computational performance. It has emerged as a powerful theory that is broadly applicable. In analogy with the HF equations, DFT is rooted in the Kohn–Sham (KS) equations with the only difference being in the way the exchange and correlation is treated. In DFT, the HF exchange is replaced with a (in general nonlocal) density-dependent exchange and correlation contribution which encapsulates the complexities of the many-electron interactions. Since the exact form of the exchange and correlation in DFT contribution is an unsolved problem, a number of approximations of increasing complexity have been developed over the years [39], most of which are available in NWChem.

The HF/KS equations are very similar in structure and are typically solved using an iterative procedure with the help of basis set expansions [16, 25, 26, 45].

Two popular basis set approaches are implemented in NWChem: (1) Gaussians and (2) Plane waves.

### Gaussian Basis Set Approach

Within the Gaussian basis set approach [16, 45], both HF/KS can be expressed as a set of matrix equations:

$$\mathbf{FC} = \mathbf{SC}\epsilon \quad (1)$$

where  $\mathbf{F}$ ,  $\mathbf{C}$ ,  $\mathbf{S}$ , and  $\epsilon$  represent the Fock, coefficient, overlap, and diagonal orbital energy matrices, respectively. The problem of solving the HF/KS equations thus boils down to solving a generalized eigenvalue problem. The Fock matrix for both HF and KS formalisms can be encompassed under a single framework as:

$$F_{\mu\nu} = H_{\mu\nu}^{\text{core}} + G_{\mu\nu}^j + \alpha G_{\mu\nu}^k + \beta G_{\mu\nu}^{x-dft} + \gamma G_{\mu\nu}^{c-dft} \quad (2)$$

where  $H^{\text{core}}$  is the one-electron contribution (kinetic and ion-electron),  $G^j$  and  $G^k$  represent the two-electron (Coulomb and explicit exchange),  $G^{x-dft}$  and  $G^{c-dft}$  are the DFT exchange and correlation parts, respectively. The mixing coefficients  $\alpha$ ,  $\beta$ , and  $\gamma$  help span the HF and DFT limits. With  $\alpha = 1$ ,  $\beta = 0$ ,  $\gamma = 0$  one gets the pure HF limit, while the pure DFT limit is obtained with  $\alpha = 0$ ,  $\beta = 1$ ,  $\gamma = 1$  and  $\alpha < 1$ ,  $\beta < 1$ ,  $\gamma = 1$  covers the phase space of nonlocal hybrid-DFT forms.

The time-consuming steps in any standard implementation are computation of the two-electron integrals, construction of the two-electron contribution to the Fock matrix, computation of the exchange-correlation contribution to the Fock matrix in the case of the DFT, diagonalization of the Fock matrix, and computation of the density matrix using the molecular orbital coefficients. Within this context, only the parallelization approaches implemented in NWChem will be discussed in the following paragraphs. The reader is also referred to other detailed work on the subject [10, 12, 15, 18].

The calculation of the two-electron integrals is the most expensive and formally scales as  $O(N^4)$  even though it can be shown that the scaling is  $\approx O(N^2)$  for large molecular systems. In most parallel implementations, including NWChem, the relevant matrices are either handled in a replicated or distributed fashion or a combination [12, 15]. The replicated data approach offers a straightforward way to achieve task parallelism and low communication. Each processor maintains a copy of the necessary data. In the case of

the two-electron contribution, the Fock ( $F$ ) and density ( $D$ ) matrices are replicated over all the processors and the integral quartets are assigned to each processor as blocks. A partial  $F$  matrix is constructed on each processor and then consolidated into a full  $F$  matrix using a global sum operation. For a reasonable work distribution and an efficient global summation, this approach is perfectly parallelizable. It is also efficient for large systems because of the amount of parallel work available especially if the integrals are evaluated on-the-fly (also known as the direct approach). However, there is a potential  $O(N^2)$  memory bottleneck. The distributed approach avoids the memory bottleneck by distributing the  $F$  and  $D$  matrices, thus placing a smaller constraint on the available local memory. However, this approach is potentially more challenging from an implementation standpoint because of the extra bookkeeping. Figure 1 illustrates the strong scaling of the Gaussian basis set DFT module.

Both ground and excited state calculations on finite systems can be performed using the Gaussian basis set-based (HF/DFT) module in NWChem.

### Plane Wave Approach

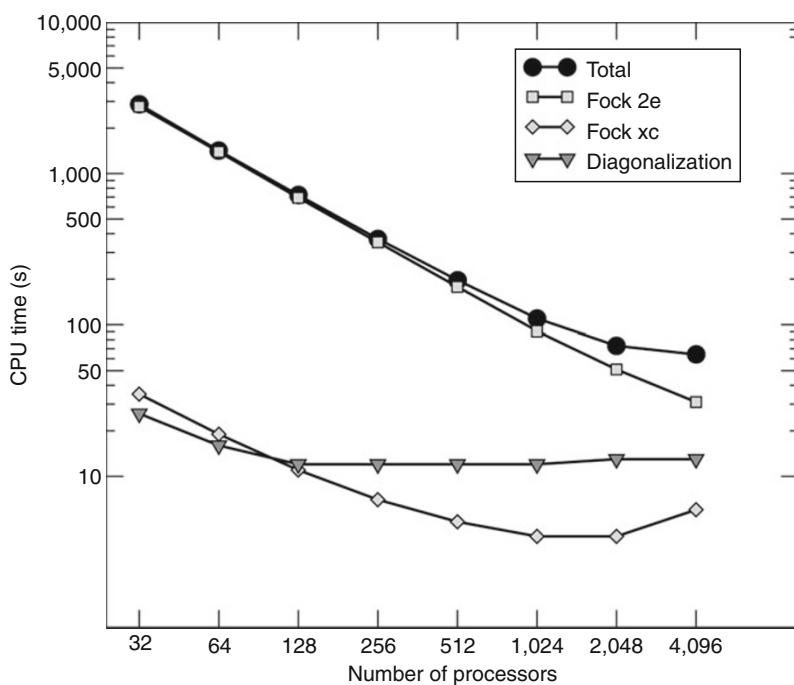

The plane wave DFT module in NWChem is composed of three components that use a common infrastructure: PSPW (a pseudopotential-based  $\Gamma$ -point code for isolated and periodic systems), BAND (a code to calculate the band structure of crystals and surfaces), and PAW (a projector-augmented-wave-based  $\Gamma$ -point code for isolated and periodic systems). Within the plane wave approach the single-particle wavefunctions of a periodic system can be expanded in general as [4, 25, 26]:

$$\psi_{jk}(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}} \sum_{\mathbf{G}} \tilde{\psi}_{jk}(\mathbf{G}) e^{i\mathbf{G}\cdot\mathbf{r}} \quad (3)$$

where  $\mathbf{k}$  is a vector in the first Brillouin zone,  $\mathbf{G}$  is the reciprocal lattice vector, and  $j$  represents the orbital index, respectively. For isolated systems like molecules, the Brillouin zone sampling is limited to the  $\Gamma$ -point ( $\mathbf{k}=0$ ) which in turn yields:

$$\psi_j(\mathbf{r}) = \sum_{\mathbf{G}} \tilde{\psi}_j(\mathbf{G}) e^{i\mathbf{G}\cdot\mathbf{r}} \quad (4)$$

The size of the plane wave basis set expansion is determined by the maximum kinetic energy cutoff ( $E_{cut}$ ) via

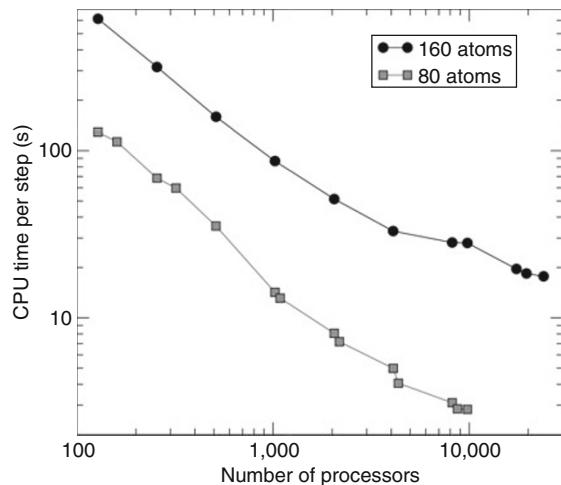

**NWChem. Fig. 1** Parallel scaling of the Gaussian basis set HF/DFT implementation on the  $C_{240}$  system. Calculations were performed using the PBE0 hybrid exchange-correlation functional and the 6-31G\* basis with a total of 3,600 basis functions for the whole system. Integral evaluations were performed using the on-the-fly (or direct) approach and Fock matrix replication. The figure shows the scaling of the various components

the following relation:

$$\frac{1}{2}|\mathbf{G}|^2 < E_{cut} \quad (5)$$

Some favorable features of the plane wave expansion include: being able to treat periodic systems in a seamless way, efficient calculation of the expansion coefficients using Fast Fourier Transform (FFT) techniques, independence of the basis with respect to nuclear positions which makes it immune to superposition, and over-completeness problems which are critical issues in local basis set approaches.

Because plane wave basis sets are typically much larger than a local basis, explicit Fock matrix construction and diagonalization is avoided in favor of direct optimization approaches like conjugate gradient minimization [38]. The most time-consuming steps of plane wave-based algorithms are the evaluation of the pseudopotential (specifically the nonlocal contribution), wavefunction orthogonalization, and exact exchange (if needed) in the description of the exchange-correlation. Several parallelization strategies [4, 5, 7, 26, 29] have been implemented in NWChem to mitigate issues such as parallel data distribution over the wavevectors, distribution of the orbitals, and distribution of the real and reciprocal space grids. The wavevector distribution is a popular approach for solid-state applications, but the scalability is hindered by the size of the Brillouin zone and the method is not applicable to the pure  $\Gamma$ -point calculations. Orbital distribution has been shown to scale favorably, but this entails storage of the entire one-electron orbital on a single node and is not practical for large molecular systems which typically require a large plane wave expansion. The most commonly implemented strategy, including NWChem, is the spatial distribution of the real and reciprocal grid points (typically along a single dimension) are stored on different processors. This approach is not only scalable, but also fairly economical from a memory management standpoint. The trade-off here is the increased communication costs due to parallel three-dimensional FFTs which plateau beyond  $\sqrt[3]{N_1 N_2 N_3}$  processors ( $\approx 100$  for typical applications). This limitation may be avoided by distributing the spatial and orbital degrees of freedom on a two-dimensional processor grid [14]. This approach is also available in NWChem.

**NWChem. Fig. 2** Parallel scaling of hybrid DFT plane wave calculations on the  $\text{Fe}_2\text{O}_3$  system for unit cells containing 80 and 160 atoms, respectively

The plane wave DFT module in NWChem also has a highly scalable algorithm [4, 10, 46] for exact exchange which makes it possible to perform calculations using hybrid exchange-correlation functionals. Using this approach, scaling to over 20,000 CPUs for modest size problems has been achieved. This is shown in Fig. 2 where the parallel scaling is demonstrated for  $\text{Fe}_2\text{O}_3$  with unit cells containing 80 and 160 atoms, respectively.

### Coupled Cluster Theory

Coupled cluster theory [3, 6, 36] (CC) is a method rooted in many-body perturbation theory (MBPT) and is considered by many to be the gold standard for accurate quantum mechanical calculations of ground and excited states. Over the years, it has grown into one of the most reliable approaches for describing correlation effects in atoms and molecules. In CC theory the wavefunction is expressed as an exponential ansatz:

$$|\Psi_0\rangle = e^{\hat{T}}|\Phi\rangle \quad (6)$$

where  $|\Phi_0\rangle$  is the ground-state function.  $\hat{T}$  is the cluster operator which produces a linear combination of excited determinants when acting on the reference function  $|\Phi\rangle$  (typically represented by the HF determinant). In CC theory, the energy is obtained as:

$$E = \langle\Phi|e^{-T}He^T|\Phi\rangle \quad (7)$$

The systematic inclusion of excitations of higher rank in the cluster operator results in a series of more accurate approximations. In the basic CCSD [40] approach (CC with singles and doubles) the cluster operator is approximated as  $T \approx T_1 + T_2$ . Similarly, in the more accurate CCSDT [34] approach (CC with singles, doubles, and triples) the cluster operator is represented as  $T \approx T_1 + T_2 + T_3$ . The higher accuracy of the CCSDT energies comes at a steep price because of the extra numerical complexity and scales as  $N^8$  with system size. Consequently, many non-iterative approaches which mediate the cost between the CCSD ( $N^6$ ) and CCSDT ( $N^8$ ) methods have dominated this field, the CCSD(T) [41] approach, which scales as  $N^7$  with system size, being the most well known and most frequently used.

Excited state calculations can be accomplished within single-reference CC theory via the linear response CC [29] (LR-CC) and equation-of-motion CC formalisms (EOMCC). Analogous to ground-state calculations, various iterative (EOMCCSD [8], EOMCCSDT [24]) and non-iterative approaches have been implemented in NWChem [10, 46].

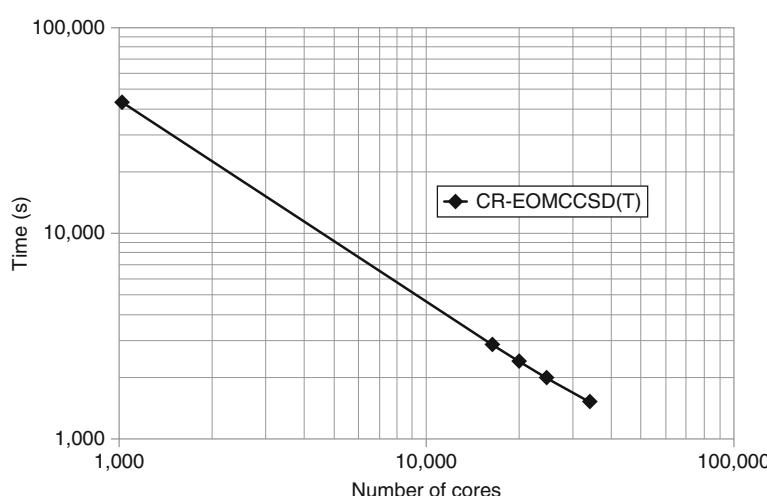

Since the CC equations involve contractions between tensors corresponding to the one- and two-electron integrals and cluster amplitudes, the task of writing efficient parallel CC code is extremely challenging. The main issues that define the overall parallel efficiency are related to (a) data storage and data transfer, (b) efficient load balancing, and (c) data flow during

the execution phase. Another significant issue is associated with the most efficient reduction of the numerical complexity of a given CC method.

NWChem provides a complete implementation of CC theory geared toward efficient execution on high-performance parallel architectures. Two classes of parallel CC codes have been implemented, a spin-free code for closed-shell systems [20] and a code based on the tensor contraction engine (TCE) [17]. It was recently demonstrated that the non-iterative (T) part of the spin-free code can be made to scale across 250,000 processors [2]. The TCE-based codes are automatically generated spin-orbital codes that can be used for a broad range of reference functions (RHF, ROHF, UHF, DFT). Here the block or tile structure of all the tensors is extensively used in the code for dynamic load balancing. This code is also parallelized using the GA library which is used to store all the tensors. The scaling of the CR-EOMCCSD(T) method is shown in Fig. 3. The reader is also referred to more recent applications that demonstrate the scaling of the CC module [22, 23].

### Classical Molecular Dynamics

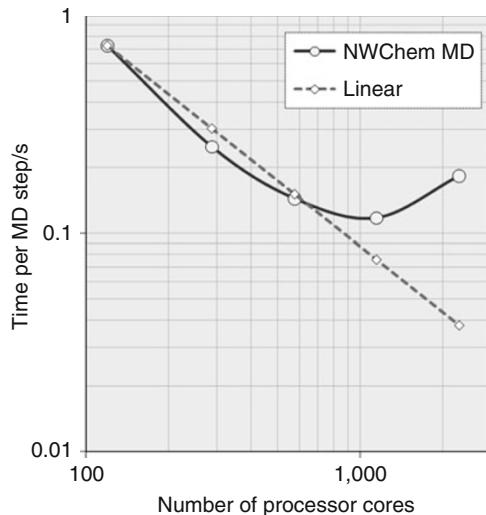

NWChem provides a highly scalable parallel framework for classical molecular dynamics (MD) simulations based on classical potentials (Amber [9]). The parallelization strategy is based on a domain decomposition approach which provides the best theoretical scalability of memory use and communication cost. In the domain

**NWChem. Fig. 3** Parallel scaling of the non-iterative triples correction ( $N^7$  (T)) in CR-EOMCCSD(T) calculations of the green fluorescent protein (GFP) with the cc-pVTZ basis set

decomposition model [43, 44] the physical space occupied by the system is distributed and the atoms are assigned to a processor based on their location. This is accomplished by dividing the total finite or periodic system being studied into slices along the three dimensions. Communication is made more efficient by logically arranging the processors in a three-dimensional grid. This permits one or more sub-domains to be assigned to a processor and preserves locality of the sub-domains which is essential for efficient communication. The domain decomposition has some advantages and disadvantages. The former includes: avoiding atomic data replication on each processor, memory reduction to hold the entire system in core. The latter includes: the need for periodic reassessments of the atoms that move between sub-domains, the need for a sophisticated dynamic load-balancing scheme for heterogeneous systems. Other challenges include dealing with systems with incommensurate spatial decompositions. The MD implementation in NWChem takes advantage of one-sided asynchronous capabilities provided by the GA toolkit, which allows for more sophisticated dynamic load-balancing algorithms to handle these issues.

Electrostatic contributions are evaluated using the smooth Particle Mesh Ewald (sPME) method [11] which employs the efficient three-dimensional Fast Fourier Transform (3D-FFT) approach. The data access patterns in the 3D-FFT, however, hinders efficient parallelization over large numbers of processors. To address this issue, a slab-based 3D-FFT is used so that the transform in two dimensions takes place on a single processor, thereby avoiding interprocessor communication. This leaves one dimension in which communication is required. The main scaling difficulty of this algorithm is that it only allows as many processors to be used for the 3D-FFT as there are slabs in the grid. To remedy this limitation and to achieve strong scaling to a larger number of processors than the number of slabs used to define the charge grid, the reciprocal space calculations are performed on a subset of the total number of processors used to carry out the simulation. Simultaneously with this subset of processors (or subgroup) performing the FFTs, the potentially much larger group of remaining processors handle the direct space interactions. The number of processors to be used for the FFTs can be specified in the input. The use of subgroups

**NWChem. Fig. 4** Time per molecular dynamics step for a SPC/E water simulation in the microcanonical ensemble with 648,000 atoms

is a standard feature of the Global Arrays toolkit. Figure 4 illustrates the time per molecular dynamics step for a SPC/E water simulation in the microcanonical ensemble with 648,000 atoms.

## Combined Quantum Mechanical Molecular Mechanics

The combined quantum mechanical molecular mechanics (QM/MM) module in NWChem provides an effective tool to study localized molecular transformations in large-scale systems such as those encountered in solution chemistry or enzyme catalysis. This approach entails using an accurate quantum mechanical (QM) method(s) in a small region of interest embedded in an environment which is treated using a lower level approximate theory (e.g., classical molecular mechanics). With this decomposition, the total energy of the system is given by the sum of the quantum ( $E_{qm}$ ) and classical energies:

$$E = E_{qm}[\mathbf{r}, \mathbf{R}; \psi] + E_{mm}[\mathbf{r}, \mathbf{R}] \quad (8)$$

where  $\mathbf{r}$ ,  $\mathbf{R}$  represents the coordinates of QM and MM regions and  $\psi$  denotes the ground or excited electronic wavefunction of the QM region. The QM contribution can be further decomposed into internal and external

contributions as [47]:

$$E_{qm} = E_{qm}^{\text{int}}(\mathbf{r}; \psi) + E_{qm}^{\text{ext}}(\mathbf{r}, \mathbf{R}; \rho) \quad (9)$$

where the internal part  $E_{qm}^{\text{int}}(\mathbf{r}; \psi)$  is the gas phase energy expression and the external part contains the electrostatic interactions of the classical charges ( $Z_I$ ) of the MM region with the electron density ( $\rho$ ):

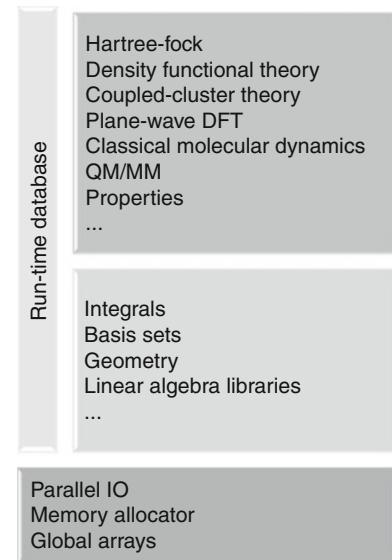

$$E_{qm}^{\text{ext}}(\mathbf{r}, \mathbf{R}; \rho) = \sum_I \int \frac{Z_I \rho(\mathbf{r}')}{|\mathbf{R}_I - \mathbf{r}'|} d\mathbf{r}' \quad (10)$$

All the classical interactions as well as the van der Waals and electrostatic interactions with the quantum region are subsumed in the classical energy term ( $E_{mm}$ ). Since a clean separation between the quantum and classical regions is not always possible, different schemes (e.g., link atoms, bond capping schemes) have to be utilized [13, 49]. The NWChem implementation supports two different treatments of link atoms – hydrogen and pseudo-carbon capping schemes.

The QM/MM module in NWChem is built as a top-level interface between the classical MD module and various QM modules and supports a wide variety of calculations like optimizations, dynamics, free energy calculations, to name a few. The scaling of QM/MM calculations is largely determined by the scaling of the underlying QM and MM implementations. We refer the reader to published review articles for further details regarding the implementation of this module [46, 47].

## Parallel Framework

NWChem uses the Global Array (GA) toolkit to scale and perform on parallel platforms [32, 33]. Figure 5 illustrates how the various modules are integrated into a single framework. Since the GA programming model includes message passing as a subset, the libraries within the toolkit can interoperate with MPI [27] for message passing. In other words, the programmer can make full use of MPI on GA and non-GA data. The GA toolkit comprises of the Memory Allocator (MA) which provides access to local memory, the Global Arrays (GA) which provides the necessary portable shared-memory programming tools, the Aggregate Remote Memory Copy Interface (ARMCI) [30] for portable and efficient remote memory copy operations (also known as one-sided communication) optimized for noncontiguous (strided, scatter/gather, I/O vector) data transfers,

**NWChem. Fig. 5** Schematic showing how the various modules in NWChem are integrated within a single framework along with the parallel libraries

and the Parallel I/O (ParIO) [31] tool to extend the nonuniform memory architecture model to disk.

The GA toolkit combines the best features of both the shared and distributed memory programming models. It implements a shared-memory programming model on distributed memory architectures in which data locality can be managed directly by the programmer. This is accomplished by explicit function calls that transfer data between a global address space (e.g., a distributed array) and local storage. This makes the GA model similar to distributed shared-memory (DSM) models that provide explicit acquire/release protocols. However, the GA model acknowledges that remote data is slower to access compared with local data and therefore allows data locality to be explicitly managed. By optimizing and selectively moving the data requested by the user, the GA model avoids problems like redundant data transfers. The GA model exposes the programmer to the hierarchical memory of modern high-performance computer systems and promotes data reuse and locality by recognizing the communication overhead for remote data transfer.

The GA library can be used in C, C++, Fortran 77, Fortran 90, and Python programs. The GA toolkit offers

support for both task and data parallelism. Task parallelism is supported via one-sided or non-collective copy operations that transfer data between global memory (distributed/shared array) and local memory. Each process can directly access data in a section of a Global Array that is logically assigned to it. Atomic operations are provided for synchronization and to assure correctness of an accumulate operation (e.g., floating-point addition that combines local and remote data) which is crucial to several electronic structure algorithms.

The data parallel computing model is supported through a set of functions that are collectively called that operate on either entire arrays or sections of Global Arrays. This set comprises BLAS-like operations (copy, additions, transpose, dot products, and matrix multiplication). Some are defined and supported for all array dimensions (e.g., addition), whereas operations like matrix multiplication are limited to two-dimensional arrays. Nevertheless, multiplication may be performed on two-dimensional subsets of higher dimensional arrays. The GA toolkit also includes interface to parallel linear algebra libraries like PeIGS and ScaLAPACK [42].

## Acknowledgments

The NWChem software and its documentation are developed at the EMSL located at PNNL, a multiprogram national laboratory, operated for the US Department of Energy by Battelle under the Contract Number DE-AC05-76RL01830. The code development is supported by the Department of Energy Office of Biological and Environmental Research, Office of Basic Energy Sciences, and the Office of Advanced Scientific Computing. Calculations reported here were performed using the Molecular Science Computing Capability (MSC) in the EMSL as well as resources of the National Energy Research Scientific Computing Center (NERSC) located at the Lawrence Berkeley Laboratory (LBL), California. The EMSL is funded by the Office of Biological and Environmental Research in the US Department of Energy.

## Omega Test

DAVID WONNACOTT  
Haverford College, Haverford, PA, USA

### Synonyms

Omega calculator; Omega library; Omega project

### Definition

The Omega Test is an algorithm for dependence analysis that was developed by Bill Pugh's Omega Project in the 1990s to enable work on advanced loop optimizations. It is notable for its manipulation of constraints on integer variables to produce a representation of dependences that is more precise than distance/direction vectors, thereby enabling advanced analyses and transformations.

### Exact Instance-Based Array Dependence Information

Optimization of loop nests requires information about dependences that is both detailed and accurate. Even

for the restricted case in which array subscripts and loop bounds must be affine functions of loop indices, testing for the existence of a dependence is equivalent to testing satisfiability of a conjunction of affine constraints on integer variables, which is NP-complete [4]. Fortunately, in practice most array subscripts and loop bounds are even simpler, and low-complexity tests such as the GCD test and Banerjee's Inequalities produce accurate results in many cases.

In the late 1980s and 1990s, Paul Feautrier and Bill Pugh led independent efforts to improve array dependence analysis with techniques that were exact for the entire affine domain and fast for the common cases [2, 9, 11]. While some researchers felt exponential algorithms had no place in compilers, others saw value in the more precise information produced by these techniques. This approach, known variously as “constraint-based analysis,” the “polyhedral model,” or “instance-wise analysis,” remains an important tool for advanced restructuring compilers, some of which make use of the original code of Pugh or Feautrier. The remainder of this article reviews the work of Pugh's Omega Project; for information about other work on this area see the web sites [21, 22].

### Traditional Dependence Abstractions

To illustrate some of the issues involved in dependence analysis, consider the codes shown in Fig. 1 – each of these loops might write an element of array A that is read in a later iteration, so each is said to exhibit an inter-iteration flow dependence based on A, which inhibits parallel execution of the loop iterations. Earlier work on dependence analysis not only approximated some affine cases, but also reported only simple dependence abstractions, e.g., identifying loops that carry a dependence or classifying dependences with direction vectors or distance vectors. Regardless of its accuracy or domain, any test that produces this information must

report that both loops carry a dependence with a distance that is not known at compile time (assuming we lack information about  $n$  and  $k$ ).

A more detailed examination of the dependences of Fig. 1 reveals that the loops can be parallelized with different strategies, as illustrated in Fig. 2 (circles correspond to iterations, with lower values of  $i$  to the left, and each arrow indicates a flow dependence between iterations). For the illustrated case ( $n = 8$  and  $k = 3$ ), Fig. 1a has dependences from iteration 0 (which writes a value into  $A[0]$ ) to iteration 7 (which reads a value from  $A[0]$ ), from 1 to 6, from 2 to 5, and from 3 to 4; Fig. 1b has dependences from 0 to 3, 1 to 4, 2 to 5, 3 to 6, and 4 to 7. These patterns suggest that there may be some cases in which we can run some of the iterations in parallel, e.g., when  $n = 8$  and  $k = 3$  we could execute iterations 0–3 of Fig. 1a simultaneously, and iterations 0–2 of Fig. 1b simultaneously. However, conclusions about program transformation must be made about the general case.

## Dependence Relations

The Omega Test describes the dependences in terms of relations among tuples of integers. To retain correspondence with the program being analyzed, these integers may be identified as inputs (e.g., the source of a dependence), outputs (the sink), or symbolic constants. A finite set of dependences can be given as a list (union) of such tuple relations, e.g., for Fig. 2a as  $\{[0] \rightarrow [7]\} \cup \{[1] \rightarrow [6]\} \cup \{[2] \rightarrow [5]\} \cup \{[3] \rightarrow [4]\}$ . Integer variables and constraints allow a representation that is both concise (allowing  $\{[i] \rightarrow [7-i] \mid 0 \leq i \leq 3\}$

```
// Example 1a
for (i=0; i<n; i++)
 a A[i] = A[n-1-i]*B[i];

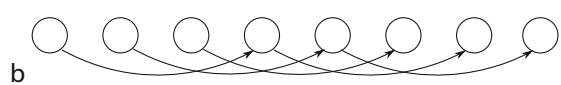

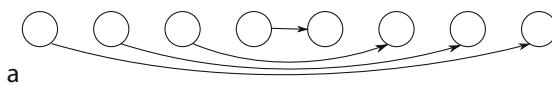

// Example 1b
for (i=0; i<n; i++)
 b A[i+k] = A[i]*B[i];
```

**Omega Test. Fig. 1** Simple loops exhibiting data dependences

for Fig. 2a) and general  $([i] \rightarrow [n-1-i] \mid 0 \leq i < \frac{n}{2})$  when  $n$  is not known, as in Fig. 1a).

These dependence relations follow directly from the application of the definition of data dependence to the program to be analyzed. A flow dependence exists between a write and a read (e.g., from iteration  $[i]$  to  $[i']$ ) when the subscript expressions are equal (e.g.,  $i = n-1-i'$  in Fig. 1a), the loop index variables are in bounds ( $0 \leq i < n \wedge 0 \leq i' < n$ ), and the dependence source precedes the sink ( $i < i'$ ). Combining these constraints produces  $\{[i] \rightarrow [i'] \mid i = n-1-i' \wedge 0 \leq i < n \wedge 0 \leq i' < n \wedge i < i'\}$  for 1a and  $\{[i] \rightarrow [i'] \mid i' = i+k \wedge 0 \leq i < n \wedge 0 \leq i' < n \wedge i < i'\}$  for 1b. These dependence relations are *exact* in the following sense: for any given values of the symbolic constants and loop indices, the constraints evaluate to true if and only if a dependence would actually exist. The constraint-manipulation algorithms of the Omega Library (see ▶Sect. Representation and Manipulation of Sets and Relations) can confirm that these relations are satisfiable and produce a simpler form, in these cases  $\{[i] \rightarrow [n-1-i] \mid 0 \leq i \wedge 2i \leq n-2\}$  ( $2i \leq n-2$  is equivalent to  $i < \frac{n}{2}$  but does not introduce division) and  $\{[i] \rightarrow [i+k] \mid 0 \leq i < n-k\}$ .

This representation of dependences extends naturally to nested loops with the introduction of additional variables in the input and output tuple – dependences among references nested in loops  $i$  and  $j$  would be represented as relations from  $[i,j]$  to  $[i',j']$ . An imperfect loop nest such as that shown in Fig. 3 raises the additional challenge of identifying the lexical position of each statement or inner loop (i.e., is it the first, second, etc. component within the loop?). This challenge can be met by interspersing (among the loop index values) constant values that give the statement position. If the  $i$  loop in Fig. 1 is the first (or only) statement in its function, and the update to  $A$  is the first (or only) statement in this loop, we could represent the dependence above as a relation from  $[1, i, 1] \rightarrow [1, i', 1]$ . For Fig. 3, the dependence from the write of  $A[i]$  to the read  $A[i-1]$  is  $\{[1, t, 2, i, 1] \rightarrow [1, t', 1, i', 1] \mid i'-1 = i \wedge t < t' \wedge 0 \leq t, t' < T \wedge 1 \leq i, i' < N-1\}$ .

**Omega Test. Fig. 2** Iteration spaces and flow dependences for Fig. 1, when  $n = 8$  and  $k = 3$

While it is possible to produce dependence distance/direction vectors from the dependence relations produced by the Omega Test, the results are often no more accurate than those produced by earlier tests such as a combination of Banerjee's inequalities and the GCD test. However, the added precision of the dependence relation can enable other forms of analysis or transformation if it is passed directly to later steps of the compiler.

## Advanced Program Analysis and Transformation

The detailed information present in a dependence relation can be used as a basis for a variety of program analyses, including analysis of the flow of values within a program's arrays, analysis of conditional dependences, and analysis of dependences that exist over only a subset of the iteration space. This information can then be used to drive a number of program transformation/optimization techniques on perfectly or imperfectly nested loops.

### Advanced Analysis Techniques: The Omega Test

Information about the iterations involved in a dependence can reveal opportunities for parallelization after transformations such as index set splitting or loop peeling. Note that any iterations that are not the source of a dependence arc (e.g., iterations 4–7 of Fig. 2a) can be executed concurrently after all other loop iterations have been completed; and those that are not a sink (iterations 0–3 in Fig. 2a) can be executed concurrently before any other has started. The Omega Library's ability to represent sets of integer tuples as well as relations can be used to show that there are never any iterations other than these nonsink and nonsource iterations for Fig. 1a, so this loop (unlike that in 1b) can be run in two sequential phases of parallel iterations.

The symbolic information present in a dependence relation can be used to detect conditional dependences. The flow dependence relation for Fig. 1b clearly implies that the flow dependence exists only when  $0 < k < n$ ; the Omega Library's projection and "gist" operations (see ▶Sect. The Gist Operation) can be used to extract this information. A compiler could introduce conditional parallelism (e.g., run the loop in parallel when  $n \leq k$ )

```

for (t = 0; t < T; t++) {
 for (i = 1; i < N-1; i++) {
 new[i] = (A[i-1] + A[i] + A[i+1]) * (1.0/3);
 }
 for (i = 1; i < N-1; i++) {
 A[i] = new[i];
 }
}

```

**Omega Test. Fig. 3** A set of "imperfectly nested" loops

or use additional analysis or queries to the programmer to attempt to prove no dependence ever exists.

By combining instance-wise information about memory aliasing with information about iterations that overwrite array elements, the Omega Test can produce information about the flow of values (termed "value-based dependence information" by the Omega Project). For example, the "memory-based" flow dependence shown above for Fig. 3 connects writes to reads in all subsequent iterations of the  $t$  loop – i.e., when  $t' > t$ . However, the value written in iteration  $t$  is overwritten in iteration  $t + 1$ , and thus never reaches any subsequent iteration. The value-based dependence relation includes this information, showing dependences only when  $t' = t + 1$ , as shown in ▶Sect. Disjunctive Normal Form. Value-based dependence information can be used for a variety of optimizations, e.g., to identify opportunities for parallelization after array privatization or expansion.

The Omega Project uses the term "Omega Test" for the production of symbolic instance-wise memory- or value-based dependence relations via the steps outlined above. More detail about the specific algorithms involved in dependence testing can be found in [16] as well as earlier publications by these authors.

### Iteration Space Transformation

Iteration space transformations can be viewed as relations between elements of the original and transformed iteration space, and thus represented and manipulated with the same infrastructure as dependence relations. Iteration spaces can be related to execution order via a simple rule such as "iterations are executed in lexicographical order," thereby turning iteration space transformation into a tool for transforming order of execution. A similar approach can be used to describe and transform the association of values to memory cells [19], though this has not been explored as thoroughly.

The “transformation as relation” framework unifies all unimodular loop transformations (e.g.,  $\{[i,j] \rightarrow [j,i]\}$  describes loop interchange) with a number of other transformations. Perhaps more importantly, this framework handles imperfect loop nests, which lie outside the domain of unimodular techniques. For example, consider the problem of fusing the inner loops of Fig. 3. Simple loop fusion can be accomplished by making  $A[i] = \text{new}[i]$  into the *second* statement in the *first*  $i$  loop, i.e.,  $\{[1,t,2,i,1] \rightarrow [1,t,1,i,2]\}$ . However, fusion without first aligning the loops is illegal;  $\{[1,t,2,i,1] \rightarrow [1,t,1,i+1,2]\}$  is a correct alignment and fusion (now element  $A[1]$  is overwritten in iteration  $i = 2$ , just after its last use in the computation of  $\text{new}[2]$ ). This transformation produces a loop nest with much better memory locality, since (barring interference) it moves each array into cache only once per time step rather than twice. Algorithms for finding useful program transformations in this framework, and for generating code from the resulting iteration space sets, are discussed in [5, 6, 10, 18].

### Iteration Space Slicing

Iteration space transformations can also be defined in terms of “iteration-space slicing”: the instance-wise analog of program slicing. This approach can express very general approaches to program transformation in terms that are relatively concise and clear.

To illustrate iteration space slicing, consider the challenge of parallelizing the code in Fig. 1b even when the dependence exists, as in Fig. 2b. Figure 4 shows the iteration space of this loop when  $n = 8$  and  $k = 3$  (as in Fig. 2b), together with the backward iteration space slice for iteration 7 (the set of other iterations that must be executed to produce the value in the target iteration). A similar backward slice for iteration 6 would include iterations 3 and 0.

It is possible to run Fig. 1b as  $k$  concurrent threads, each of which updates every  $k$ th element. A simple test could be used to identify and parallelize this specific

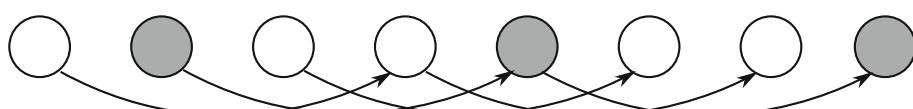

case (a one-dimensional loop with a single constant-distance dependence), but iteration space slicing provides a concise way to generalize this idea: find the backward slices to the iterations that are not the source of any dependence – if these slices do not intersect, they can be run concurrently to produce the result of the loop nest.

In some cases, it may be necessary to find the iteration space slice needed to compute one result given that another slice has already been completed. For example, consider the challenge of increasing the memory locality of Fig. 3 by more than the factor of two achieved in ►Sect. Iteration Space Transformation. Figure 5 shows the iteration space of a sample run of the original form of this code: each time step is shown as a column of circles representing the computations of  $\text{new}[i]$ , followed by a column of squares representing the copy into  $A[i]$ . The slice needed to compute  $A[1]$  is shown as dashed iterations surrounded by a dashed border; the marginal slice needed for  $A[2]$  given that  $A[1]$  has been computed is shown as shaded iterations. Executing this code as a series of sequential slices can greatly improve the memory locality (given a cache large enough to hold the results of a few slices, this can reduce memory traffic from  $O(T \cdot N)$  to  $O(N)$  in the absence of interference, producing dramatic speedups for slow memory systems [19]).

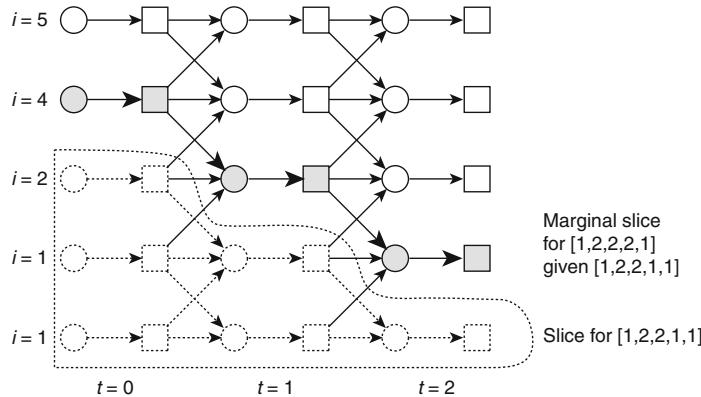

Algorithms for iteration space slicing, for producing transformations with it, and for generating code to execute slices are described in [12, 13, 19].

### Representation and Manipulation of Sets and Relations

The Omega Library (or simply “Omega” when in context) employs a number of techniques to transform the constraints extracted from programs in ►Sect. Exact Instance-Based Array Dependence Information into answers to the questions of ►Sect. Advanced Program

**Omega Test. Fig. 4** The backward iteration space slice for iteration 7 of Fig. 2b

**Omega Test. Fig. 5** Iteration space and two slices for Fig. 3,  $T = 3, N = 7$

**Analysis and Transformation.** The details of representation and manipulation depend on the nature of the constraints and the question being asked.

Most algorithms can be expressed either in terms of individual (in)equations or higher-order operations on relations and/or sets. For example, a compiler could construct each memory-based flow dependence relation by creating appropriate tuples for input and output variables and then examining loop bounds, subscript expressions, etc., to produce the appropriate constraints on the tuples' variables. Alternatively, it could first define a set for the iteration space  $I$  of each statement  $S$  ( $I_s$ ), and a relation  $M$  mapping loop iteration to array index for each array reference  $R$  ( $M_R$ ), and relations  $T$  for forward-in-time order for various loop depths, and then construct a flow dependence by combining these, i.e., the dependence from access  $x$  to  $y$  could be found by taking  $(M_x \bullet (M_y)^{-1}) \cap T_{xy}$  and restricting its domain to  $I_x$  and its range to  $I_y$ .

Some operations on relations or sets simply involve re-labeling of free variables, e.g., swapping the input and output tuples to find  $R^{-1}$  from a relation  $R$ . Others such as intersection ( $\cap$ ) involve matching up variables from input and output tuples, and possibly converting free variables to quantified variables; in the relational join and composition operations (for  $R_1 \bullet R_2$  or the equivalent  $R_2 \circ R_1$ ),  $R_1$ 's input tuple becomes the input tuple,  $R_2$ 's output tuple the output tuple, and  $R_1$ 's outputs and  $R_2$ 's inputs become existentially quantified variables, all constrained to the intersection of the constraints from  $R_1$  and  $R_2$ . Finally, some operations such as transitive closure are defined in Omega only as relational operators.

The remainder of this section gives an overview of the algorithms used in the Omega Library. It progresses from less-expressive to more-expressive constraint languages, roughly following the historical development of the algorithms of the Omega Library, and gives descriptions in terms of collections of (in)equations rather than relations or sets. For more detail on these algorithms or the relationship between high- and low-level operations, see the cited papers, or [7] for transitive closure algorithms.

## Conjunctions of Affine Equations and Inequations

The fundamental data structure of the Omega Library represents a conjunction of affine equations and inequations with integer coefficients (Omega does not currently represent disequations such as  $n \neq m$ , so hereafter the term inequation refers only to  $<$ ,  $\leq$ ,  $\geq$ , and  $>$  constraints, each of which is converted to  $\geq$  form internally). Each individual (in)equation is immediately reduced to lowest terms (e.g., turning  $3x + 9y + 21 = 0$  into  $x + 3y + 7 = 0$ ), and hash keys that ignore constant terms are used to quickly detect (and remove) simple redundancies (e.g.,  $a - 2b \geq 0$  and  $a - 2b + 10 \geq 0$  have the same hash key and the latter can be removed). The hashing system also detects (and replaces) pairs of inequations that are equivalent to an equation (e.g.,  $i \geq 5$  and  $i \leq 5$  are converted to  $i = 5$ ).

High-level operations for these conjunctions rely on lower-level operations on sets of (in)equations, such as variable elimination and redundancy detection. Variable elimination is also referred to as “projection” or

finding the “shadow” of a set or relation, since finding the two-dimensional shadow of a three-dimensional object can be thought of as an example of this operation. Note, however, that the shadow of the integer points in a set/relation is *not* always the same as the integer points in the shadow (as per the discussion of Fig. 6 below).

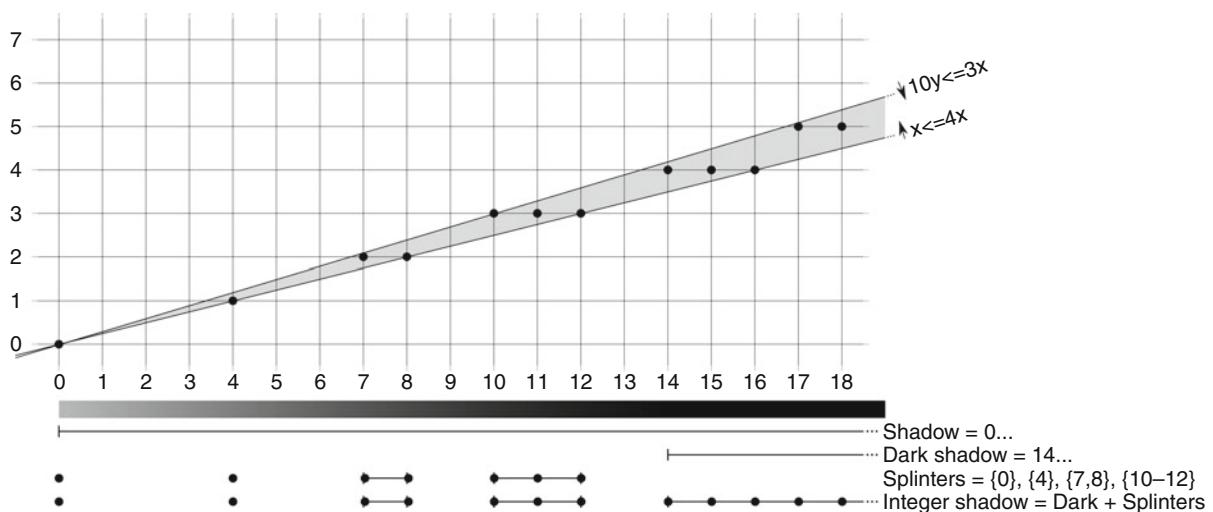

To illustrate Omega’s variable elimination and redundancy detection abilities, recall the dependence from Fig. 1b. Checking for possible dependence corresponds to existentially quantifying a dependence relation’s free variables (inputs, outputs, and symbolic constants), in this example checking the formula  $(\exists i, i', n, k : i' = i + k \wedge 0 \leq i < n \wedge 0 \leq i' < n \wedge i < i')$ . None of the six (in)equations of this formula is redundant with respect to any one other, so all are retained to the start of our query. Omega begins by using equations to eliminate variables: given  $i' = i + k$  it could replace all occurrences of  $i'$  with  $i + k$ , producing the formula  $(\exists i, n, k : 0 \leq i < n \wedge 0 \leq i + k < n \wedge 0 < k)$ . (Additional properties of integer arithmetic are used to eliminate an equation even when no variable has a unit coefficient, as discussed in [9].)

Upon running out of equations, Omega moves on to eliminate variables involved in inequations. Inequations are removed in several passes, with quick passes occurring first. Omega checks for variables that are bounded only on one side (i.e., have no lower bounds or no upper

bounds). Such variables cannot affect the satisfiability of the system, so they can be removed, along with all constraints on them – in this example,  $n$ , then  $k$ , and then  $i$  are removed in turn, producing an empty conjunction, i.e., True.

To illustrate some of the other algorithms used for affine conjunctions, we consider what would happen in this example if we knew  $n \leq 1,000$  (perhaps the loop in Fig. 1 is guarded by the test if  $n \leq 1,000$ ), i.e.,  $(\exists i, n, k : 0 \leq i < n \wedge 0 \leq i + k < n \wedge 0 < k \wedge n \leq 1,000)$ . In the absence of variables bounded on only one side, Omega examines groups of three inequalities to determine if any two contradict a third or make it redundant. In our running example,  $i + k < n$  and  $0 < k$  make  $i < n$  redundant, and  $0 \leq i$  and  $0 < k$  make  $0 \leq i + k$  redundant, reducing the query to  $(\exists i, n, k : 0 \leq i \wedge i + k < n \wedge 0 < k \wedge n \leq 1,000)$ .

Omega then moves on to its most general technique: an adaptation of Fourier’s method of variable elimination. Fourier’s method can be used to eliminate a variable  $v$  in a conjunction of affine inequations, by replacing the set of inequations on  $v$  with the set of all possible combinations of one upper and one lower bound on  $v$  – for example, replacing  $0 \leq i$  and  $i < n - k$  with  $0 < n - k$ . The original conjunction has a rational solution if and only if the new one does; the new system has one variable fewer, but may have many more inequations.

**Omega Test. Fig. 6** Shadow and dark shadow metaphors for integer variable elimination

The Omega Library uses an extension of Fourier’s method that preserves the presence of *integer* solutions. This process eliminates a variable by comparing the result of Fourier’s original technique (which produces the “shadow”) with a variant Pugh calls a “dark shadow” – a lower-dimensional conjunction that has integer solutions *only if* the original did. The set of integer solutions to the lower-dimensional system is the union of this dark shadow and the “splinter” solutions that lie within the shadow but outside the dark shadow [9].

Omega repeatedly eliminates variables to produce a trivially testable system with at most one variable, possibly producing  $(\exists n, k : 0 < n - k \wedge 0 < k \wedge n \leq 1,000)$  and then  $(\exists n : 0 < n \leq 1,000)$  in our running example. Since the query is now clearly satisfiable, the Omega Test concludes that there must be some values of the constants  $n$  and  $k$  for which a dependence exists between some iterations.

The example above, like most occurring during dependence analysis, does not illustrate the use of splintering to project integer solutions. Figure 6 shows an example for the inequations  $10y \leq 3x \wedge x \leq 4y$ , which have integer solutions for  $x = 0, 4, 7, 8, 10, 11, 12$  and  $x \geq 14$ . If Omega were to eliminate  $y$  during satisfiability testing of  $10y \leq 3x \wedge x \leq 4y \wedge x \leq 100$ , it would find that the dark shadow ( $14 \leq x \leq 100$ ) is satisfiable, and report True; if it were to eliminate  $y$  during satisfiability testing of  $10y \leq 3x \wedge x \leq 4y \wedge x \leq 12$ , it would find the rational shadow is satisfiable but the dark shadow is not, and proceed to explore the splinters.

The number of inequations can grow exponentially in the number of variables eliminated by Fourier’s method, and the need to compute splinters can only make matters worse. To control this problem in practice, Omega first eliminates variables that do not introduce splintering (projecting away  $x$  instead of  $y$  in Fig. 6, since the rational and dark shadows on the  $y$  axis are identical), and from these nonsplintering variables selects those that minimize the growth in the number of inequations. These steps appear to control the growth of inequalities during dependence analysis [9, 15].

## The Gist Operation

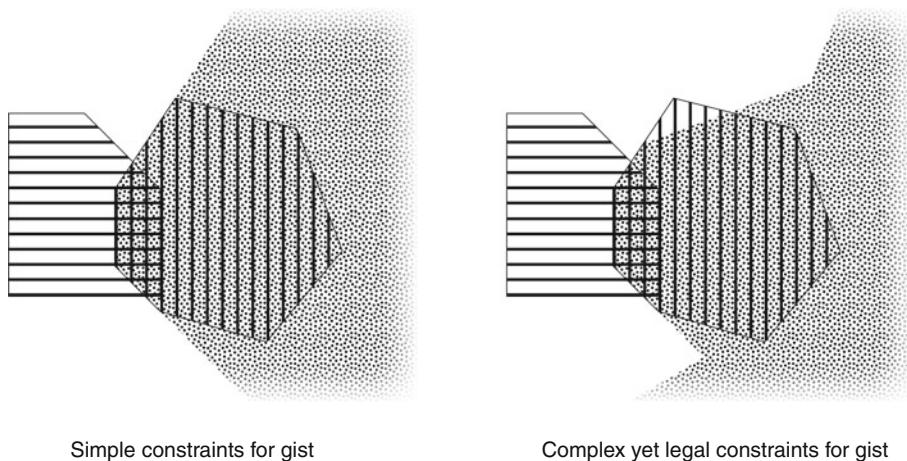

As noted in ►Sect. Advanced Analysis Techniques: The Omega Test, we may wish to classify the flow dependence of Fig. 1b as “conditional,” since there are values

of  $n$  and  $k$  for which no dependence exists and the iterations of the loop can be run in parallel. A simple definition of conditional dependence could be implemented by eliminating the loop index variables and identifying any nontautology as conditional. For this example,  $(\exists i, i' : i' = i + k \wedge 0 \leq i < n \wedge 0 \leq i' < n \wedge i < i')$ , or simply  $(0 < k < n)$ , is not a tautology, and this dependence would thus be marked as conditional.

Unfortunately, this simple definition would categorize as “conditional” almost any dependence inside a loop with a symbolic upper bound, such as that in 1a – projecting away  $i$  and  $i'$  leaves  $(2 \leq n)$ , but of course when  $n < 2$  there is no point in parallelizing the loop. To avoid such “false positives,” the Omega Test defines as conditional any dependence that does not exist under some conditions when we still wish to optimize the code, e.g., when a loop we wish to parallelize runs multiple iterations.

This definition makes use of the Omega Library’s “gist” operation as well as projection. Informally, the “gist” of one set of constraints  $p$  (i.e., those in which a dependence exists) given some other conditions  $q$  (i.e., those in which we care about the dependence) is the “interesting” information about  $p$  given that  $q$  is true. To give precise semantics while allowing flexibility in the processing of “interesting information,” gist is formally defined in terms of the values in the sets/relations being constrained, not the collection of constraints giving the bounds: “(gist  $p$  given  $q$ )” is any set/relation such that  $p \wedge q = (\text{gist } p \text{ given } q) \wedge q$ . Figure 7 gives a graphical illustration of the gist operation. Both examples illustrate, with a speckled region, the gist of a vertically striped region given a horizontally striped region. Both cases illustrate the formal definition of gist, as the speckled region overlaps the horizontally striped region in the same way the vertically striped region does. The option on the left illustrates the “usual” behavior that is produced by the algorithm described below: the gist is a superset of the original vertically striped region, with simple extensions of boundaries that defined that region. The possibility of results like that on the right allows flexibility in the definition of “simple” that is important when working with nonconvex sets.

When  $p$  and  $q$  are conjunctions of affine (in)equations, the Omega Library computes (gist  $p$  given  $q$ ) by first using the redundancy detection steps described above to check the (in)equations of  $p$  for

**Omega Test. Fig. 7** Examples of the gist operation: usual and unusual-but-legal options

redundancy with respect to  $p \wedge q$  (to check an (in)equation  $p_i$ , it uses  $p_i$ 's hash key to determine if any other single (in)equation might make  $p_i$  redundant; checks for variables that are not bounded in one direction that thus might show  $p_i$  cannot be redundant; and (if  $p_i$  is an inequation) compares  $p_i$  with pairs of inequations). If these “quick tests” fail to classify an (in)equation as redundant or not, Omega optionally performs the definitive but potentially expensive satisfiability test of a conjunction of all (in)equations from  $p \wedge q$  but with  $p_i$  negated. The conjunction of (in)equations of  $p$  that are not marked as redundant in  $p \wedge q$  is then returned as (gist  $p$  given  $q$ ).

Returning to the codes of Fig. 1, the flow dependence from Example 1b is marked as conditional, as  $(\text{gist} (0 < k < n) \text{ given } n > 1) = (0 < k < n)$ . Example 1a's dependence is not, since,  $(\text{gist} (2 \leq n) \text{ given } n > 1) = \text{True}$ . More details on the gist operation, such as the algorithms used when  $p$  and  $q$  are not both conjunctions of (in)equations, can be found in [14, 16, 20].

## Disjunctive Normal Form

Value-based dependence analysis, and certain cases of memory-based analysis (e.g., for programs with conditional statements) may produce constraints that are not simple conjunctions of equations and inequations.

In Fig. 3, the memory-based dependence from the write to  $A[i]$  to the read of  $A[i-1]$  is  $\{[1, t, 2, i, 1] \rightarrow [1, t', 1, i', 1] | i' - 1 = i \wedge 0 \leq t, t' < T \wedge 1 \leq i, i' < N - 1 \wedge t < t'\}$ , or more concisely  $\{[1, t, 2, i, 1] \rightarrow [1, t', 1, i+1, 1] | 0 \leq$

$t < t' < T \wedge 1 \leq i \leq N - 3\}$ . To describe the actual flow of values, the Omega Test must rule out all cases in which the value written to  $A[i]$  is overwritten before the read, i.e., any iteration  $\{[1, t'', 2, i'', 1]\}$  that writes to the same location (so  $i'' = i$ ) and occurs between the original write and the read (so  $t < t'' < t'$ ) during a valid execution of the statement ( $0 \leq t'' < T \wedge 1 \leq i'' \leq N - 1$ ); in other words it must represent the dependence relation

$$\begin{aligned} & \{ [1, t, 2, i, 1] \rightarrow [1, t', 1, i+1, 1] \mid 0 \leq t < t' < T \wedge 1 \\ & \quad \leq i \leq N-3 \wedge \\ & \quad \neg (\exists t'', i'' : t'' = i \wedge t < t'' < t' \wedge 0 \leq t'' < \\ & \quad T \wedge 1 \leq i'' < N-1) \} \end{aligned}$$

Omega handles such formulae by converting them into disjunctive normal form, i.e., a list of conjunctions of the form given in ▶Sect. Conjunction of Affine Equations and Inequations whose disjunction is equivalent to the original formula. Conversion to disjunctive normal form can increase the size of the formula exponentially; in practice, the explosion in formula size during dependence analysis is largely due to constraints that, once negated, contradict the positive constraints (on the first line of our example formula). This problem can be controlled by applying the rule  $a \wedge \neg b = a \wedge \neg(\text{gist } b \text{ given } a)$ . (Refer back to Fig. 7 for the intuition behind this rule – since the speckled region ( $\text{gist } b \text{ given } a$ ) must intersect  $a$  in exactly the way  $b$

did, so must the complement of the speckled region  $\neg(\text{gist } b \text{ given } a)$  intersect  $a$  as  $\neg b$  does.) This use of gist turns the formula above into

$$\{[1, t, 2, i, 1] \rightarrow [1, t', 1, i + 1, 1] \mid 0 \leq t < t' < T \wedge 1 \leq i \leq N - 3 \wedge \neg(t \leq t' - 2)\}.$$

The inequation  $t \leq t' - 2$  can then be negated to produce  $t' \leq t + 1$  rather than the disjunction of eight inequations that would have arisen without gist. In this context, Omega applies only the “quick tests” for gist, as there is no point in the optional full computation here. Techniques from ▶Sect. Conjunctions of Affine Equations and Inequations show our example formula is satisfiable and further simplify it to our final description of the value-based flow dependence:

$$\{[1, t, 2, i, 1] \rightarrow [1, t + 1, 1, i + 1, 1] \mid 0 \leq t < T - 2 \wedge 1 \leq i \leq N - 3\}.$$

The Omega Library can apply this conversion to disjunctive normal form recursively, allowing it to operate on the full language of “Presburger Arithmetic”: arbitrary formulae involving conjunction, disjunction, and negation of linear equations and inequations. Note that this logic has super-exponential complexity [3], and queries lacking the properties discussed above may well exhaust all available time or memory or produce integer overflow.

The Omega Test actually performs value-based analysis in a slightly different way from that described here, to “factor out” the effects of an overwrite on many different dependences (see [16, 20] for this and other details). However, the need for, and implementation of, negated constraints follows the principles stated here.

## Non-affine Terms and Uninterpreted Function Symbols

The constraint-manipulation techniques of the previous paragraphs can be used for memory-based, value-based, and conditional dependence analysis as long as the terms that are gathered from the program are affine functions of the loop bounds and symbolic constants. When some program term is not affine, many dependence tests simply report a maximally conservative approximation (“some dependence of some sort might exist here”) without further analysis. The Omega

Test can use two abilities of the Omega Library to produce more precise results, in many cases ruling out dependences despite the presence of nonaffine terms.

The simplest approach to handling nonaffine terms is to approximate the troublesome constraint but retain precise information about other constraints. The Omega Library provides a special constraint *UNKNOWN*, to be used in place of any constraint that cannot be represented exactly. Its presence indicates an approximation of some sort, but does not prevent Omega from manipulating other constraints or producing an exact final result in some cases (note that  $(\text{UNKNOWN} \vee \text{True}) = \text{True}$ ) and  $(\text{UNKNOWN} \wedge \text{False}) = \text{False}$ ); however, since the two unrepresentable constraints may arise from unrelated terms in a program,  $\neg\text{UNKNOWN}$  does not contradict *UNKNOWN*, and  $(\text{UNKNOWN} \wedge \neg\text{UNKNOWN} = \text{UNKNOWN})$ .

For example, suppose Fig. 1b updated  $A[i^*k]$  rather than  $A[i+k]$  — the constraint  $i' = i + k$  must be replaced with  $i' = i \cdot k$ , but of course this is outside the domain of the Omega Library. (Polynomial terms in dependence constraints were explored in [8] and by a number of authors not related to the Omega Project, but never released in Omega.) Thus, the Omega Test instead produces the relation  $\{[i] \rightarrow [i'] \mid \text{UNKNOWN} \wedge 0 \leq i < n \wedge 0 \leq i' < n \wedge i < i'\}$ .

A more detailed description can be created by replacing the unrepresentable *term* rather than the entire unrepresentable *constraint*. Omega records such a term as an *uninterpreted function symbol* — a term that indicates a value that may depend on some parameters. For example,  $i \cdot k$  depends only on  $i$  and  $k$ , and can thus be represented as  $f(k, i)$  for some function  $f$ . While *UNKNOWNs* cannot be combined in any informative way, two occurrences of the same function *can* be combined in any context in which their parameters can be proved to be equal, e.g.,  $(f(k, i) > x \wedge i = i' \wedge f(k', i') < x - 5 \wedge k' = k)$  can be simplified to False. This principle holds even when  $f$  is not a familiar mathematical function, most notably *any* expression  $e$  nested in loops  $i_1, i_2, i_3, \dots, i_n$  can be represented  $f_e(i_1, i_2, i_3, \dots, i_n)$ . The use of function symbols can improve the precision of dependence analysis, and when this does not eliminate a dependence, the Omega Test may be able to disprove it by including user assertions involving function symbols (if the programmer has provided them).

Presburger Arithmetic with uninterpreted function symbols is undecidable in general, and the Omega Library currently restricts function parameters to be a prefix of the input or output tuple of the relation. The Omega Test uses these tuples to represent the values of loop index variables source and sink of a dependence, and thus must approximate in cases in which a function is applied to some other values, in particular the values of loop indices at the time of an overwrite that kills a value-based dependence (i.e.,  $t''$  and  $i''$  in the relation in ►Sect. Disjunctive Normal Form). Further detail about the treatment of nonaffine constraints in the Omega Test, including empirical studies, can be found in [16].

## Current Status and Future Directions

The Omega Project's constraint manipulation algorithms are described in the aforesited references and the dissertations of Bill Pugh's students. Algorithms with relatively stable implementations were generally released as the Omega Library, a freely available code base which can still be found on the Internet (an open-source version containing updates from a number of Omega Library users can be found at <http://github.com/davewathaverford/the-omega-project/>). Notable omissions from the Omega Library code base include the code for iteration-space slicing, implementations of algorithms for polynomial constraints, some "corner cases" of the full Presburger satisfiability-testing algorithm, and any way of handling cases in which the core implementation of integer variable elimination produces extremely large coefficients. The Omega Library is generally distributed with the Omega Calculator, a text-based interface that allows convenient access to the operations of the library.

The constraint-based/polyhedral approach that was pioneered by Bill Pugh's Omega Project and by Paul Feautrier and his colleagues in France remains central to a number of ongoing compiler research projects. It is also a valuable tool in industrial compilers such as that produced by Reservoir Labs, Inc. For a discussion of the state-of-the-art before this work, see Michael Wolfe's "High-Performance Compilers for Parallel Computing" [17]; additional discussion of the instance-wise approach to reasoning about program transformations can be found in Jean-Francois Collard's "Reasoning

About Program Transformations: Imperative Programming and Flow of Data" [1].

A number of constraint-manipulation program analysis/transformation techniques and associated libraries have been developed since the release of the Omega Library. These typically contain more modern algorithms for a number of advanced functions of Omega, such as code generation, or more general implementations of underlying constraint algorithms, for example avoiding Omega's use of limited-range integers. As of the writing of this article, most do not support all of the techniques described in this article, notably:

- Algorithms that are (at least in principle) exact for integer variables
- Algorithms for the full domain of Presburger Arithmetic
- Separation of dependence analysis and transformation from the core constraint system via
  - An API allowing high-level relation/set operations and low-level operations
  - A text-based interface to allow easy exploration of the abilities of the system
- Special terms for communicating with the core constraint system about information not in its primary domain, e.g., function symbols
- Tagging of approximations to distinguish them from exact results
- Iteration space slicing (never released with Omega)

O

### Definition

OpenMP is an application programming interface for parallelizing sequential programs written in C, C++, and Fortran on shared-memory platforms. It provides a collection of compiler directives, a runtime library, and environment variables to enable programmers to specify the parallelism they desire to exploit in a program.

### Discussion

#### Introduction

The OpenMP Application Programming Interface (API) is a parallel programming model for shared-memory computer systems intended to provide a straightforward means of exploiting concurrency inherent in many algorithms. With the insertion of compiler directives, the programmer directs the compiler to parallelize portions of the code at a high level.

Originally designed to target loop-centric algorithms, version 3.0 of the API introduced the ability to define explicit tasks that may be executed concurrently. The OpenMP API is an agreement among hardware and software vendors that make up the OpenMP Architecture Review Board (ARB). The origins of the API are found in a set of compiler directives for writing parallel Fortran compiled by the Parallel Computing Forum (PCF) in the late 1980s. In 1997, the newly formed ARB introduced the first OpenMP specification for a set of

directives for use with Fortran and OpenMP compilers soon followed. Bindings for C and C++ have since been defined and the feature set has grown. Version 3.0, the most recent version, was ratified in 2008. The ARB is a non-profit corporation comprised of members from industry and academia, which owns the OpenMP brand and manages the OpenMP specification.

OpenMP does not require the programmer to explicitly decompose data and control flow to produce parallel computation. This fragmented style of programming is characterized by low-level programming to control the details of the concurrency. Rather, OpenMP allows the programmer to take a high-level view of parallelism and leave the details of the concurrency to the compiler. With the insertion of OpenMP directives, the programmer can specify what portions of sequential code should be executed in parallel. To a non-OpenMP compiler, the directives look like comments and are ignored. So by observing a few rules, one application can be both sequential and parallel, a very good quality that is quite useful in development and testing. Another benefit is the ability to incrementally apply OpenMP constructs to create a parallel program from existing sequential codes. Rather than start from scratch, the programmer can insert parallelism into a portion of the code and leave the rest sequential, repeating this process until the desired speedup is realized. This also means that to use OpenMP one need only learn a small set of constructs, not an entirely new language.

For a sample of how to use OpenMP, consider this fragment of C code that multiplies two matrices, *a* and *b*, and storing the result in a third matrix, *c*.

```
initialize_arrays(a,b,c,K,M,N);

#pragma omp parallel private(i,j,k)
shared (a,b,c)
{
 #pragma omp for schedule(auto)
 for (i = 0; i < N; i++)
 for (k = 0; k < K; k++)
 for (j = 0; j < M; j++)
 c[i][j] = c[i][j] + a[i][k]*b
 [k][j];
} /* end omp parallel */
```

As with any sequential program, execution starts with a single thread of control. The `#pragma omp`

identifies a line of code to be an OpenMP parallel directive, which specifies a structured block of code that should be treated as a parallel region. In this case the parallel region is enclosed with `{}`. When the initial thread of control reaches a parallel directive, it creates a team of threads, all of which will then execute the code in the parallel region. The initial thread becomes the team's master thread while the others are the slaves. The entire team will be available to share the work of the parallel region. This parallel construct includes a private clause and a shared clause. These are used to designate how variables are to be treated in the parallel region. In this case, the loop iteration variables will be treated local to individual threads while the matrices will be shared. Improperly characterized data can lead to incorrect results and errors, so this must be carefully considered. These and other clauses will be discussed later. This need to designate private and shared data is essentially what sets shared-memory programming from other methods.

The next directive identified by `#pragma omp` identifies the `for` construct, which designates that the execution of the immediately following loop is to be executed in parallel. Iterations of the loop will among the threads of the team in the enclosing parallel region according to the specified loop schedule. In this example, the `auto` schedule will allow the compiler and runtime to decide on the actually scheduling of the loop iterations.

## Overview of Features

The OpenMP API relies on directives, library routines, and environment variables for expressing the parallelism desired in a given program. Some of these were mentioned previously. A directive and its accompanying structured block form a *construct*. Directives may have various clauses associated to provide further information to the OpenMP implementation. As seen above, directives for C and C++ begin with `#pragma omp`. Directives in Fortran can begin with `!$omp`, but other options are available.

The fundamental `parallel` directive defines a `parallel region`, marking the structured block of code therein should be executed by multiple of threads. Without a parallel construct, the code will be executed sequentially. Each parallel construct designates whether data should be treated as private or shared. Data not

explicitly designated with a clause is shared by default. Since a parallel region is formed with a structured block, it must have only one entry point and one exit point. A program is *non-conforming* if it branches into or out of a parallel region.

Various constructs may be used with the parallel construct to designate worksharing, tasks, synchronization, and more. The worksharing constructs include the loop, sections, single, and workshare constructs. Each worksharing construct must bind to an active parallel region before its effects will be realized. Worksharing directives encountered by a single thread are ignored and the accompanying code will be executed sequentially, i.e., outside of a parallel region or inside a parallel region with a team of one thread. Clauses used with a parallel directive may be used to designate conditional use, the number of threads, data sharing properties, and reductions, some of which will be discussed below. Worksharing constructs end with an implicit barrier causing all threads to wait for the construct to complete. A worksharing construct that appears in a function or subroutine that is invoked from within a parallel region is called an *orphan* directive. Orphan directives may also be called from outside a parallel region allowing sequential or parallel execution of the function.

Worksharing constructs are used to define how the work in a block of code should be distributed across the executing threads. The loop construct (in C/C++ `for`, in Fortran `do`) is used to execute iterations of loops concurrently. The *sections* construct allows multiple blocks of code to be executed concurrently, each by a single thread. The *single* construct associates with the immediately following structured block for execution by a single, arbitrary thread. The *workshare* construct is supported only for directing the parallel execution of Fortran programs written using Fortran 90 array syntax.

Synchronization of threads in a team is achieved through another set of constructs. A barrier is a point of execution where threads must wait for all other threads in the current team before proceeding. While many constructs have implicit barriers, an explicit barrier is accomplished with the *barrier* directive. Barriers are used to avoid data race conditions. Access to shared data can be isolated to a critical region and protected using the *critical* directive or single assignment statements with the *atomic* directive. Explicit locks are also available for more flexible access of shared data.

Data in OpenMP programs is shared by the threads in the team by default. Any modification of shared data is guaranteed to be available to other threads after the next barrier or other synchronization point in the program. However, this is not always appropriate and some data will need to be local, or private, to each thread. A variable designated as *private* is replicated among the threads as a local copy. If the private variable needs to be initialized by the value of the corresponding variable immediately prior to the construct, the variable should be designated *firstprivate*. If the final value of a private variable is needed after the construct completes, the variable can be designated as *lastprivate*, whereby the final value of the variable inside the construct will be saved for the corresponding variable. Variables may also be designated as *reduction* variables with an associated operator. These variables will be used privately by each thread to perform its share of the work and then combined according to the operator as each thread completes its chunk of work.

OpenMP also specifies how a programmer may interact with the runtime environment. The API defines a set of internal control variables (ICVs) for controlling the execution at runtime. These include controlling the number of threads in a thread team, enabling nested parallelism, and specifying the scheduling of iterations in loop constructs. These ICVs may be accessed by setting environment variables or using runtime library routines. In some cases, the ICV may be set with a clause in the proper directive.

## Loop Parallelism

Since a significant amount of work occurs in loops, it is important to exploit any parallelism present. Any work that can be executed without depending on the outcome of other work can be executed concurrently. This kind of concurrency often occurs in the iterations of the loops. As long as an each iteration does not depend in some way on the outcome of a previous iteration, iterations can be executed concurrently. Existing loop-carried dependences can often be removed with some reorganization to reveal concurrency.

The most commonly used worksharing construct is the loop construct, which is marked with

```
#pragma omp for [clause[, ,] clause]...
for-loops
```

in C/C++ and

```
!$omp do [clause[, clause]...]
do-loops
[!$omp end do [nowait]]
```

in Fortran. This directs the implementation to distribute loop iterations among available threads. The number of iterations in the loop must be countable with an integer and use a fixed increment. This means only `for` loops in C/C++ and `do` loops in Fortran. Some rewriting of the loop may be necessary to expose parallelism. Clauses included can be used to prescribe the loop construct's data environment and loop scheduling as well as others.

Loop scheduling refers to how loop iterations are assigned to threads in the team. These are easily specified, using the clause

```
schedule(kind[, chunk_size])
```

The `kind` of clause can be `static`, `dynamic`, `guided`, `auto`, or `runtime`. If no loop schedule is specified, a static schedule will be used. This schedule will "chunk" loop iterations together in contiguous non-empty sets. Each chunk will be assigned to a thread in a round-robin fashion. The size of a chunk is set by the `chunk_size` value. If the chunk size is not specified, all chunks will be approximately the same size and at most one chunk will be assigned to each thread in the team. For varying workloads, the dynamic and guided schedules may be more appropriate. With the dynamic schedule, each thread will continually grab a chunk iterations until all chunks have been executed, using a chunk size of one if none is specified. Similar to this is the guided schedule except that the chunk size decreases as threads subsequent chunks. Then chunk size is set to be a proportion of the remaining iterations. The auto schedule allows the implementation to decide the schedule, which may be any possible distribution of iterations amongst the thread team. The runtime schedule defers the actual the scheduling of threads until execution, at which time the schedule and chunk size are read from environment variables via a library routine.

## Task Parallelism

More flexibility is often needed to exploit parallelism in code, especially where the amount of parallelism is unknown, as with recursive algorithms or processing pointer-based structures. When the task directive is encountered by a thread, the associated block of code will be made ready for execution at sometime in the future. There is no guarantee when the task will be executed. When the task is given to a thread for execution, it will be executed sequentially. The implementation is allowed to suspend the execution and resume at a later time. By default, the thread that begins a task must complete the task in its entirety. Any suspension in the execution of the task must be resumed on the thread on which it began. This is called a *tied* task. A task designated *untied* may resume suspended execution on any thread. There is no guarantee of the ordering of task execution or completion; tasks will be completed with the use of task synchronization constructs. Tasks may be suspended or resumed when a thread reaches a task scheduling point. Task scheduling points occur at the point immediately following explicit task creation, the end of the task construct, any barriers, and in the taskwait region. The `taskwait` directive causes the task to wait on all child tasks it has generated.

## Implementation

Implementations of OpenMP usually consists of an OpenMP-aware compiler and its runtime library (RTL). The compiler is responsible for recognizing and properly translating the program's OpenMP constructs while the RTL is responsible for thread creation and management at execution time. Most mainstream compilers that implement C, C++, and Fortran are capable of translating OpenMP. Any directives and RTL calls are translated along with the base-language program when the proper compiler options are used. Omission of these options will cause OpenMP directives to be ignored and result in a sequential program.

Some constructs are merely replaced with a call to the RTL, like the barrier and taskwait. Implementations typically convert the structured block marked by a parallel directive into a separate procedure in a process called outlining. Any references to shared variables are replaced with pointers to the variables' memory locations and passed to the outlined procedure as arguments. Private variables are local to the outlined procedure. Values for firstprivate variables are also passed as

arguments. A runtime library routine will fork the necessary threads and pass the outlined procedure to each thread with the needed arguments. Threads often sleep when not involved in an active team. The user can direct whether the threads will sleep or busy-wait when idle for performance considerations.

A parallel loop will likely have each thread execute a runtime routine to determine iteration chunks prior to executing the iterations, followed by a call to a barrier routine. A guided or dynamic schedule may have threads carry out more than one set of iterations by invoking a routine to get a remaining set of iterations. These schedules will have slightly more overhead because of this additional coordination. However, these schedules may execute the work fast enough to justify the added overhead.

A task can also be outlined to a procedure and variables passed as arguments similar to the parallel construct. Variables in tasks are firstprivate by default and their values must be saved at the time of task generation. Shared variables may be replaced with pointers to their memory locations as with the parallel construct. Each task is saved for execution at some time in the future, likely in a queue. The actual scheduling of the execution of the tasks is left to implementation dependence and varies greatly. OpenMP allow for work stealing, allowing a thread to take unfinished from other threads. By default, a task must be executed in its entirety by exactly one thread. If task is defined to be *untied*, it may finish execution on a different thread, making it a candidate for work stealing. As such, implementations may actually employ more than one schedule.

## Performance of OpenMP Programs

While OpenMP makes parallel programs easy to write, some extra work is usually necessary to allow complex programs to scale to high numbers of processors. Inherent in parallel programming is the presence of overhead, or work that would not otherwise be done in a sequential execution of the code. Each construct used will require some overhead to set up the parallel execution environment, so limiting their use to the presence of sufficient parallel work is advised. In addition to avoiding unnecessary overhead, the use of the memory hierarchy needs some careful attention.

Good performance of an OpenMP program begins with the optimizing of its sequential counterpart. This often involves reorganizing array accesses in loops and

removal of redundant code which may not be done by the compiler. Once a satisfactory version of the sequential code is obtained, OpenMP constructs may be inserted one at a time, ensuring with each insertion the resulting execution remains valid. This ability to add parallelism incrementally is one of OpenMP's strong points. One guiding principal in this process should be to keep all threads doing meaningful work as much as possible.

Use of the parallel construct is generally quite expensive as it must deal with the management of the thread teams. The number of parallel constructs should be few, enclosing as much code as possible. An *if* clause is available to create a parallel region only on the condition that sufficient parallel work can be achieved. Synchronization of threads is also expensive, so it is important to consider carefully when it is necessary and avoid it otherwise. Since workshare constructs have implied barriers, it is easy to have redundant barriers occur in code without being obvious. The *nowait* clause can be used to remove such implied barriers.

Since OpenMP is a shared-memory programming model some forethought as to how shared variables will be accessed is necessary. It is also prudent to minimize cache misses. Ensuring that array accesses in loops occur according to the base-language specification is one easy method. For instance, Fortran arrays are stored in memory in column-major order while C and C++ arrays are row-major. Nested loops should take this into account. Otherwise loops will likely access non-contiguous data on each subsequent iteration, causing a cache miss each time the array is accessed.

Cache coherent systems have a side effect known as *false sharing*, the interference among threads writing to different locations within the same cache line. A write by one thread will cause the system to notify the other caches of this modification causing them to update their copy of that entire cache line. Other threads accessing different locations in the cache line will have to wait for this update. While the threads in this case are not accessing shared data, the cache line is shared. This is a matter of performance, not correctness, but can prevent a program from scaling to a large number of threads.

In the following example, a `parallel do` construct exhibits false sharing. If *N* is the number of threads, each thread will execute one iteration of the loop given the chunk size of 1. When each thread updates one element of *b* it also invalidates the cache

line containing it. All other threads accessing that cache line will be affected and will need to get a new copy before their respective array elements are even modified.

```
!$OMP PARALLEL DO shared(b,N)
 schedule(static,1)
 DO i = 1,N,1
 b(i) = 4 * SIN(i*1.0)
 END DO
```

While array padding can help prevent false sharing, a better solution is to avoid the conditions in which false sharing will occur. When multiple threads are modifying shared data in the same cache line(s) in rapid succession, false sharing is likely to considerably impact performance.

Ensuring a balanced workload among the threads will also lead to better performance. The time spent in computation between synchronization points should be comparable. Use of the runtime schedule is helpful in experimenting to find the best loop schedule to balance the load in a given program.

## Correctness Considerations

It is actually quite easy to inadvertently introduce bugs into OpenMP programs. Bugs in shared-memory programming are usually very subtle and difficult to find. One such bug, the data race condition, involves the silent corruption of data during execution that is hard to detect as it may not manifest itself but on only a small fraction of the time. A data race condition occurs when multiple threads concurrently access the same shared data with at least one of the threads attempting to modify the data. Since there is no guarantee of the order in which the threads access data, this may lead to an incorrect result. Data race conditions may result from the lack of proper synchronization, like using a nowait incorrectly or neglecting to enclose such data access in a critical region.

It is usually good practice to minimize the sharing of variables since this can be problematic. By privatizing variables that do not need to be shared, data race conditions and other issues can be avoided. And, since variables are shared by default, overlooked variables may be unintentionally shared. For example, in a Fortran loop, the index variables are always treated as private, but they are only private in a parallel-for loop

in C. So in C/C++, the index variable of an inner loop will be shared if not explicitly privatized. Overlooked shared variables are also a source of the data race condition.

Another problem is the misunderstanding of which constructs have an implied barrier and which do not. In many cases, the single and the master constructs may be used for the same purpose. However, the former has an implied barrier and the latter does not. When using the master construct, it is important to know if an explicit barrier is needed afterwards. With the single, a nowait may be warranted to remove an unnecessary barrier.

Barriers may also lead to deadlock during execution if they are not used properly. An explicit barrier must be executed by all threads in the current thread team. If any thread does not reach the barrier, all the other threads will be waiting at the barrier for a thread that will never arrive. Another source of deadlock is the improper nesting of explicit locks. Deadlocked code will appear to be executing work but will never finish. These conditions are easily avoided with careful use of these constructs.

## Future Directions

The ARB is actively considering new strategies and features to add to or enhance the current API, deliberating on changes frequently being proposed by researchers. The ARB seeks to only make changes in the API that are generally acceptable to all vendors on all platforms. The challenge they face is to keep the API small enough to be relatively easy to use yet robust enough to offer sufficient expressivity for existing parallelism. Proposals under consideration include error handling mechanisms, support for performance tools, enhancing the current task interface, providing the mapping of work and data to threads, and the ability to exploit heterogeneous architectures such as GPUs and accelerators.

## Bibliographic Notes and Further Reading

The Parallel Computing Forum was an informal group comprised of representatives from industry and academia. Their parallel Fortran extensions were published in 1991 as a set of compiler directives for parallelizing loops. Though an official subcommittee for the American National Standards Institute (ANSI) was formed and a new standard drafted based on PCF in 1994, it was never adopted when interest dwindled and other parallel programming models gained attention. In the latter half of that decade, the OpenMP ARB formed and introduced the first version of OpenMP, based on the PCF work, in 1997. Later, a C/C++ specification was developed. These two specifications eventually were merged into a single document. Version 3.0 of the specification was ratified in 2008. Plans are underway in 2009 for versions 3.1 and 4.0.

In addition to the current specification of the API, the OpenMP website [1] provides information about the current specification, news about OpenMP, tutorials, a discussion forum, and links to more information about OpenMP.

The International Workshop on OpenMP ([www.iwomp.org](http://www.iwomp.org)) is an annual series of workshops for OpenMP research since 2005 and it is an excellent source for ongoing research by OpenMP users and developers and the ARB. Publications are available annually. Recent papers of interests include [task paper].

Books by Chapman [6] and Chandra [4] provide more detailed discussions of OpenMP, its use, and its implementation.

## OpenMP Profiling with OmpP

KARL FÜRLINGER

Ludwig-Maximilians-Universität München, Munich, Germany

### Synonyms

Collection of summary statistics; Performance analysis of openMP applications; Profiling

### Definition

Profiling is the process of gathering summary statistics about the execution of programs. Metrics of interest for OpenMP applications are the breakdown of time spent by threads in various sections of the program to

focus optimization efforts and the analysis of inefficiencies resulting from the parallel execution such as load imbalance and contention for locks and critical sections. Profiling is in contrast to tracing where individual time-stamped events are recorded and analyzed.

## Discussion

### Introduction

OpenMP is a successful approach for writing shared-memory thread-parallel programs. It currently enjoys a renewed interest in high-performance computing and other areas due to the shift toward multicore computing and it is fully supported by every major compiler. Extensions of OpenMP for programming GPU accelerators are also currently investigated [19] and under consideration for inclusion into a future version of the OpenMP specification.

As with any programming model, developers are interested in improving the efficiency of their codes and a number of performance tools are available to help in understanding the execution characteristics of applications. However, the lack of a standardized monitoring interface often renders the performance analysis process more involved, complex, and error-prone than it is for other programming models.

OpenMP is a language extension (and not a library, like MPI) and the compiler is responsible for transforming the program into threaded code. As a consequence, even a detailed analysis of the execution of the threads in the underlying low-level threading package is of limited use to understand the behavior on the OpenMP level. For example, compilers frequently transform parallel regions into outlined routines and the mapping of routine names (the machine's model of the execution) to the original source code (the user's model of the execution) is nontrivial. Vendor tools (paired with a compiler) can overcome this problem because they are aware of the transformations a compiler can employ and the naming scheme used for generating functions. Portable tools cannot have this kind of intricate knowledge for every compiler and OpenMP runtime and have to resort to other mechanisms, discussed later in this entry.

The rest of this entry is organized as follows: Section “►Profiling Tools Supplied by Vendors” discusses the vendor-provided solutions for OpenMP profiling, while Sect. “►Platform-Independent Monitoring”

describes how platform-independent monitoring can be achieved using a source-to-source translator called Opari. Section “►OpenMP Profiling with `ompP`” introduces the profiling tool `ompP` which is built on Opari to gather a variety of useful execution metrics for OpenMP applications. Sections “►Overheads Analysis” and “►Scalability Analysis” discuss the analysis of execution overheads and the scalability of applications based on the data delivered by `ompP`, respectively. Section “►Future Directions” concludes with an outlook on the path forward.

### Profiling Tools Supplied by Vendors

OpenMP is today supported by the compilers of every major computer vendor and the GNU compiler collection has OpenMP support since version 4.2. Most vendors also offer performance tools, such as the Intel Thread Profiler [17], Sun Studio [27], or Cray Pat [5], supporting users in analyzing the performance of their OpenMP codes.

The vendor tools mostly rely on statistical sampling and take advantage of the knowledge of the inner workings of the runtime and the transformations applied by the compiler. Typical performance issues that can be successfully detected by these tools are situations of insufficient parallelism, locking overheads, load imbalances, and in some cases memory performance issues such as false sharing.

A proposal for a platform-independent standard interface for profiling was created by SUN [18]. With this proposal, tools could register for notifications from the runtime and ask for it to supply the mapping from the runtime to user execution model. The proposal is the basis of SUN's own tool suite and is mostly used for statistical profiling there. The proposal is not part of the OpenMP specification but was accepted as an official white paper by the OpenMP Architecture Review Board (ARB). So far, acceptance of the proposal outside of SUN has been limited, however, and independent tool developers have to resort to other methods.

### Platform-Independent Monitoring

All approaches for monitoring OpenMP code in a platform-independent way in tools such as `ompP` [7], Vampir [4, 23], TAU [20, 26], KOJAK [28], and Scalasca [16] today use source code instrumentation. This approach has some shortcomings, for example, it

```

1 POMP_Parallel_fork [master]
2 #pragma omp parallel {
3 POMP_Parallel_begin [team]
4
5 /* user code in
6 parallel region */
7
8 POMP_Barrier_enter [team]
9 #pragma omp barrier
10 POMP_Barrier_exit [team]
11 POMP_Parallel_end [team]
12 }
13 POMP_Parallel_join [master]

```

The diagram illustrates the nesting of subregions for the OpenMP parallel construct. The main region is labeled "main". Inside it, there is a "body" region, which contains a "barr" (barrier) region, and finally an "exit" region.

**OpenMP Profiling with OmpP. Fig. 1** Instrumentation added by Opari for the OpenMP parallel construct. The original code is shown in boldface, the square brackets denote the threads that execute a particular POMP call. The right part shows the subregion nesting used by ompP

requires the user to recompile their code for instrumentation. However, it has been found in practice to work well for many applications and the usage of automated preprocessor scripts eases the burden for developers.

The monitoring approach used by all the aforementioned tools is based on a source code preprocessor called Opari [22]. Opari is a part of the KOJAK and Scalasca toolsets and it adds calls inside and around OpenMP pragmas according to the POMP specification [21]. An example source code fragment with Opari instrumentation is shown in Fig. 1: In this example, the user code is a simple parallel region (lines 2, 5, 6, and 12 in bold font represent the original user code), all other lines are added by Opari. POMP\_Parallel\_{fork|join} calls are placed on the outside of the parallel construct and POMP\_Parallel\_{begin|end} calls are placed as the first and last statements inside the parallel region, respectively. An additional explicit barrier and corresponding POMP\_Barrier\_{enter|exit} calls (lines 8–10) are placed toward the end of the parallel region as well. Doing so converts the implicit barrier at the end of the parallel region into an explicit barrier that can subsequently be monitored by tools, for example, to detect load imbalances among threads.

### OpenMP Profiling with ompP

ompP [7] is a profiling tool for OpenMP based on source-code instrumentation using Opari. ompP implements the POMP interface to monitor the execution of the instrumented application. An application is linked

```

#pragma omp parallel
{
 #pragma omp critical
 {
 sleep(1.0);
 }
}

```

**OpenMP Profiling with OmpP. Fig. 2** A simple OpenMP code fragment with a critical section

with ompP's profiling library and on program termination a profiling report is written to a file. Environment variables can be used to influence various settings of the data collection and reporting process.

Figure 2 shows an example OpenMP program fragment. The fragment contains a critical section inside a parallel region and the critical section only contains a call to `sleep()` for 1s. Figure 3 shows the corresponding profile for the critical section: this critical section was unnamed (for named critical sections the name would appear instead of "default") and that it is located at lines 34–37 in a file named "main.c." ompP's internal designation for this region is R00002.

The profile represents an execution with four threads. Each line displays data for a particular thread and the last line sums over all threads. A number of columns depict the actual measured profiling values. Column names that end in a capital "C" represent counts while columns ending with a capital "T" represent times. In this example, each thread executed the critical construct and that the total execution time

| R00002 main.c (34-37) (default) CRITICAL |       |       |       |        |       |
|------------------------------------------|-------|-------|-------|--------|-------|
| TID                                      | execT | execC | bodyT | enterT | exitT |
| 0                                        | 3.00  | 1     | 1.00  | 2.00   | 0.00  |
| 1                                        | 1.00  | 1     | 1.00  | 0.00   | 0.00  |
| 2                                        | 2.00  | 1     | 1.00  | 1.00   | 0.00  |
| 3                                        | 4.00  | 1     | 1.00  | 3.00   | 0.00  |
| SUM                                      | 10.01 | 4     | 4.00  | 6.00   | 0.00  |

**OpenMP Profiling with OmpP.** Fig. 3 An example of ompP’s profiling data for an OpenMP critical section. The body of this critical section contains only a call to `sleep(1.0)`

(`execT`) varies from 1.0 s to 4.0 s. `bodyT` is the time inside the body of the critical construct and it is 1.0 s corresponding to the time in `sleep()`, while `enterT` is the time (if any) threads have to wait before they can enter the critical section. In the example in Fig. 3, thread 1 was the first one to enter, then thread 2 entered after waiting 1.0 s, then thread 0 after waiting 2.0 s, and so on.

ompP reports timings and counts in the style shown in Fig. 3 for all OpenMP constructs. Table 1 shows the full table of constructs supported by ompP and the timing and count categories used in the profiling report. `execT` and `execC` are always reported and represent the entire construct. An additional breakdown is provided for some constructs, such as the `startupT` and `shutdownT` for the time required starting up and tearing down the threads of a parallel region, respectively. This breakdown is based on the subdivision of regions into subregions, as shown on the right-hand side of Fig. 1. If applicable, a region is thought of being composed of a subregion for entering (`enter`), exiting (`exit`), a main body (`body`), and a barrier (`barr`), and `main = enter + body + barr + exit` always holds.

In addition to the basic flat region profiles such as the ones shown in Fig. 3, ompP supports a number of more advanced features.

- ompP records the application’s call graph and the nesting of the OpenMP regions and computes inclusive and exclusive times from it. This allows performance data for the same region involved from different execution paths to be analyzed separately.
- It allows the monitoring of hardware performance counter values using PAPI [3, 24]. If a PAPI installation is available on a machine, ompP will include the necessary functionality to set up, start, and stop the counters for all OpenMP constructs.

- ompP computes the parallel coverage (i.e., the fraction of total execution time spent in parallel regions). According to Amdahl’s law [1] a high parallel coverage is quintessential to achieve satisfactory speedups and high parallel efficiency as the number of threads increases.
- Another feature of ompP is continuous and incremental profiling [6, 10]. Instead of capturing only a single profile at the end of the execution, this technique allows an attribution of profile features on the timeline axis without the overheads typically associated with tracing.
- A further recent technique aimed at providing temporal runtime information without storing full traces is capturing and analyzing the execution control flow of applications. The method described in [12, 13] shows that this can be achieved with low overhead and small modifications to the data collection process. The resulting flow graphs are designed for interactive exploration together with performance data in the form of timings and hardware performance counter statistics to determine phase-based and iterative behavior [11, 14].

## Overheads Analysis

Any parallel algorithm and the execution of a parallel program will usually involve some overheads limiting the scalability and the parallel efficiency. Typical sources of overheads are synchronization (the need to serialize the access to a shared resource, for example) or any time spent in setting up and destroying the threads of parallel execution.

An example of this is also shown in Fig. 3. `enterT` is the time threads have to wait to enter the critical section. From an application’s standpoint threads idle and do not do useful work on behalf of the application and hence `enterT` constitutes a form of synchronization overhead (since it arises due to the fact that the threads have to synchronize their activity). Considering the timings reported by ompP, a total of four different overhead classes can be identified.

**Synchronization:** Overheads that arise because threads need to coordinate their activity. An example is the waiting time to enter a critical section or to acquire a lock.

**OpenMP Profiling with OmpP. Table 1** All timing and count categories reported by `ompP` for various OpenMP constructs

| construct          | main  |       | enter  |          | body  |          |          |         |         | barr     | exit  |          |
|--------------------|-------|-------|--------|----------|-------|----------|----------|---------|---------|----------|-------|----------|
|                    | execT | execC | enterT | startUpT | bodyT | sectionT | sectionC | singleT | singleC | exitBarT | exitT | shutdwnT |
| MASTER             | •     | •     |        |          |       |          |          |         |         |          |       |          |

*Imbalance:* Overhead due to different amounts of work performed by threads and subsequent idle waiting time, for example, in work-sharing regions.

*Limited Parallelism:* This category represents overhead resulting from unparallelized or only partly parallelized regions of code. An example is the idle waiting time threads experience while one thread executes a `single` construct.

*Thread Management:* Time spent by the runtime system for managing the application's threads. That is, time for creation and destruction of threads in parallel regions and overhead incurred in critical sections and locks for signaling the lock or critical section as available.

[Table 2](#) shows the classification of the timings reported by `ompP` into no overhead (•) or one of the four overhead classes: S for synchronization overhead, I for imbalance, L for Limited Parallelism, and T for Thread management overhead.

`ompP`'s application profile includes an overhead analysis report which offers various interesting insights into where an application wastefully spends its time. The first part of the overhead analysis report shows the

total runtime (this corresponds to the duration of the overview section of the profiling report). Then the total number of parallel regions is reported (this includes combined worksharing-parallel regions) and then the parallel coverage is listed. The parallel coverage is the amount of execution time spent in parallel regions. A low parallel coverage limits the speedup that can be achieved by parallel execution.

The following two sections list overheads according to the classification scheme described in [Table 2](#) and discussed in detail in [8]. The difference between these two sections is the order in which parallel regions are listed and the way in which percentages are computed. In "Overheads wrt. whole program" the percentages are computed with respect to the total execution time (i.e.,  $\text{duration} \times \text{number of threads}$ ) and this section hence allows the easy identification of regions that cause high overheads for the whole application.

## Scalability Analysis

The scalability of an application or of individual parallel regions within an application can be analyzed in detail

**OpenMP Profiling with OmpP. Table 2** Overhead classification of the times reported by `ompP` into one of the four overhead classes. Synchronization (S), Load Imbalance (I), Thread Management (M), Limited Parallelism (L)

---

----- `ompP` Overhead Analysis Report -----

---

Total runtime (wallclock) : 16.38 sec [4 threads]

Number of parallel regions : 10

Parallel coverage : 10.93 sec (66.73%)

Parallel regions sorted by wallclock time:

|        | Type     | Location          | Wallclock (%) |
|--------|----------|-------------------|---------------|
| R00004 | PARALLEL | muldoe.F (63-145) | 4.01 (24.45)  |
| R00007 | PARALLEL | muldoe.F (63-145) | 3.99 (24.34)  |

...

Overheads wrt. whole program:

| Total  | Ovhds (%) | = Synch (%)  | + Imbal (%) | + Limpar (%) | + Mgmt (%)  |             |
|--------|-----------|--------------|-------------|--------------|-------------|-------------|
| R00007 | 15.95     | 0.22 ( 0.34) | 0.00 (0.00) | 0.22 (0.34)  | 0.00 (0.00) | 0.00 (0.00) |
| R00004 | 16.02     | 0.16 ( 0.25) | 0.00 (0.00) | 0.16 (0.25)  | 0.00 (0.00) | 0.00 (0.00) |

by computing an overhead breakdown while varying the number of OpenMP threads for the execution.

Assuming a constant workload and increasing number of threads (i.e., a strong scaling study), one can plot scalability graphs like the one shown in Fig. 4. Here the number of threads is plotted on the horizontal axis and the total aggregated execution time (summed over all threads) is plotted on the vertical axis. The topmost line is derived from the overall wallclock execution time of an application. From this total time, one can subtract the four overhead classes (synchronization, load imbalance, thread management, and limited parallelism) for each thread count. A perfectly scaling code (linear decrease in the execution time the number of threads is increased) would result in a horizontal line in this type of scalability graph. A line inclining from the horizontal corresponds to imperfect scaling and a declining from the horizontal points toward superlinear speedup.

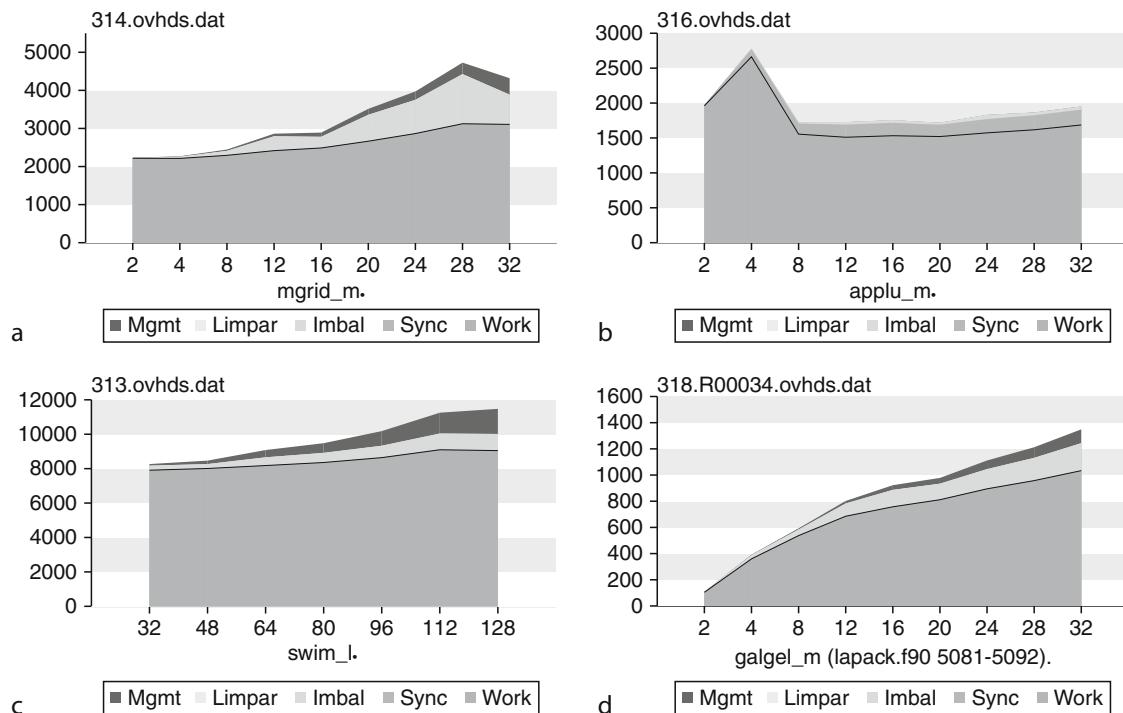

Figures 4a, b, and c are scalability graphs of full applications from the SPEC OpenMP benchmark suite ([2, 25]), corresponding to the “mgrid,” “applu” and

“swim” applications, respectively. Evidently the scaling behavior of these applications is widely different. A detailed discussion of the scaling properties of several of the SPEC OpenMP benchmarks can be found in [9].

In addition to scalability graphs for the whole application, `ompP` offers the option to analyze the scaling of individual parallel regions. As the workload characteristics of parallel regions within a program may vary considerably, so can their scalability characteristics and each region might have a different operating sweet spot in terms of computing throughput or energy efficiency. As an example, Fig. 4d shows an example for a scalability graph of an individual region of the application “galgel.”

## Future Directions

OpenMP is a continually evolving standard and new features pose new requirements and challenges for performance profiling. A recent major feature introduced with version 3.0 of the OpenMP specification is

**OpenMP Profiling with OmpP. Fig. 4** Scalability graphs for some of the applications of the SPEC OpenMP benchmark suite. Suffix \_m refers to the medium size benchmark while suffix \_l denotes large size benchmark. The horizontal axis denotes processor (thread) count and the vertical is the accumulated execution time (over all threads) in seconds

*tasking* – the ability to dynamically specify and enqueue small chunks of work for later execution.

A preliminary study [15] investigated the feasibility of extending the source code-based instrumentation approach to handle the new tasking-related constructs. The resulting modified version of `ompP` could successfully handle many common use cases for tasking. The notion of overheads had to be adapted, however, to reflect the fact that with tasking threads reaching the end of a parallel region are no longer idle but can in fact start fetching and executing tasks from the task pool.

One use case, that of *untied* tasks, proved to be a challenge. With untied tasks, an executing thread can stop and resume task execution at any time and in fact a different thread can pick up where the previous thread left off. These events are impossible to be observed purely based on source code instrumentation without a standardized callback mechanism that would notify a tool of such an occurrence.

To overcome these issues in particular and to simplify usage of `ompP` in general, tying together instrumentation sources from multiple layers, such as source code instrumentation, interposing on the native threading library, and incorporating the SUN whitepaper seems like a promising way for the path forward.

There is a long-standing and successful family of SHMEM APIs but there is no standard and implementations differ from each other in various subtle ways, hindering acceptance, portability, and in some cases, program correctness. We discuss the differences between SHMEM implementations and contrast SHMEM with other extant libraries supporting RMA semantics to provide motivation for a standards-based OpenSHMEM with the requisite breadth of functionality.

The Message Passing Interface (MPI) [1] is currently the most widely used communication model for large-scale simulation-based scientific parallel applications. Of these applications, a large number rely on two-sided communication mechanisms. Two-sided communication mechanisms require both sides of the exchange (source and destination) to actively participate, such as in MPI\_SEND and MPI\_RECV. While many algorithms benefit from the coupling of data transfer and synchronization that two-sided mechanisms provide, there exists a substantial number of algorithms that do not benefit from this coupling, and in fact may be hindered by the induced overhead of the synchronization.

The one-sided communication mechanisms are capable of decoupling the data transfer from the synchronization of the communication source and target. Remote memory access (RMA) is a one-sided communication mechanism that allows data to be transferred from one process memory space to another (remote) process memory space. The RMA operation is described entirely by one process (the active side) without the direct intervention of the other process (the passive side). Irregular communication patterns, in which data source and data target are not known *a priori* (as demonstrated in the GUPs [2] benchmark), often benefit from one-sided communication models such as RMA.

One of the most widely used one-sided communication models is SHMEM which stands for Symmetric Hierarchical MEMory access, so named for providing a view of distributed memory through the use of references to symmetric data storage on each sub-domain of a scalable system. While some sources (incorrectly) identify SHMEM as “SHared MEMory access,” it should be noted that SHMEM is unrelated to AT&T System V Shared Memory as implemented by the shmat, shmctl, shmget, etc. UNIX system calls. SHMEM [3] has a long

### Definition

OpenSHMEM is a standards-based partitioned global address space (PGAS) one-sided communications library.

history as a parallel programming model, having been used extensively on a number of products since 1993, including Cray T3D, Cray X1E, the Cray XT3/4, SGI Origin, SGI Altix, clusters based on the Quadrics interconnect, and to a very limited extent, Infiniband-based clusters.

- History of SHMEM
  - Cray SHMEM
    - \* SHMEM first introduced by Cray Research Inc. in 1993 for Cray T3D
    - \* Cray is acquired by SGI in 1996
    - \* Cray is acquired by Tera in 2000 (MTA)
    - \* Platforms: Cray T3D, T3E, C90, J90, SV1, SV2, X1, X2, XE, XMT, XT
  - SGI SHMEM
    - \* SGI purchases Cray Research Inc. and SHMEM was integrated into SGI's Message Passing Toolkit (MPT)
    - \* SGI currently owns the rights to SHMEM and OpenSHMEM
    - \* Platforms: Origin, Altix 4700, Altix XE, Altix ICE, Altix UV

Despite being supported by a variety of vendors there is no standard defining the SHMEM memory model or programming interface. Consistencies (where they exist) and extensions across the various implementations have been driven by the needs of an enthusiastic user community. The lack of a SHMEM standard has allowed each implementation to differ in both interface and semantics from vendor to vendor and even product line to product line, which has to this point limited broader acceptance. For an introduction to the SHMEM programming model, please see any of the following: [4, 5] or [6].

The SHMEM API and SHMEM in general encompass the following ideas:

- Single Program/Multiple Data (SPMD) style
- Characteristics: One-sided, data passing, RDMA, RMA, PGAS
- Put, Get, Atomic Updates (AMO) to reference remote memory or memories
- Remote memory/arrays are symmetric
- SHMEM decouples data transfer from synchronization
- Barriers and polling synchronization are used
- Collectives
- Explicit control over data transfer
- Low latency communications
- Library programming interface to PGAS
- SHMEM is a suitable under-layer for some PGAS implementations
- SHMEM is a viable alternative to MPI

In addition to SHMEM, a number of other parallel communication libraries currently support the one-sided communication model via RMA. These RMA APIs exhibit much commonality but also several core differences. In this entry, we will compare the most widely used RMA APIs for high performance computing to the SHMEM model.

The following RMA models will be considered in this entry:

*SGI SHMEM:* SGI SHMEM [7] (SGI-SHMEM) has one of the richest sets of RMA operations and is currently supported on the NUMAlink-based and Infiniband-based Altix product lines.

*Cray SHMEM - Unicos MP:* Cray SHMEM on the Unicos MP [8] (MP-SHMEM) is very similar to SGI-SHMEM and is currently supported on the XIE supercomputer.

*Cray SHMEM - Unicos LC:* Cray SHMEM on the Unicos LC [9] (LC-SHMEM) is a subset of SHMEM on the Unicos MP but lacks a number of key items such as full data-type support. Unicos LC is currently available on the Cray XT 3/4/5 supercomputers.

*Quadrics SHMEM:* Quadrics SHMEM [10] (Q-SHMEM) supports most of the communication mechanisms available in Unicos MP but lacks a number of key items that enhance usability.

**Cyclops-64 SHMEM:** Cyclops-64 SHMEM [11] (C64-SHMEM) is a SHMEM API which supports the Cyclops-64 architecture. Most of the core features of Cray SHMEM are available with some additional interfaces specific to the Cyclops-64 architecture.

**GASNet:** GASNet [12] is a lower level interface with minimal RMA support intended to be used as a communication mechanism for other parallel programming models and environments. As such, it is missing many of the usability features of the SHMEM family of RMA APIs. GASNet also differs from the other communication models due to its unique support for active messages.

**ARMCI:** ARMCI [13] is another lower level interface designed to support higher level protocols and programming models such as Global Arrays.

**MPI-2:** MPI-2 [14] provides a one-sided interface that has not been widely adopted for a number of reasons [15] but was intended to provide a portable alternative to SHMEM and other one-sided communication models.

In order to effectively compare these RMA APIs, we will define the following areas of functionality:

**Symmetric Objects:** Symmetric objects provide a mechanism to address remote variables using the address of the corresponding local variable.

**Remote Write:** Put operations across a number of primitive data-types as well as contiguous, strided, or indexed memory locations

**Remote Read:** Get operations across a number of primitive data-types as well as contiguous, strided, or indexed memory locations

**Synchronization:** Two basic types:

- Task Synchronization – synchronization operation between tasks, such as barriers and locks
- Memory Synchronization – memory polling, and ordering of remote and local memory reads and writes

**Atomic Memory Operations:** Compare/Mask Swap, fetch-and-add, increment

**Reductions:** Reductions across a number of primitive data-types and reduction operations such as and, or, min, and max

**Collective Communication:** Broadcast, collect, and fcollect operations

## Symmetric Objects

In SGI-SHMEM, MP-SHMEM, LC-SHMEM, and Q-SHMEM some data objects are said to be “symmetric” across multiple PEs. For a single-executable program, launched on multiple PEs, all statically allocated objects are symmetric across all PEs. Additionally, objects allocated dynamically via symmetric allocation (by calling SHMEM’s `shmalloc()` collectively) are also symmetric across all PEs. These symmetric data objects greatly simplify RMA operations by allowing the active side to initiate a remote operation on the passive side by specifying the address of the local symmetric data object. The RMA operation proceeds as if the address specified were the address of the passive side’s symmetric data object. In the absence of symmetric data objects, the address of the passive side’s data object must be communicated to the active side for use in the RMA (Remote) operation. In SHMEM, such objects are known as asymmetric objects. Asymmetric objects include stack variables as well as those objects dynamically allocated by nonsymmetric means (e.g., `malloc()`). Care must be taken in referencing asymmetric objects as the local (active side) address calculation will likely not result in the correct address on the remote (passive) side, though some implementations will not fail if asymmetric addresses strictly refer to local (active side) objects, e.g., the source for a PUT or the target for a GET. *Remote access to asymmetric objects is an extension that is not supported by SGI’s SHMEM or OpenSHMEM V1.0*

Symmetric data objects are not supported on the other RMA (Remote) APIs. GASNet requires that the active side specify the address of the data object on the remote side. ARMCI provides a collective memory allocation mechanism that allows each process to allocate memory locally and share the memory location with its peers. While convenient, this is no different from allocating memory locally and gathering the addresses from other PEs. SHMEM provides similar functionality via `shmalloc` with one difference, the memory allocated in `shmalloc` is symmetric (the Symmetric Heap). This allows RMA (Remote) operations to the remote memory by simply specifying addresses within the local symmetric memory. All SHMEM implementations discussed in this entry provide symmetric memory allocation. MPI-2 uses a hybrid approach by requiring processes to participate in the creation of a “window” for

RMA (Remote) operations. The active side can then specify the target's location for the RMA (Remote) operation via a displacement in the window.

It is important to note that symmetric data objects require either special hardware, compiler, or library support. The use of the address of a local data object in an RMA (Remote) operation to a remote PE indicates that the data object is symmetric. A (pre-)compiler can detect this usage and take appropriate action to ensure that the remote data object is properly addressed. SGI-SHMEM, MP-SHMEM, LC-SHMEM, and Q-SHMEM support symmetric data objects, asymmetric data objects, and symmetric memory allocation. C64-SHMEM supports only asymmetric data objects and symmetric memory allocation.

Code listing 1 (a slightly modified example from [8]) illustrates the use of symmetric data objects. Note the declaration of the “static short target” array and its use as the remote destination in `shmem_short_put`. The use of the “static” keyword results in the target array being symmetric on all PEs in the program. Each PE is able to transfer data to the target array by simply specifying the local address of the symmetric data object which is to receive the data. This aids programmability as the address of the target all PEs other than 0 need not be exchanged with the active side (PE 0) prior to the RMA (Remote memory operation) – an important reduction network data-flow, particularly for large systems with irregular data flows. Conversely, the declaration of the “short source” array is asymmetric. Because the put handles the references to the source array only on the active (local) side, the asymmetric source object is handled correctly. Note that C64-SHMEM does not support this mechanism and relies on the use of symmetric memory allocation. Other code examples are included in the examples section.

## Remote Write/Read

Remote Read/Write operations are the basic building blocks of any RMA API. Generally, these are referred to as put/get operations, and in the most basic form allow one processing element (PE) to transfer data from a local memory location to a remote memory location belonging to another PE, or vice versa.

*Remote Write:* In a Remote Write operation (PUT), the initiating (active side) PE is the *source* and the

remote (passive side) PE is the *target*. The active side PE specifies the local (active side) PE's (source) memory from which the data will be sent, and the remote (passive side) PE's (target) memory to which the data will be written. MP-SHMEM, LC-SHMEM, Q-SHMEM, and C64-SHMEM all provide the semantic that after `shmem_put` returns, the data specified for transfer has been buffered; this local completion on the active side does not equate to remote completion of the put on the passive side. LC-SHMEM, Q-SHMEM, and C64-SHMEM also provide a non-blocking PUT operation `shmem_put_nb` which may return before the data is buffered for transfer. Local completion of non-blocking remote (RMA) writes are guaranteed either when `shmem_test_nb` returns success or `shmem_wait_nb` returns. Unlike MPI requests, it is invalid to wait on a non-blocking operation after test returns success.

*Remote Read:* In a Remote Read operation (GET), the initiating (active side) PE is the *target* and the remote (passive side) PE is the *source*. The active side PE specifies the remote (passive side) PE's (source) memory from which the data will be retrieved, and the local (active side) PE's (target) memory to which the data will be written. In MP-SHMEM, LC-SHMEM, Q-SHMEM, and C64-SHMEM `shmem_get` returns after data has been delivered to the initiator PE's memory. LC-SHMEM, Q-SHMEM, and C64-SHMEM provide a non-blocking GET operation `shmem_get_nb` which does not block until the data specified for transfer has been delivered to the active side. Local completion of non-blocking RMA (Remote) Read operations is guaranteed either when `shmem_test_nb` (or `shmem_poll_nb` on C64-SHMEM) returns success or `shmem_wait_nb` returns.

**Table 2** details the primitive data-types supported by Remote Read/Write. Not surprisingly, ARMCI and GASNet only support byte level transfers as they are lower level APIs meant to provide a basis for higher level languages or APIs. The 16 bit, 4 byte, etc., “data-types” are simply syntactic sugar for the generalized byte level data-type supported by all APIs. None of the SHMEM libraries directly support unsigned integers or higher precision types beyond long long and double. Unsigned

```

#include <mpp/shmem.h>
#define SIZE 16
int
main(int argc, char* argv[])
{
 short source[SIZE]; /* local, not symmetric */
 static short target[SIZE]; /* static makes it symmetric */
 int i;
 int num_pe = atoi(argv[1]); /* no. of PEs taken from command-line */

 start_pes(num_pe);

 if (_my_pe(0) == 0) {
 /* initialize array */
 for(i = 0; i < SIZE; i++)
 source[i] = i;

 /* put "size" words into target on each PE */
 for(i = 1; i < num_pe; i++)
 shmem_short_put(target, source, SIZE, i);
 }
 shmem_barrier_all(); /* sync sender and receiver */
 if (_my_pe() != 0) {
 printf("target on PE %d is \t", _my_pe());
 for(i = 0; i < SIZE; i++)
 printf("%hd", target[i]);
 printf("\n");
 }
 shmem_barrier_all(); /* sync before exiting */
 return 0;
}

```

OpenSHMEM - Toward a Unified RMA Model. Fig. 1 RMA (Remote operation) using a symmetric data object

OpenSHMEM - Toward a Unified RMA Model. Table 1 Symmetric data objects and memory allocation

| Type                        | SGI | MP  | LC  | Q   | C64 | GASNet | ARMCI | MPI-2 |

types can be used in put/get operations by using the appropriate byte size transfer at the cost of convenience.

In addition to data-type support, these RMA (Remote) APIs offer different access patterns for PUT/GET operations.

*Contiguous Memory Access:* Contiguous memory is specified by the active side as both the source and destination for a PUT or GET operation.

*Strided:* Strided access allows transfers of elements of a memory region with a stride between them. This is a compact representation suitable for regular data layouts such as multi-dimensional arrays.

*Indexed:* This access pattern provides more flexibility than strided access as there is no requirement for a constant stride. This added flexibility requires that

an index array be used to describe the elements within the source and target arrays, and is therefore less compact than the strided data description.

*Generalized I/O Vectors:* Generalized I/O vectors allow transfers to/from discontinuous regions that are made up of contiguous elements of like length. An array of pointers is specified for both the initiator and the target. Each entry in the array specifies the starting address of a contiguous memory region of length K. Both arrays are of length N.

*Arbitrary Discontiguous:* This access mode allows transfers to/from discontinuous regions with minimal restrictions. Contiguous elements within the discontinuous regions may be of any byte length. The total byte length of all contiguous elements must be equal at both the initiator and the target. This access

| Arbitrary Discontinuous | No  | No  | No  | No  | No  | No     | No    | Unknown |

mode uses a pair of arrays to describe the memory locations and the length of each element at the memory location. Four arrays are therefore necessary to describe the memory layout for both the initiator and the target.

Note that MPI-2 supports Indexed, Strided, and Generalized I/O Vectors through the use of derived data-types.

## Synchronization

While SHMEM provides a barrier semantic which intertwines synchronization with remote completion, it also provides three somewhat more subtle tools for

enforcing ordering semantics on the sequence of memory updates arriving at a PE: fence, quiet, and wait.

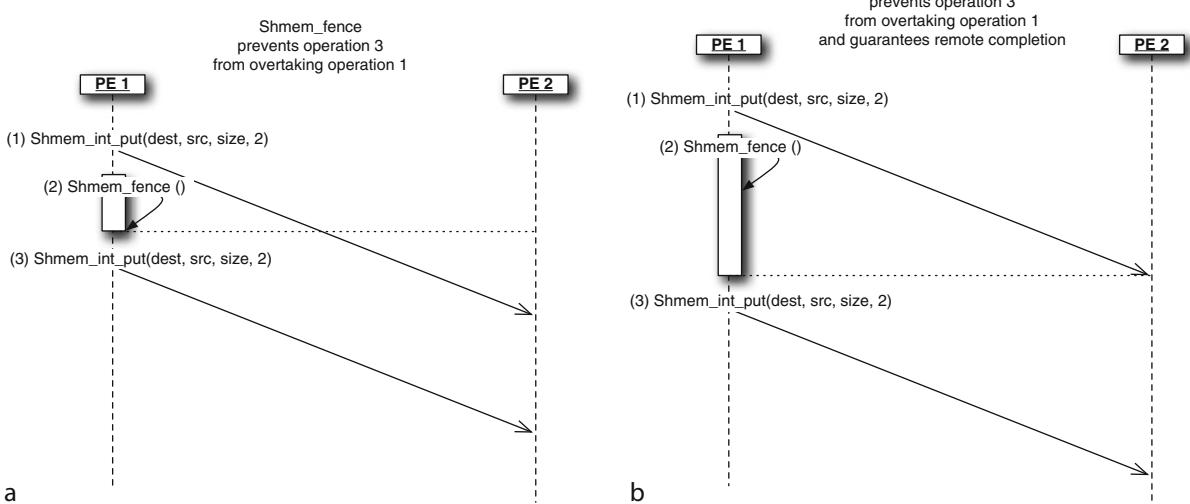

**Fence:** SHMEM Fence ensures ordering of PUT operations to a specific PE. In SGI-SHMEM, MP-SHMEM, and LC-SHMEM, the fence operation forces ordering of the completion of PUT operations on a remote PE. Specifically, while the order of posting of PUT operations on the remote PE is not generally guaranteed, the fence does provide a guarantee that on the remote (passive) side the PUTs issued from a particular source PE before the fence will be completed before the PUTs issued by that source PE after the fence are completed.

Note that this does not guarantee that the remote (passive) side will have completed the PUTs when the fence operation returns on the active side. Q-SHMEM and C64-SHMEM support `shmem_fence` via `shmem_quiet` and add the additional semantic that all outstanding PUT operations will be delivered to the target PE prior to return from the function. [Figure 2](#) illustrates the semantics of `shmem_fence`.

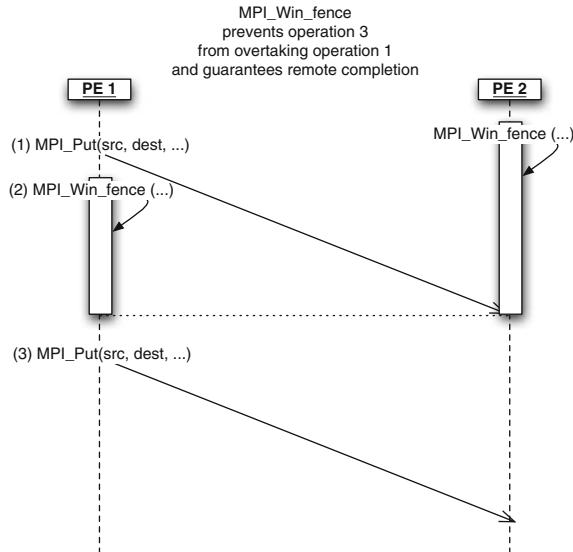

ARMCI provides a fence operation similar to that of Q-SHMEM in that it blocks until all PUTS are delivered to the remote PE. GASNet provides blocking and non-blocking versions of PUT. A blocking PUT will not return until data is delivered to the remote PE. A wait on a non-blocking PUT will not return until data is delivered to the remote PE. Fence (and Quiet) are therefore not necessary in GASNet as both are implicit in the semantics of blocking and non-blocking PUT operations. The GASNet blocking interface combines the semantics of RMA (Remote) initializations, ordering, and remote completion. Applications that do not need the additional semantics may incur additional overhead. GASNet's non-blocking PUT operations separate RMA (Remote operations) initialization from ordering and remote completion, but fail to separate ordering from remote completion.

MPI-2 specifies an MPI\_WIN\_FENCE operation, but differs dramatically from Fence in SHMEM. MPI\_WIN\_FENCE is a collective operation on the group of WIN requiring both the active and passive sides to participate, whereas SHMEM fence is called only on the active side. In addition, MPI\_WIN\_FENCE ensures that all outstanding RMA calls on a window (regardless of origin) are synchronized. Fence in SHMEM may be thought of strictly as an ordering semantic and not as a PE synchronization semantic as in MPI. [Figure 3](#) illustrates the semantics of MPI\_Win\_fence.

*Quiet:* SHMEM quiet ensures ordering of PUT operations to all PEs. In SGI-SHMEM, MP-SHMEM, and LC-SHMEM, the quiet operation ensures the order of PUT operations. All incoming PUT operations issued by any PE and local load and store operations started prior to the quiet call are guaranteed to be complete at their targets and visible to all other PEs prior to any remote or local access to the corresponding target's memory or any synchronization operations that follow the call to `shmem_quiet`. Q-SHMEM and C64-SHMEM extend the semantic in that data is delivered at the remote PE at the return of `shmem_quiet`. This additional semantic intertwines remote completion and ordering which may impose unnecessary overhead to applications

OpenSHMEM - Toward a Unified RMA Model. **Fig. 2** Example of fence **(a)** SGI-, MP-, and LC-SHMEM **(b)** Q- and C64-SHMEM

**OpenSHMEM - Toward a Unified RMA Model. Fig. 3**  
Example of MPI\_Win\_fence

that only require the ordering semantic and not remote completion. Figure 4 illustrates the semantics of shmem\_quiet.

ARMCI provides Quiet through a fence\_all operation similar to Q-SHMEM and C64-SHMEM in that data is guaranteed to be delivered at the remote PEs when fence\_all returns. Again, the ordering semantic is intertwined with remote completion.

**Barrier:** The SHMEM barrier is a collective synchronization routine in which no PE may leave the barrier prior to all PEs entering the barrier. SGI-SHMEM, MP-SHMEM, LC-SHMEM, and Q-SHMEM additionally require the semantic that all outstanding PUT operations are remotely visible prior to the return of the barrier operation. This additional semantic intertwines PE synchronization and remote completion of outstanding write operations. C64-SHMEM does not add this additional semantic.

**Wait:** SHMEM wait waits for a memory location or variable to change on the local PE. This allows synchronization between two PEs. SGI-SHMEM, MP-SHMEM, LC-SHMEM, Q-SHMEM, and C64-SHMEM all support shmem\_wait the other RMA implementations do not provide a similar semantic.

A possible improvement in these semantics would involve separating RMA initialization, RMA ordering, remote completion, and PE synchronization.

## Atomic Memory Operations

An atomic memory operation (AMO) provides the capability to perform simple operations on the passive side of the RMA operation. The SHMEM model provides five common AMO capabilities.

**Swap:** Writes the value specified by the initiator PE to the target PE location and returns the target value prior to the update.

**Compare and Swap:** Compares the conditional value specified by the initiator PE to the target PE location, and if they are equal, it writes the value specified by the initiator PE to the target PE location. The return value is the target PE location's value prior to update.

**Mask and Swap:** Writes the value specified by the initiator PE to the target PE location updating only the bits in the target location as specified in the mask value. The return value is the target PE location's value prior to update.

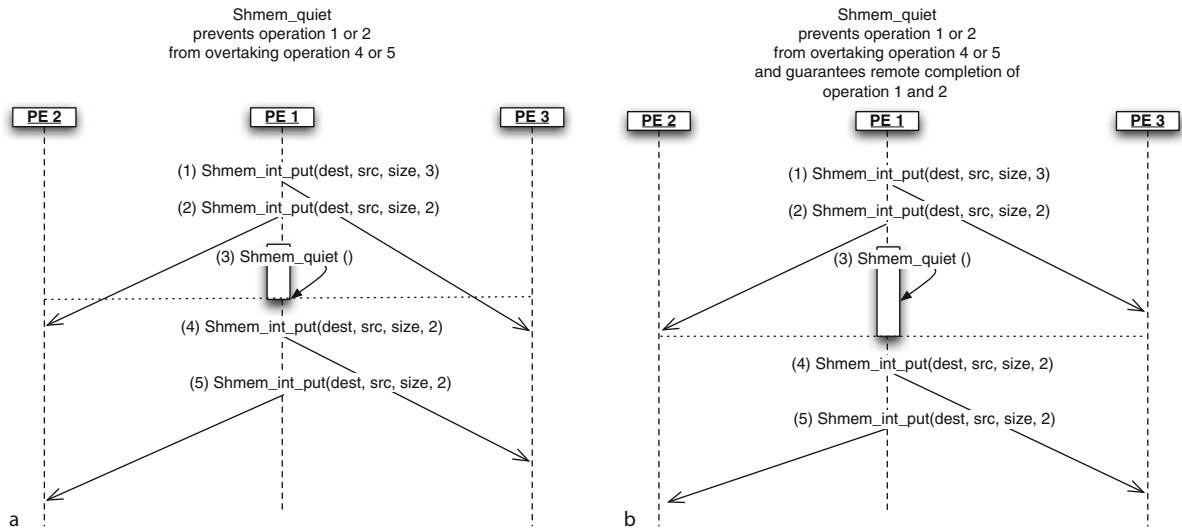

**Fetch and Add:** Atomically adds the value specified by the initiator PE to the target PE location's value. The return value is the target PE location's value prior to the update.

**Fetch and Increment:** Special case of Fetch and Add with implicit add value of 1.

**Extended Atomic Operation Support:** Cyclops-64 includes a general purpose atomic operations: **long** shmem\_atomic\_op(**long** \*target, **long** value, **long** pe,atomic\_t op), which performs the atomic operation specified by atomic\_t op on the specified target. The number of atomic operations supported is quite large and corresponds to Cyclops-64 intrinsic operations.

A more complete list of AMOs along with their definitions which comes from [10] is shown in the OpenSHMEM section of this entry.

Rather than providing atomics as defined above, MPI-2 provides MPI\_ACCUMULATE. While MPI\_ACCUMULATE provides atomic updates of local and remote variables the value of the variable prior to update is not returned to the caller. Atomic swap (and variants) are not supported by MPI-2. The following operations are available for MPI\_ACCUMULATE:

Circular shift in UPC

LC-SHMEM, and Q-SHMEM all provide the same reduction operations differing only in the supported data-types as detailed previously. GASNet provides no reduction operations. ARMCI supports some of the reduction operations of SHMEM. MPI-2 supports all the SHMEM reduction operations as well as reductions based on logical operations.

## Collective Communication

Collective communication is uniformly supported across SGI-SHMEM, MP-SHMEM, LC-SHMEM, and Q-SHMEM. C64-SHMEM and other communication libraries differ in their support for these (or similarly defined) operations.

*Broadcast:* Transfers data from the root PE to the active set of PEs. The active set of PEs is specified using a starting PE and a  $\log_2$  stride between consecutive PEs.

*Collect:* Gathers data from the source array into the target array across all PEs in the active set. Each

PE contributes their source array which is concatenated into the target array on all the PEs in the active set in ascending PE order. Source arrays can differ in size from PE to PE. MPI-2 provides MPI\_ALL\_GATHERV which provides similar semantics to Collect.

*fcollect:* A special case of Collect in which all source arrays are of the same size. This allows for an optimized implementation. MPI-2 provides MPI\_ALL\_GATHER which provides similar semantics to fcollect.

## Tool Support

Few performance tools have been developed specifically for SHMEM and Partitioned Global Address languages. The challenge comes as a result that traditional two-sided communication analyses do not apply to sided data accesses to “symmetric,” or shared variables as the library calls are decoupled from point-to-point synchronization. An event-based performance analysis tool [16] was developed to support both SHMEM and UPC which uses a wrapper function approach to gather SHMEM events. Tools such as CrayPat, TAU, and SCALASCA use similar approaches to profile and trace SHMEM calls. However, the wrapper function approach might not work well for future SHMEM-aware compilers since some might inline and replace SHMEM calls with direct shared memory accesses on certain architectures. GASP [17] has been used as an alternative mechanism to gather performance events for GASNet which is implicit from the communication library API. None of these approaches have been sanctioned for standardization or have been officially adopted for SHMEM. However, work is on the way.

Commercial available debuggers [18, 19] and compile time static checkers [20, 21] have limited support for SHMEM and UPC not to say tools that optimize them. In the case of OpenSHMEM, the semantics of the library can allow compilers or static checkers to report the incorrect use of SHMEM library calls. For example, compiler-based tools can easily check if arguments to the data access calls meet the “symmetric” storage for some variables, check if variables are accessed within bounds, and detect incorrect type usage in `shmemb_put32/64` calls. Such semantic checker tools can be invoked as preprocessors to help the

user reduce the amount of errors detected at runtime. Research needs to be done to find proper ways to optimize SHMEM in compilers. Traditional dataflow frameworks such as SSA (single-static assignment) have been extended in tools for MPI to handle two-sided communication and few for one-sided communications but not specifically for OpenSHMEM programs; and these technologies still have to be introduced in production compilers. The OpenSHMEM community needs to promote the development of tools that facilitate the usage of SHMEM programs as few tools exist for this as for now.

## Toward an Open SHMEM standard

When comparing the various implementations of SHMEM and other RMA APIs, we see that semantics vary dramatically. Not only do SHMEM RMA semantics differ from other RMA implementations (as expected) but different SHMEM implementations differ from each other. Support for primitive data types varies. Discontiguous RMA operations and Atomic RMA operations are not uniformly supported. Synchronization and completion semantics differ substantially which can cause valid programs on one architecture to be completely invalid on another. Symmetric data objects that dramatically aid the programmer are unique to the SHMEM model but are not uniformly supported. There are a number of capabilities that are available from implementations that differ from the SGI SHMEM baseline version. Below is a brief list of potential future additions to OpenSHMEM:

- Support for Multiple Host Channel Adapters (Rails)
- Support for non-Blocking Transfers
- Support for Events
- Additional Atomic Memory Operations and Collectives
- Potential options for NUMA/Hybrid architectures
- Additional communications transport mechanisms
- OpenSHMEM I/O library enhancements
- OpenSHMEM tools and Compiler enhancements
- Enabling exa-scale applications

An OpenSHMEM standard can address the lack of uniformity across the available SHMEM implementations. Standardization levels can be established to provide a base level that all SHMEM implementations must support in order to meet the standard, with higher levels

available for additional functionality and platform specific features.

In 2008, an initial dialogue was started between SGI and a small not-for-profit company called Open Source Software Solutions, Inc.(OSSS). The purpose of the dialogue was to determine if an agreement could be reached for SGI's approval of an open source version of SHMEM that would serve as an umbrella standard under which to unify all of the already existing implementations into one cohesive API. As part of this discussion, OSSS held a BOF on OpenSHMEM at SC08 to discuss this plan. The BOF was well attended by all of the vendors interested in supporting OpenSHMEM/SHMEM, and many of the interested parties in the SHMEM user community. The unanimous opinion of the attendees favored continuing the process toward developing OpenSHMEM as a community standard. The final agreement between SGI and OSSS was signed in 2010. The agreement allows OSSS to use the name OpenSHMEM and directly reference SHMEM going forward. The base version of OpenSHMEM V1.0 is based on the SGI man pages. The "look and feel" of OpenSHMEM needs to preserve the original "look and feel" of the SGI SHMEM. OpenSHMEM version 1.0 has been released and input for version 2.0 is being actively solicited.

There are a number of enhancements under discussion for version 2.0 and future offerings. Some of the features specific to one implementation or another as listed in the preceding tables and elements will be incorporated into later versions of OpenSHMEM. OpenSHMEM will be supported on a variety of commodity networks (including Infiniband from both Mellanox and QLogic) as well as several proprietary networks (Cray, SGI, HP, and IBM). The OpenSHMEM mail reflector is hosted at ORNL and can be joined by sending a request via the OpenSHMEM list server at <https://email.ornl.gov/mailman/listinfo/openshmem>. Future enhancements and RFIs will be sent to developers and other interested parties via this mechanism. Source code examples, Validation and Verification suites, performance analysis, and OpenSHMEM compliance will be hosted at the OpenSHMEM Web site at <http://www.openshmem.org>, and the OpenSHMEM standard will be owned and maintained by OSSS.

With the inexorable march toward exa-scale, programming methodologies such as OpenSHMEM will certainly find their place in enabling extreme scale architectures. By virtue of decoupling data motion from synchronization, OpenSHMEM exposes the potential for synergistic application improvements by scaling more readily than two-sided models, and by minimizing data motion, thus affording the possibility of concomitant savings in power consumption by applications. These gains, along with portability, programmability, productivity, and adoption, will secure OpenSHMEM a place for future extreme scale systems.

## Synonyms

Parallel operating system; Resource management for parallel computers; Runtime system

## Definition

An operating system manages the processors and other resources of a parallel computing system. Multiple instances of individual operating systems and the runtime system form a parallel operating system, which manages the resources of the entire machine and provides services for users and system administrators to obtain information and control various aspects of the machine and the application jobs that run on it.

## Discussion

### Introduction

A parallel computing system employs two or more processing elements (PE) which can be single or multicore

CPUs plus attached Graphic Processing Units (GPU) or other accelerators. Usually the PEs are general-purpose microprocessors, but specialized CPUs have been used. These PEs and other resources in the system need to be managed so they can run parallel jobs and be used effectively.

Some of the tasks of an OS for a parallel system are the same as the tasks a traditional OS performs for a desktop computer or a server. These include starting a job (or process), memory management, and I/O to disks and other peripherals. There are additional tasks an OS for a parallel system must perform or support. For example, in a distributed memory system where not every CPU has access to all memory in the system, data must be transferred between memories. The data is transmitted inside messages, and the OS must provide functions for sending and receiving these messages, or provide functions for applications to access the network interface directly in a safe manner.

Larger parallel machines often use a batch system to schedule jobs. Users submit their requests for a certain number of nodes, how long they will need them, and what application they want to run. The batch system then schedules job launches based on node availability and job priority. The batch system interacts with the OS to allocate nodes, launch jobs, and terminate jobs that have exceeded their requested execution time.

Yet another task that an OS for a parallel system must perform, that is not needed on personal computers, is process coordination across the machine. Very often the processes that are part of a parallel application need to communicate and synchronize with each other. Some parallel systems provide hardware or special networks for such operations, and the OS provides primitives to access these.

Parallel OSs also face constraints that general-purpose OSs do not have. On some large parallel machines, there is relatively little memory for each PE. The more of that memory is consumed by the OS, the less is available for the applications. Since every megabyte wasted is multiplied by the number of PEs in the system, this can be a significant cost.

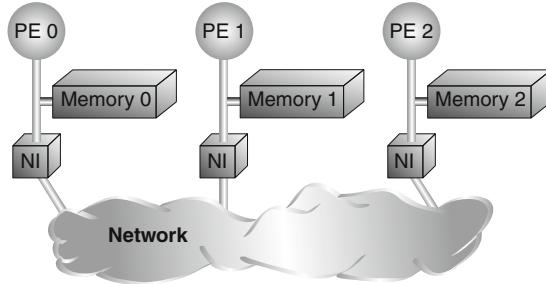

General-purpose OSs do a lot of housekeeping tasks, such as checking for email or the status of an attached printer, while waiting for a key stroke or mouse click from the user. While these administrative tasks do not take a lot of time, they can slow down a parallel

application in the following way. When the individual copies of an OS running on multiple PEs, or the application itself, exchange messages or synchronize activities, they need to interact with each other. When one of them is busy with administrative tasks, it delays all other processes that are part of the synchronization. When the busy OS finds time to service a request and then needs an acknowledgement or more information from another PE, it itself may be delayed because the other OS is now doing administrative tasks instead of responding to requests. This cascading effect is called *OS noise* and can slow down parallel applications. The main strategy to avoid this problem in a parallel OS is to disable services such as email and printing, which are not needed on the PEs of a parallel system. Other strategies include synchronizing timer interrupts and OS services in general and dedicating specific processor cores to OS work.

In addition to the tasks a parallel OS must perform and the constraints it faces, there are also a few things that make a parallel OS simpler. Usually, the PEs in a system are all of the same type and have very few peripherals. That means that a, possibly customized, parallel OS needs to support only a few hardware devices and a lot of functionality, for example, driving a display, is not needed within the OS. Often it is enough to manage the CPU, memory, and the network interface, since no other peripherals are attached or used. Many large-scale systems have no local disks, and the necessary device drivers and file systems need not be present in the OS. In such a case, I/O is done using messages to an external parallel file system running on a disk farm separate from the parallel compute system. This leads to opportunities for simplifications and helps reducing the memory footprint of the OS and the noise it introduces into the system.

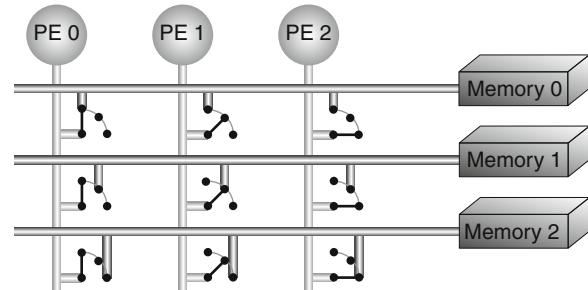

## Parallel Computing Systems

There are two main categories of parallel computing systems: message-passing and shared-memory systems. In a message-passing system, each PE has local memory that it can access directly, using load and store operations. Each PE is also connected to a network that allows data to move from the memory of one PE to the memory of another PE. In order to access data stored in memory attached to a remote PE, the data has to be moved from

**Operating System Strategies. Fig. 1**

A multicomputer consists of PEs that each have their own local memory. Data is moved from one PE to another using explicit message passing. The Network Interface (NI) connects the system bus of a PE to the network

**Operating System Strategies. Fig. 2**

In a shared-memory system, all PEs have access to all memory. A bus or, as in this picture, a crossbar switch connects the PEs to the available memory modules

one memory to the other using *explicit message passing*. Large-scale supercomputers by companies like Cray and IBM are of this type. Clusters, which are built out of commodity computers (desktops or servers), are also message-passing systems. The individual computers in a cluster are connected with a commodity network such as Ethernet or Infiniband, while supercomputers often employ vendor specific networks. Systems where the PEs do not share memory are called multicomputers. Large enough clusters and message-passing systems are sometimes called Massively Parallel Processors (MPP). Figure 1 shows an example of a multicomputer.

In a shared-memory system, all PEs have access to all of the memory in the system. Figure 2 shows an example. The diagram shows a crossbar switch where hardware sets the switches and enables access to memory based on the address the PE uses in its load or store instruction. Smaller and less expensive systems use a bus instead of a crossbar switch. Systems that use a crossbar switch or a shared memory bus have Uniform Memory Access (UMA) where the cost of accessing any memory location is roughly the same. UMA systems are often called Symmetric Multi Processors (SMP) and sometimes multiprocessors.

Larger systems, with many PEs, are Non-Uniform Memory Access (NUMA) machines. Accessing local memory is much faster than accessing the memory that is attached to a remote PE. Although memory access in a shared-memory system may not be uniform, the process of moving data is done by hardware and largely hidden from the program doing the access. A program simply issues load and store instructions to

global addresses which the system resolves, if necessary, by moving data from a remote memory to the PE doing the request. This is in stark contrast to explicit message passing and changes how these systems are programmed and the services an OS must provide.

The OS in a shared-memory system is responsible for enforcing memory access restrictions by configuring the underlying hardware accordingly and providing abstractions for sharing data among processes when needed. In a message-passing system, the OS must provide mechanisms for explicitly passing messages from one PE to another and enforce access restrictions to local memory and the network interface to protect other parts of the system from malicious messages.

Coherency, when a data change in remote memory becomes visible to a local PE, and how write access conflicts are handled depends on the hardware available in a shared-memory system. The OS may provide synchronization and access coordination primitives. The OS is also responsible to initialize the hardware, for example, to set caches to write-through or write-back.

The networks connecting the PEs in a message-passing system range from commodity networks used in clusters to custom hardware used in some supercomputers. A network consists of routers that are connected to each other and form a topology such as a 2-D or 3-D mesh, a hypercube, or a tree. The PEs connect to the routers via a network interface. Some network interfaces are simple, and the OS is responsible to trigger data movement in or out of the network. High-end network interfaces have processors and memory of their own and can be programmed to process incoming data

and make decisions where in memory the data needs to be deposited. For systems like that, the OS is responsible to restrict unprivileged access and provide abstractions to control and program the network interface.

Parallel computing systems are often partitioned so that each node in the system serves a specific purpose. [Figure 3](#) shows an example. Each node is an individual computer of the many that make up a multicomputer. A node in a multicomputer consists of memory, one or more PEs, and a connection to the network. Some nodes have additional network connections that are used by users to log into the system. When they do, they land on one of the service nodes from where they launch and control parallel applications. Often, development and compiling of parallel applications is done on the service nodes as well. The service partition in [Fig. 3](#) consists of the light-colored spheres at the top left.

The majority of nodes in a parallel system are reserved for computation. The cubes in [Fig. 3](#) represent those nodes. Users or a batch processing system launch jobs from the service partition. The runtime system allocates nodes from the compute partition and instructs the OSs on these nodes to start the processes of that application.

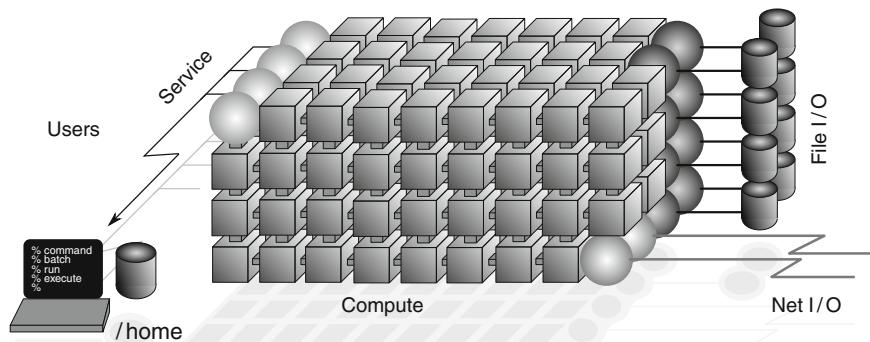

Many larger systems have a parallel file system that is external to the parallel machine itself. In the partitioning model, dedicated I/O nodes, the dark spheres on the right of [Fig. 3](#), are used to coordinate traffic to these external disks. The compute nodes send messages containing file data to the I/O nodes. The file system running on the I/O nodes then deposits the data on the disks. The compute nodes themselves do not

need to run a file system themselves. Some systems may be connected to other, wide-area, networks. Additional I/O nodes are sometimes used to handle the traffic to and from these networks (bottom right in [Fig. 3](#)).

Some clusters have local disks on each node since they consist of commercial, off-the-shelf computers that often come with built-in disks. The usage of these local disks is somewhat problematic on compute nodes for anything other than temporary data during the run of a job. Once the job finishes and the compute nodes are reallocated to another job, it becomes difficult to locate and retrieve the data from the earlier job run. Sometimes service nodes in clusters also serve as compute nodes, but better performance can be achieved using a strict separation of compute and service nodes.

### Overview of OS Approaches

Most clusters and supercomputers today run an OS that is a version of UNIX, such as various versions of Linux, IBM's AIX, or Sun Microsystem's Solaris. These are usually slightly modified or tuned versions of the corresponding desktop and server OSs. An alternative approach is to run a lightweight kernel on the compute nodes and a full-featured OS on the service and I/O nodes. Systems employing this approach include IBM's Blue Gene which runs the Compute Node Kernel (CNK) [7], Cray's XT-3 which runs Catamount [10], Intel's ASCI Red at Sandia National Laboratories which ran Cougar (a port of Puma [14]), and the Intel Paragon which had the option of running the Sandia/University of New Mexico OS (SUNMOS) [11].

**Operating System Strategies. Fig. 3** Partitioning of a system by dedicating nodes to usage functions such as compute, service, and I/O [10]

In the late 1980s and early 1990s, lightweight kernels were required because the supercomputers of that time had very limited amounts of memory available and every last bit of performance needed to be available to the parallel applications. That meant the OS had to have a very small memory footprint and very low processing overhead.

With the advent of clusters in the late 1990s, the situation began to change. Users began to demand features such as multithreading and shared libraries on parallel systems. Because the processors had become more powerful, users were often willing to sacrifice some performance in return for the additional features and convenience of programming. Today most parallel computers run full-featured OSs, while only a few high-end systems use lightweight kernels to ensure performance and scalability.

Desktop and server OSs are designed to allow multiple users or multiple tasks to share the available resources. Memory is partitioned and allocated to the currently running processes. The OS is responsible for memory allocation and protection, making sure that a process has access to only its portion of the memory. In addition, the OS provides control mechanisms to share memory among processes when that is needed for data exchanges. CPU cycles are bundled into time slices and allocated to processes which are currently ready to run. This happens many times per second and provides the illusion to a user that multiple processes are making progress at the same time, even when there is only a single CPU present in the computer.

For the most part, these traditional OS services are not needed in a parallel computer. Instead of time-sharing individual CPUs, whole sets of PEs (CPUs) are allocated to a single application that uses the PEs in parallel to solve a computationally intensive problem. This method of allocating resources is called *space-sharing*. Multiple applications may be running simultaneously on a parallel system, but each application has been allocated memory and PEs for its exclusive use.

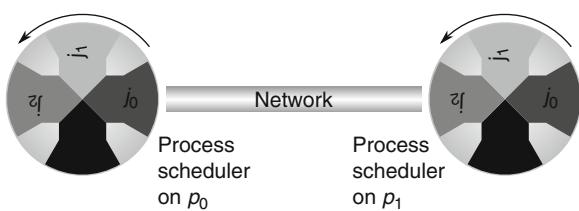

The main reason for space-sharing rather than time-sharing a parallel machine is throughput: The number of jobs a parallel system can complete in a given amount of time. This number depends on how long each job takes to complete. If the PEs of a parallel system were to run multiple jobs concurrently, completion time of a job would increase with the number of PEs it uses.

Using Fig. 4 as an example, let us assume there are multiple jobs,  $j_0 \dots j_3$ , running concurrently on PEs  $p_0$  and  $p_1$ . Since the activities on the individual PEs are not synchronized, it will happen that in a given time slice  $j_0$  is active on  $p_0$ , while  $j_2$  is active on  $p_1$ . If  $j_0$  needs to frequently transfer data between  $p_0$  and  $p_1$ , it will have to wait for its process to become active on  $p_1$  every time it requests an answer. Only active processes can send and reply to messages. When the OS on  $p_1$  makes  $j_0$  active there through a context switch,  $j_0$  will be able to send a reply from  $p_1$ . By the time the reply arrives at  $p_0$ ,  $j_0$  may not be active on that PE anymore, now causing wasted time for  $j_0$  on  $p_1$  waiting for an answer.

On some systems, the process schedulers can be synchronized, leading to a mode of operation called *gang scheduling*. Gang scheduling is not very common and difficult to achieve on large machines due to signal delays from one end of the machine to the other.

## Parallel OS Functionality

In most cases, each node of a parallel system runs one copy of the OS which manages all the resources local to that node. The collection of individual OSs on all the nodes of a parallel system forms the parallel OS and runtime system that controls the machine. In addition to the local OS services, this collection of system software must provide the ability to allocate nodes, launch and control parallel applications, for example, stopping and terminating all processes of a parallel job. In addition, services for debugging, determining system status, and parallel file I/O are usually available.

**Operating System Strategies. Fig. 4**

The two wheels represent the process schedules on  $p_0$  and  $p_1$ . Each process on these two PEs gets its turn to run in a round-robin fashion. Only a running process can send and reply to messages. If the rotation of the wheels (process scheduling) is not synchronized, delays occur because communicating processes have to wait for each other

Parallel jobs can be launched by users interactively from the service partition or through a batch scheduling system. In the latter case, users submit scripts to the batch system that contains information about what application the user wishes to run, how much time it needs to complete, and how many nodes it uses. The batch system queues these requests and when compute nodes become available selects the highest priority jobs and those that will best utilize the system and launches them. This is done in conjunction with the local OSs, but is usually a separate utility.

Whether a job is launched interactively by a user or by the batch system, the job launcher must interact with a node allocator to select the compute nodes that will be used to run the job. A node allocator can be simple and select from the available node list in a sequential fashion. More sophisticated allocators attempt to group the individual processes of an application physically close together on nodes that have one or only a few network hops between them. When the processes of a parallel application are scattered throughout a parallel system, their network traffic can interfere with the traffic from other applications, or traffic to and from the I/O nodes. Message latency also increases when application processes are further apart from each other.

Once nodes are allocated to a job, the launcher must interact with the OS instances on the selected nodes and initiate the start of the processes on each node. This involves coordination and sometimes synchronization among the selected nodes. Once the application is running, the job launcher serves as a collection point for standard input and output for each process of the application and as a control center. The job launcher can terminate the application and often serves as a conduit for debugging and signaling the application processes. Although not strictly part of the OS, the job launcher interacts with the OS on the nodes to control the processes. It also interacts with the node allocator, which is often a separate process, to allocate and release compute nodes. The node allocator often has an interface that allows users and system administrators to obtain status information, such as how many nodes are available for allocation, down for servicing, or currently running interactive or batch jobs.

Memory in early parallel systems was a scarce commodity and the OS had to be designed to consume

as little as possible of that resource. For example, an early version of OSF/1-AD, the OS for the Intel Paragon, consumed more than half of the 16 MB of memory installed on each node for its own code, message buffers, and other data structures. SUNMOS, another OS available for that machine, consumed only a few hundred kilo bytes. Cost of memory for that machine was a factor and wasting half of it on administrative services was not cost effective and limited the scope of scientific simulations that could be run.

Memory has become a lot cheaper since then and is now available in abundance, but conserving it may still be important. For example, some members of IBM's Blue Gene family of computers have a large number of PEs but a modest 512 MB of memory per PE. The future will increase the number of compute cores per processor, which in many systems may not be followed with an equal increase in memory size per core. Some systems may employ new types of memory, for example, FLASH memory which retains its content after a loss of power. Such new memory technologies may be, initially, more expensive and smaller in capacity leading to a need to conserve memory.

While a desktop OS should not waste memory either, it is not quite as critical there. Desktop systems and servers employ a technique called demand paging to provide the illusion that a system has much more memory than is physically available. When the physical memory becomes full, the OS will migrate less frequently used data to the swap area on a local disk and bring it back into memory later when it is needed again. In parallel systems, even on clusters with local disks, demand paging is usually disabled. The long delays of swapping and the unpredictable timing of it harm a parallel system much more because all processes of a single application must make progress together. Each time one of them is delayed, the whole application is delayed.

The individual instances of an OS on each PE run mostly independent of each other. This makes it more difficult to gather information about the system as a whole and exert control over it. For example, it might be interesting to see how busy the individual CPUs in a system are and how many processes are currently running on each. Another interesting statistic is the amount of available memory on each PE. Information like that can

be used to diagnose the health of a system and pinpoint problems. On a UNIX desktop system or server, there are many different utilities to gather such information.

The goal of a Single System Image (SSI) is to provide similar functionality, but for all PEs in a system. Instead of issuing commands to all PEs in a system, which can deliver a daunting amount of information, SSI usually allows commands to be restricted to a subset of PEs, for example, the ones currently running a given job. Examples of SSI systems include BProc, MOSIX, and OpenSSI. In addition to process control, some SSI provide functionality such as process migration, process check-pointing, a shared file system with a single root, and inter-process communications (IPC) between processes independent of their location. Implementing an SSI is easier on a shared-memory system where processes have access to all of memory and sharing data is automated by the hardware. An SSI for a multicomputer using message passing is much more difficult. Typically, full-featured SSI scale to a few tens of nodes, while those with a more restrictive set of features have been shown to run on up to a few hundred nodes. An SSI is integrated into the OS of a parallel computer, or, if SSI is a separate module, needs to make use of services the OS provides.

File I/O, and I/O in general, is a quandary on a parallel system. One problem in large systems is that not enough pathways are available to reach a shared storage device, which leads to network congestion. A second problem is the sharing of files and metadata, which contains information about the status of individual files and directories. For example, if many thousand processes start creating files in a single directory, the information for that directory must be continuously updated which creates an access bottleneck due to locking, unlocking, and synchronizing of these data structures.

Parallel file systems, not usually found on desktop systems or servers, attempt to alleviate the problem. A parallel file system often runs on the dedicated nodes of an I/O partition. These nodes, not burdened with compute tasks, can aggregate the data flow in and out of a parallel storage system and consolidate many of the updates and synchronizations that would otherwise have to happen individually. Parallel file systems in use on clusters and other large parallel computers include PVFS and Lustre.

## Lightweight Versus Full-Featured Operating Systems

Lightweight kernels are used on the compute nodes of some very large parallel systems. Often they are criticized for not providing enough functionality for today's highly complex and multi-layered parallel applications. Some argue that lightweight kernels are difficult to maintain since few people are familiar with them. This section briefly explores why lightweight kernels are a good fit for large message-passing systems.

In a partitioned systems like the one in Fig. 3, instances of a lightweight kernel run on the compute nodes, while the service and I/O nodes run a full-featured OS. This allows a lightweight kernel to be tailored to the hardware of a compute node, which is often much simpler than the hardware found in service and I/O nodes. For example, sometimes specialized or proprietary drivers are needed on I/O nodes to access the attached storage devices. Compute nodes on the other hand are often kept simple to reduce cost and power consumption. Their main components are often limited to one or more CPUs, local memory, and a network interface. OS functionality and device drivers for anything beyond that are not needed and often consume resources, such as memory and CPU cycles, if present.

Large parallel systems usually do not have local disks attached to compute nodes. That means the OSs on these nodes do not need to provide any file systems or device drivers for disks. File I/O requests by the application are converted into messages and sent off to the I/O nodes and external storage devices that handle them.

A large functional block in a modern OS deals with multiprocess management and scheduling. Algorithms to prioritize processes and to ensure fair scheduling are complex and must be able to deal with hundreds of concurrent processes. Since the nodes of a message-passing system are space shared, only one or a handful of processes run on each CPU. Some early lightweight kernels went so far as to allow only a single active process at a time and used cooperative scheduling to switch from one process to another. While this may seem like a throwback to an earlier time in OS design, it has several advantages: Expensive context switches are few, frequent and disrupting timer interrupts are not needed, and the code section for process control inside the kernel becomes much simpler. A desktop OS interrupts

running applications from 100 to 1,000 times per second to check whether there are any administrative tasks for it to do and to potentially context switch to another process. A typical lightweight kernel receives ten interrupts per second and is much quicker in determining whether a context switch is needed. Other than possibly sending a heartbeat signal to a Reliability, Availability, and Serviceability (RAS) system, a lightweight kernel has no other administrative tasks while it is running an application. This greatly reduces the noise signature of a lightweight kernel and gives more CPU cycles to the application.

Another large functional block in a full-featured OS deals with demand paging. Demand paging, even if local disks are available, is bad for the performance of a parallel system. While this feature can be turned off, a lot of the underlying data structures and assumptions remain, even when not in use. For example, page sizes are small to allow the OS more flexibility in allocating and releasing memory, and demand paging. Furthermore, pages that are adjacent to each other in the virtual address space are usually scattered all across physical memory. This increases the number of Translation Look-aside Buffer (TLB) entries needed and limits data transfers to and from most network interfaces to a single page at a time.

A lightweight kernel does not support demand paging and can manage memory as a set of physically contiguous large pages. This leads to performance improvements because the TLB entries are never exhausted, since the few page table entries that are needed usually fit in the TLB. Further performance improvements come from larger data transfers between the network interface and the memory. Large transfers are more efficient and lead to higher bandwidth.

A somewhat related problem has to do with shared and dynamically loaded libraries. Many lightweight kernels require statically linked applications. This is counter to modern software development strategies and is one of the main complaints about lightweight kernels. The processes of a parallel application are fairly well synchronized and reach a given section of code at about the same time. If at that point a shared library needs to be loaded, thousands or hundred thousands of PEs request that particular library. This leads to a massive bottleneck when all these requests converge at a single point in the file system. Because of that, and because of

the simplified way of dealing with memory, lightweight kernels are usually prevented from offering shared and dynamically loaded libraries.

In a message-passing system, moving data from the network into memory has to be done with as little overhead as possible. Traditionally, network interfaces deposit incoming data into buffers managed by the OS. When the application requests the data, the OS copies it from the buffer into the memory location the application requested. This technique works well when the network is much slower than the memory system, and when data packets are small. Modern parallel computers have networks that are often as fast or faster than the memory can copy data, and many parallel applications transmit large messages. Moving data from the network interface to memory and then again from one memory location to another causes delays in message delivery and consumes valuable memory bandwidth.

It is therefore advantageous for the network interface to move incoming messages directly into the memory location where the application expects the data. There are several requirements to make this possible. The Application Programming Interface (API) must allow pre-posting of receives. This allows an application to inform the OS or the network interface where future messages can be deposited. The traditional socket API used for TCP/IP programming does not provide this functionality; data is copied after it has arrived and the application has issued a receive request. The Message Passing Interface (MPI) API was designed for parallel computing and enables preposting of receive requests.

Sophisticated network interfaces used in message-passing systems have the ability to deliver data anywhere in local memory and can filter and direct incoming messages according to criteria such as which process the message is destined for, which process sent the message, its length, and a set of tag bits that can be used by the application to route messages to specific memory locations. To make optimal use of such network interface capabilities, the OS must allow incoming messages to be handled by the hardware without expensive OS interrupts. This is called *OS bypass*. The goal is to avoid invoking the OS on standard message deliveries. However, the OS is still responsible for protection and must be invoked during initial setup, perhaps while the application is initializing. Even with OS bypass it must not be

possible for unrelated processes to harm each other or access each others' private data.

Because a lightweight kernel can arrange physical pages in sequential order, the hardware in a network interface that is required to deliver messages larger than a page size can be much simpler; the network interface does not need its own virtual memory controller. In such a system, there is a one-to-one mapping of virtual to physical addresses which makes it easier to designate a memory region for delivery of messages: Only a starting address and a length are required. This further reduces the hardware complexity of the network interface and makes interaction of an application directly with the network interface more efficient and simpler.

The goal of a lightweight kernel is to turn over most hardware resources of a node to the application, while maintaining protection barriers between unrelated processes and protecting the rest of the system from errant or malicious processes. It is possible to design, implement, and maintain a lightweight kernel with a small group of programmers in a short amount of time. However, the talent pool to perform this kind of work is limited, and lightweight kernels do not offer some features that modern parallel applications demand. Whether these demands make sense on extremely large-scale systems is debatable.

### The Next Big Challenge: Resilience

Future high-end systems are expected to grow in size and part count. Because of that it is also expected that failures in software and hardware will become more common. For large applications that use a significant number of nodes in such a machine, that means they will almost certainly be interrupted by a failing component before the computation has a chance to complete. To nonetheless make progress, applications save their state and intermediate results frequently to disk. During a restart after an interruption, that data is read back from the disk and the application continues where it has left off. This is called *checkpointing* or *checkpoint/restart*.

Writing a checkpoint is time consuming, especially when many nodes do it at the same time. Delaying the writing of checkpoints risks that too much work is lost and has to be redone after an interruption. Current models predict that, even with optimal checkpoint intervals, when job sizes approach 100,000 nodes, applications will spend more than 50% of their

total execution time writing checkpoints, restarting, and redoing lost computations. Clearly, that is not an efficient use of such large and expensive machines. Research into making applications more resilient is under way.

Checkpoint/restart can be done automatically by the OS since the OS knows what portions of memory a process is using. There might be data structures the application uses which it can reconstruct easily without having to save and restore them. Without hints from the application, the OS will have to checkpoint these data structures, making automatic checkpointing somewhat less efficient than application checkpointing or application-directed checkpointing. Before a checkpoint can be written, the application must quiesce to ensure data does not change while checkpointing is in progress. That means no messages must be in transit during that time. Again, this can be done at the user level or with the help of the OS.

In the future, OSs may provide additional features to aggregate checkpoint data and to trigger checkpoints when a failure is imminent. Aggregating checkpoint data from multiple nodes on intermediate nodes before it is sent off to disk storage may allow an OS to schedule massive writes to storage and coordinate them with I/O from other applications currently running. Additional functions, such as data consolidation and compression, may also be feasible. Sometimes the onset of a failure can be predicted. For example, a stark increase in single-bit errors in an Error Correction Code (ECC) protected memory module indicates that an uncorrectable double-bit error is not far off. It makes sense to create a checkpoint at that time and restart the process on the failing node somewhere else in the system.

### Future Directions

The largest computing systems in the world have reached the petascale, and exascale systems are on the horizon. These are systems that will deliver performance in the thousands of petaflops. Early arrivals will look similar to today's large-scale systems. They will consist of thousands of nodes connected by a message-passing network. Each node will have multiple CPUs, each with tens or hundreds of cores. No one knows how these extreme scale systems will evolve after that.

Furthermore, application developers are hoping for a new programming model beyond the traditional MPI

and C/C++/Fortran interface. But, again, there is no consensus yet what that will be. Depending on the architecture of these future systems and how they will be used, OS technology needs to evolve as well. It is possible that some of the protection mechanisms of today's OSs will be implemented in hardware. Whole sections of a machine can then be turned over to an application, to be used in the fashion that provides the most benefit. Commonly used functions will be in libraries, and system control utilities interact with the hardware directly. Since the future is so uncertain, it is more likely that OSs and runtime systems take on an even bigger role to support the new hardware and provide new usage models to applications. For that, it may be possible that whole cores or CPUs will be dedicated to running portions of the OS and to accelerate message passing.

Some applications can make use of the compute capabilities a GPU provides. In the future, more systems will be delivered with GPUs and other specialized processors to accelerate computing. Again, programming and usage models for such systems are still emerging and the role OSs will play to make these accelerators accessible is unclear at the moment.

## Bibliographic Notes and Further Reading

Many of the functions and services an OS for a parallel system provides are the same as the ones in most modern OSs. Standard textbooks, such as [8, 12, 13],

provide good introductions to the various general OS topics mentioned in this article. Understanding some of the hardware and the architecture of computers in general and parallel systems in particular is also necessary to understand OSs. The best book for that is [5]. A good introduction to the issues involved in designing and evaluating a parallel file system is [6].

The evolution of a family of lightweight kernels and the experience from developing and using them is described in [10]. The Compute Node Kernel (CNK) in use on IBM's Blue Gene machines is discussed in [7]. Puma [14] and its predecessor, the Sandia/University of New Mexico OS (SUNMOS) [11], were lightweight kernels for early massively parallel machines such as the nCUBE 2, the Intel Paragon, and Intel's ASCI Red at Sandia National Laboratories.

Performance comparisons between a full-featured OS and a lightweight kernel can be found in [2, 3]. Another comparison of an earlier system is in [11]. The experiences designing and deploying one of the earliest large clusters, including the system software required to do it, are chronicled in [1]. An explanation of the partitioning of a system into service, compute, and I/O partition is also in [1]. A brief overview of SSI is presented in [4] and a more thorough treatment is in Chap. 11 of [9].

## Definition

Axiomatic verification, although a general term, refers usually to the method, introduced by Bob Floyd [4] and Tony Hoare [7] for sequential programs, of proving that a program satisfies a specification formulated as a predicate pair of a pre- and a postcondition. Precondition  $P$  states the assumptions made of the program variables before program  $S$  executes. Postcondition  $R$  characterizes the state of the program variables after program  $S$  terminates, if it does (partial correctness). Sometimes, termination is part of the proof obligation (total correctness). The proof obligation is usually denoted by the so-called *Hoare triple*  $\{P\} S \{R\}$ .

The verification method proceeds by inserting intermediate assertions between the program's statements and proving the resulting Hoare triples, based on a number of axiomatic inference rules. Susan Owicki and David Gries extended the axiom system to parallel programs with shared memory [13, 14].

## Discussion

### Overview

Hoare's axiom system, also called *Hoare logic*, provides one axiomatic inference rule for each of the following language constructs: empty statement, assignment ( $:=$ ), sequential composition ( $;$ ), binary deterministic choice (**if**), and iteration (**while**). Two further rules are

needed to make propositional logic work properly. An axiomatic inference rule is written as follows:

$$\frac{\text{Obligations to be proved}}{\text{Conclusion that can be inferred without proof}}$$

The reader of this entry is expected to have a basic knowledge of Hoare logic.

The extension to parallel programs comes in two flavors: a general setting [13] and a restricted setting [14]. The general setting allows for more concurrency but burdens the programmer with, possibly, complex proof obligations. The restricted setting takes some of the burden of proof away from the programmer and relegates it to the compiler, at the expense of a possible loss of concurrency.

In each of the two settings, there is one language construct that introduces parallelism (parallel composition) and one that curtails it (synchronization and exclusion).

## The General Setting

### The Axioms

- *Parallel composition:*

$$\frac{\{P_1\} S_1 \{R_1\}, \dots, \{P_n\} S_n \{R_n\} \text{ are interference-free}}{\{P_1 \wedge \dots \wedge P_n\} \text{ cobegin } S_1 // \dots // S_n \text{ coend } \{R_1 \wedge \dots \wedge R_n\}}$$

The  $S_i$  are called *processes* and are executed in parallel. The  $n$  proof obligations concern the respective processes in isolation. Interference freedom is explained below.

- *Synchronization and exclusion:*

$$\frac{\{P \wedge B\} S \{R\}}{\{P\} \text{ await } B \text{ then } S \text{ end } \{R\}}$$

This rule rests on the assumption that the **await** statement is implemented as a test-and-set operation, i.e., the successful test of  $B$  is followed directly by the execution of  $S$  and all of this must proceed without interference. A comparison with the rule for the **if** statement [7] reveals that **await** does not require a poststate satisfying  $R$  if  $B$  is false, while **if** does. Instead, **await** suspends execution until some parallel statement makes  $B$  true.

The **await** statement has recently received support via the concept of transactional memory (see the corresponding encyclopedia entry).

### Interference Freedom

Shared variables are protected only inside an **await** statement but can also appear elsewhere in the program. To ensure that unprotected shared variables are being treated properly, one must prove that an assignment to a shared variable in one process does not affect the assertions made in the proof of any other parallel process. Thus, if execution of  $S_i$  falsifies neither any precondition of a statement in  $S_j$  nor the postcondition of  $S_j$ , then execution of  $S_i$  cannot interfere with the *proof* of  $S_j$ , and the proof of  $S_j$  is valid even in the face of parallel execution of  $S_i$  with  $S_j$ .

More formally, the proof obligation is as follows:

- Consider every process  $S_i$  of the parallel statement and every statement  $S$  of  $S_i$  that is not inside the body of an **await**.
- For every assertion  $Q$  in the proof of some process other than  $S_i$ , but not in the body of an **await**, prove  $\{Q \wedge \text{pre}(S)\} S \{Q\}$ .

This property is called *interference freedom*. The concept of interference freedom brought the complexity of correctness proofs of parallel programs down to a manageable size. For a program with  $n$  processes, each with  $m$  statements, the computational complexity of the proof obligation is in  $O(n^2 m^2)$ . Further, in many cases, the proof of each process can be organized such that many of the assertions can be written in terms of an invariant, which reduces the proof obligation further to showing that this invariant is not interfered with.

The validity of the noninterference argument rests on two further assumptions:

- *At-most-once property:* Every expression  $e$  in the program accesses at most one nonlocal, mutable variable and does so at most once. In every assignment  $x := e$ , expression  $e$  is at-most-once and  $x$  is local, or  $x$  is a simple variable (i.e., not a data aggregation like an array) and  $e$  accesses no nonlocal, mutable variable.

For example, if  $x$  is nonlocal,  $x := x + 1$  is not at-most-once, since  $x$  is once read and once written. However, with local variable  $t$ , in the equivalent program  $x := t; t := x + 1$ , both assignments are at-most-once. In this way, any program violating the at-most-once property can be refined to one satisfying it.

- *Memory interlock:* Parallel accesses to a fixed memory cell are serialized by hardware.

The **await** statement is a device to exclude portions of the program from the obligation of a noninterference proof. Assertions placed inside the body of an **await** are presumed to be shielded from interference.

The shorthand  $[S]$  stands for the atomic statement: **await true then S end**.

## Auxiliary Variables

The above rules do not guarantee the relative completeness of the method, i.e., that every correct program is provable (modulo the incompleteness of integer arithmetic due to Gödel). For example, one cannot prove that

**cobegin**  $[x := x+1] // [x := x+1]$  **coend**

increases variable  $x$  by 2, while one can prove that

**cobegin**  $[x := x+1] // [x := x+2]$  **coend**

increases  $x$  by 3 (see the example proofs below). The reason is that the two processes in the former parallel statement are indistinguishable, so the individual progress made by each process cannot be accounted for. In order to make it recognizable, one must introduce auxiliary variables (also called history variables) that log the individual progress but do not influence the flow of data or control of the program that is subject to proof. Then, one must assume by axiom that the proof, which holds for the program with auxiliary variables, also holds for the program without auxiliary variables.

- *Auxiliary variable:*

A set  $AV$  of auxiliary variables of a program contains only variables  $x$  that appear in assignments  $x := e$ , where  $e$  may contain any kind of variable (auxiliary or not).

- *Auxiliary variable axiom:*

Let  $S$  be a program with auxiliary variables and  $S'$  the corresponding program with all assignments to auxiliary variables removed.

$$\frac{\{P\} S \{R\}}{\{P\} S' \{R\}}$$

There is an algorithm that introduces into a program the necessary auxiliary variables to conduct the

proof [12]. It floods the program with auxiliary variables. Typically, the programmer takes up the intellectual challenge instead and inserts a few, well-chosen variables.

The auxiliary variable axiom is very powerful. It also supports the removal of **await** statements, should they become unnecessary after the removal of auxiliary variables.

## Total Correctness

For total correctness, i.e., termination (or at least progress for a nonterminating program), three extra steps are necessary. First, termination functions must be provided for loops in order to prove that the individual processes terminate. Second, it must be shown that the parallel composition does not cause any interference with these termination functions. Third, it must be proved that the **await** statements do not cause deadlock in the parallel composition. Owicky and Gries provide a sufficient, static proof condition for the absence of deadlocks [13].

## Examples

*Claim:*

$$\{x = 0\}$$

**cobegin**

$$[x := x+1] // [x := x+2]$$

**coend**

$$\{x = 3\}$$

*Proof outline:*

$$\begin{aligned} & \{x=0\} \\ & \{(x=0 \vee x=2) \wedge (x=0 \vee x=1)\} \\ & \text{cobegin} \\ & \quad \{x=0 \vee x=2\} \qquad \{x=0 \vee x=1\} \\ & \quad [x := x+1] \qquad // \qquad [x := x+2] \\ & \quad \{x=1 \vee x=3\} \qquad \{x=2 \vee x=3\} \\ & \text{coend} \\ & \quad \{(x=1 \vee x=3) \wedge (x=2 \vee x=3)\} \\ & \quad \{x=3\} \end{aligned}$$

Noninterference argument:

$$\begin{aligned} & \{(x=0 \vee x=1) \wedge (x=0 \vee x=2)\} [x := x+1] \{x = 0 \vee x = 1\} \\ & \{(x=2 \vee x=3) \wedge (x=0 \vee x=2)\} [x := x+1] \{x = 2 \vee x = 3\} \\ & \{(x=0 \vee x=2) \wedge (x=0 \vee x=1)\} [x := x+2] \{x = 0 \vee x = 2\} \\ & \{(x=1 \vee x=3) \wedge (x=0 \vee x=1)\} [x := x+2] \{x = 1 \vee x = 3\} \end{aligned}$$

Note that some noninterference must be proved, even though the two processes are fully exclusive: their respective pre- and postconditions must still be checked.

To prove the following program, auxiliary variables and an invariant to relate them are necessary.

*Claim:*

$$\{x = 0\}$$

**cobegin**

$$[x := x+1] // [x := x+1]$$

**coend**

$$\{x = 2\}$$

*Proof outline:* The invariant is  $I: x=y+z$

$$\begin{array}{c} \{x=0\} \\ y := 0; z := 0 \\ \{y=0 \wedge z=0 \wedge I\} \\ \text{cobegin} \\ \{y=0 \wedge I\} \quad \{z=0 \wedge I\} \\ [x := x+1; y := 1] \quad // \quad [x := x+1; z := 1] \\ \{y=1 \wedge I\} \quad \{z=1 \wedge I\} \\ \text{coend} \\ \{y=1 \wedge z=1 \wedge I\} \\ \{x=2\} \end{array}$$

Noninterference argument:

$$\begin{aligned} &\{(z=0 \wedge I) \wedge (y=0 \wedge I)\}[x := x + 1; y := 1] \{z=0 \wedge I\} \\ &\{(z=1 \wedge I) \wedge (y=0 \wedge I)\}[x := x + 1; y := 1] \{z=1 \wedge I\} \\ &\{(y=0 \wedge I) \wedge (z=0 \wedge I)\}[x := x + 1; z := 1] \{y=0 \wedge I\} \\ &\{(y=1 \wedge I) \wedge (z=0 \wedge I)\}[x := x + 1; z := 1] \{y=1 \wedge I\} \end{aligned}$$

Our final example is again the two processes  $x := x+1$  and  $x := x+2$  but with the exclusion lifted. Thus, they must be made at-most-once. The proof of partial correctness succeeds, except that the proof obligation of noninterference cannot be met.

*Claim:*

$$\{x = 0\}$$

**cobegin**

$$t := x+1; x := t // u := x+2; x := u$$

**coend**

$$\{x = 3\}$$

*Proof outline:*

$$\begin{array}{c} \{x=0\} \\ \{(x=0 \vee x=2) \wedge (x=0 \vee x=1)\} \end{array}$$

**cobegin**

$$\{x=0 \vee x=2\} \quad \{x=0 \vee x=1\}$$

$$t := x+1 \quad u := x+2$$

$$\{t=1 \vee t=3\} \quad // \quad \{u=2 \vee u=3\}$$

$$x := t \quad x := u$$

$$\{x=1 \vee x=3\} \quad \{x=2 \vee x=3\}$$

**coend**

$$\{(x=1 \vee x=3) \wedge (x=2 \vee x=3)\}$$

$$\{x=3\}$$

Noninterference argument:

$x := u$  affects the postcondition of  $x := t$ , i.e., the following proof obligation is not a valid Hoare triple:

$$\{(x=1 \vee x=3) \wedge (u=2 \vee u=3)\} x := u \{x=1 \vee x=3\}$$

The same holds vice versa. There is interference: the program is not correct.

## The Restricted Setting

### The Axioms

- *Parallel composition:* Let  $r$  be a set of program variables.

$$\frac{\{P_1\} S_1 \{R_1\} \wedge \dots \wedge \{P_n\} S_n \{R_n\} \wedge \text{FREE} \wedge \text{RES}}{\{P_1 \wedge \dots \wedge P_n \wedge I(r)\}}$$

$$\text{resource } r : \text{cobegin } S_1 // \dots // S_n \text{ coend} \\ \{R_1 \wedge \dots \wedge R_n \wedge I(r)\}$$

*FREE:* no variable free in  $P_i$  or  $R_i$  is being changed by  $S_j$  ( $j \neq i$ )

*RES:* invariant  $I(r)$  refers only to variables in  $r$

- *Synchronization and exclusion:*

$$\frac{\{P \wedge B \wedge I(r)\} S \{R \wedge I(r)\}}{\{P\} \text{with } r \text{ when } B \text{ do } S \text{ end } \{R\}}$$

The **with-when** statement is a conditional critical region, i.e., it is executed under mutual exclusion.

The rules in this setting work only if the following syntactic restrictions are obeyed:

- Any process may access a resource variable only inside a critical region protecting this variable.
- Any variable changed by process  $S_i$  may be accessed by process  $S_j$  ( $j \neq i$ ) only if it is a resource variable.

Thus, while shared variables must be in the resource, local variables need be in the resource only if the invariant refers to them.

These restrictions can be checked by a compiler. This check takes the place of the proof of interference freedom necessary in the general setting.

### Example

In the following claim, the shorthand  $[S]$  stands for **with  $r$  when true do  $S$  end**.

*Claim:*

$\{x = 0\}$

**resource  $r(x)$ :**

**cobegin**  $[x := x+1] // [x := x+2]$  **coend**

$\{x = 3\}$

*Proof outline:* The invariant is  $I(r) : x = y + z$

```

 $\{x=0\}$
 $y := 0; z := 0$
 $\{y=0 \wedge z=0 \wedge I(r)\}$
resource $r(x, y, z)$:
cobegin
 with r when true do $\{y=0\}$ with r when true do $\{z=0\}$
 $\{y=0 \wedge I(r)\}$ $\{z=0 \wedge I(r)\}$
 $x := x+1; y := 1$ $//$ $x := x+2; z := 2$
 $\{y=1 \wedge I(r)\}$ $\{z=2 \wedge I(r)\}$
 end end
 $\{y=1\}$ $\{z=2\}$
coend
 $\{y=1 \wedge z=2 \wedge I(r)\}$
 $\{x=3\}$

```

Variables  $y$  and  $z$  are accessed locally but, because the invariant refers to them, they must be part of the resource.

### Bibliographic Notes and Further Reading

The Owicki–Gries verification method received much attention in the late 1970s and remains useful to this day. It provided the first rigorous treatment of the semantics of imperative shared-memory programs, and its notion of interference freedom is at the core of later

methods. The seminal idea was that the execution of one process should not interfere with the *proof of correctness of another process*, rather than with its execution.

The necessity of the auxiliary variable axiom demonstrated the price that one has to pay for the ability to reason first about processes individually and then about their parallel composition. If the parallel program is considered as a whole, there is no need for auxiliary variables [9, 10].

The Owicki–Gries method demonstrated that proofs of parallel programs are feasible but require an effort that is, in the worst case, quadratic in the number of statements across all processes that are being composed in parallel. This cannot be avoided if shared updates are allowed to happen without synchronization. Further, proofs can be engineered to use invariants in order to reduce the proof effort.

Soundararajan [15] was able to do without auxiliary variables and without the noninterference proof by introducing instead history variables into the assertions (so-called hidden variables [9]). Inherently, their manipulation is of similar complexity but involves no intuition, similarly to Owicki’s algorithm for “flooding” the program with auxiliary variables [12].

The technical complexity of the general setting revealed the intricacies of unbridled parallelism. Still, it played a significant role in helping to prove implementations of intricate algorithms like Dekker’s algorithm for mutual exclusion or the concurrent garbage collector for LISP data structures [5].

The restricted setting was laid out before Owicki and Gries by Hoare [8]. It is relevant in practice today for the verification of monitors. A monitor is an abstract data structure whose operations are conditional critical regions. See the corresponding encyclopedia entry.

The Owicki–Gries method was extended in at least two ways to address distributed-memory parallelism [1, 11]. The lack of shared updates in distributed programs raised the hope for simpler proofs. Unfortunately, the axiom system turned out to be more complex rather than simpler. First, an additional proof step is needed (the so-called cooperation proof [1] or satisfaction proof [11]): the communication operations **send** and **receive** must be matched to mutual pairs whose semantics is essentially the same as that of an assignment. Second, interference freedom may still have to be proved as well. All program variables are local but, in general, there is still the need for shared auxiliary variables.

A methodology for the development of parallel programs, which is similar to the one proposed for sequential programs by Dijkstra [2] and Gries [6], has been proposed by Feijen and van Gasteren [3]. It is based on the Owicki-Gries verification method.

Parallelization

### Discussion

Parafrase was a successful project allowing experimentation in source-to-source translation of FORTRAN programs. Parafrase was the work of David J. Kuck and his students at the University of Illinois at Urbana-Champaign. It was supported largely by NSF. The name of system is due to Stott Parker. A wide variety of optimization strategies were developed by researchers, and the performance achieved was measured using a broad cross section of applications, across a variety of theoretical and actual machines. Parafrase was successful because it reduced the effort required of the researcher to implement an optimization strategy, and to perform experiments.

Parafrase was structured much like a multi-pass compiler of the same era. The FORTRAN program being compiled was processed one routine at a time. A scanner consumed the source code for a FORTRAN routine and built an equivalent representation in the Internal Language (IL). Then a series of passes that transformed the IL in various ways was run. The researcher would select the passes based on the goals of the research. Then lastly, a FORTRAN code regenerator pass was run. This entire process was repeated for each of the routines in the input program. The FORTRAN program output by Parafrase could be compiled by a FORTRAN compiler and run on any machine.

Because the ultimate goal of Parafrase was to regenerate optimized FORTRAN code, the IL used by Parafrase was considerably different than the IL found in a compiler. The IL used by Parafrase was a relatively

straight forward representation of FORTRAN source, with some additional look-aside tables to hold summary information about variables and loop structures. Each pass was required to accept and generate this common IL.

Having an IL that was very close to FORTRAN enabled Parafrase to provide an easily understandable IL dump by simply pretty printing the FORTRAN program that was represented in the data structures. The pretty printer could be invoked by Parafrase at the end of a pass, or called by the pass itself to display intermediate results. This made it easy for the researcher to see what an optimization was doing because the researcher only had to understand FORTRAN, not the details of some unusual IL.

Parafrase also included an IL verification phase that could be enabled to run after any pass to ensure that that pass was following the rules. This was especially useful when identifying which pass was incorrectly processing a FORTRAN routine.

Because all of the passes were required to accept and generate the common IL, the passes could be run in any order. This flexibility allowed the researcher to construct a specialized ordering of the passes to achieve specific goals. Very early in Parafrase's life, the ability to specify the order of the passes in a text file was added. This enabled the researcher to adjust the order of the passes without having to rebuild the executable image of Parafrase.

Parafrase was implemented in PL/I and run on an IBM System/360 before virtual memory. With all of the passes and the limited amount of physical memory available, the executable had to be built using the technique of overlays. By placing each pass in its own overlay, the passes would all share the same memory address space, thus reducing the memory foot print. Of course, it was a little more complicated than that, and the obscure interface to IBM's link editor to build the overlays was understood by only a few people. A build tool was created for Parafrase to automatically

identify an appropriate overlay structure, to create the appropriate link editor commands, and to build the overlay executable, thus relieving the researcher from understanding the messy details of this process.

When researchers started to use Parafrase on more than just toy programs, it was quickly discovered that a scanner handling ANSI FORTRAN was not nearly strong enough. The various extensions to FORTAN promoted by computer manufacturers had changed common use. The only solution was to add these extensions to the Parafrase scanner, and to extend the IL where needed to include them. Eventually, VAX, CDC, HP, IBM, and other manufactures extensions were implemented. Some syntax extensions were just syntactic sugar, and were translated away by the scanner. Others required unique extensions to the IL.

Another unexpected discovery when processing non-toy programs was that most FORTRAN programs contained hand optimized code targeting a particular machine. For most of the research performed with Parafrase, the ideal input program was one that was not hand optimized.

Consider the case of exploring the impact of vectorization on a program. If the loops in the program that could be vectorized were unrolled by hand in the original code, then the vector length and the reference pattern for each vector operand would be different than if the loops were not unrolled in the original program. Vector lengths would be shorter, and operands

would be less likely to be contiguous. On most vector capable machines, these changes would seriously impact performance.

Consequently, a collection of de-optimization passes were written for Parafrase. It was impossible to write de-optimization passes for every hand optimization. There were just too many. Instead, we kept track of how many important loops exhibited a particular hand optimization, and whenever a sufficiently large number of loops exhibited a particular hand optimization, we wrote a de-optimization pass to address the issue.

Parafrase ended up having de-optimization passes and optimization passes that performed inverses of each other for many of the common optimizations. For example: Loop rerolling and loop unrolling, forward substitution and code floating, and loop distribution and loop fusion.

The research efforts supported by Parafrase dealt with optimization techniques for supporting new types of hardware acceleration devices: vector processors, streaming memory systems, cache memory systems, multiple functional units, parallel processors, and memory banks. At the time, the impact of any one of these acceleration devices on the performance of ordinary programs was not well understood.

The optimization techniques to automatically exploit these acceleration devices were not well understood. Parafrase provided a reasonable vehicle to explore optimization techniques.

## Parallel Computing

DAVID J. KUCK

Intel Corporation, Champaign, IL, USA

## Definition

Parallel computing covers a broad range of topics, including algorithms and applications, programming languages, operating systems, and computer architecture. Each of these must be specialized to support parallel computing, and all must be designed and implemented coherently to provide highly efficient parallel computations.

## Discussion

### Introduction and History

All computations transform data – logically and arithmetically – following a series of algorithms. The broad goals of parallel computing are to improve the speed or functional ease with which this is done. Speed and functionality goals can usually be met, but in many practical cases, difficulties arise that present far more complexity than does traditional sequential computing. The following gives an overview of background issues and the current state of parallel computing.

The long and diverse history of computing is intertwined with parallelism. There will be no attempt here to formulate a rigorous definition of parallel computing. Instead, an introduction to parallel computing can be provided by sketching the many uses for parallelism over time. Computer system *performance* has always been the key driver of *hardware parallelism*. On the other hand, *software parallelism* has been driven by both performance and application functionality.

The baseline of parallelism is serial computing, and in the beginning, some computers operated in bit-serial fashion. One bit, the minimal information unit in a computer, was processed at a time. To improve speed, multiple bits were fetched from memory and transformed in parallel, a process that continued up to word-level computation (32 or 64 bits). This required making all data paths in a system – memory, processor, and interconnection – one word wide. Fast parallel algorithms for individual arithmetic operations occupied the research agenda in early computing, into the 1960s.

## Parallel Communication Models

- [Bandwidth-Latency Models \(BSP, LogP\)](#)

Some early machines used one hardware (HW) technology to implement all parts of a computer, from processor to memory. Over time, as technology advanced and more performance was demanded, distinct technologies were used in different parts of machines – e.g., transistors for processing and magnetic cores for memory. As processor technology speeds increased more quickly than memory, parallel memory units were introduced to match the data rates (i.e., bandwidths measured in bits per second) of processors. As one part of the processor became a performance bottleneck relative to others, multiple units (e.g., 2 adders) were introduced within the processor.

The idea of performing more than one arithmetic operation in parallel is an obvious way to improve performance, and was mentioned by the first computer designer, Charles Babbage (who designed a mechanical digital computer in the 1840s [1, 2]). Eventually, reasonably balanced systems for various types of computation became well understood, and parallelism as above was employed to produce very efficient uniprocessor systems. *Simultaneous operation* on whole words and *overlap* of various operations are the basic principles that support parallelism.

After sufficient HW has been invested to produce a good architecture using various types of low-level parallelism, the clock speed (which determines the time of a computer's most basic steps) can be increased to speed up a system. From the beginning, new device technology allowed faster clocks; from the 1960s on, this and architectural refinements drove system performance. But at the high end of performance demands, the ability to change the internal structure of a system by simply adding low-level parallelism became increasingly difficult and yielded slower growth. Architectural refinements were added to keep systems balanced (e.g., cache memory hierarchies) as technology advances drove processor performance faster than off-chip memories.

## Parallel Architectures

System clock speed determines the bandwidth (bits/sec) of various computer elements, and the clock speed depends on the basic technology available. Physical issues underlie technology, including:

- Transistor density in an integrated circuit limits clock speed

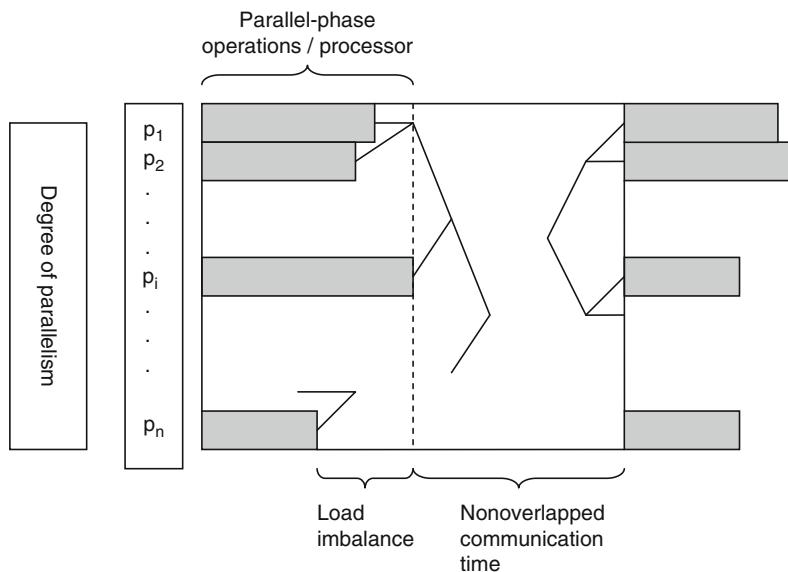

- The speed of light limits data transmission time or latency (measured in seconds)
- Manufacturing costs of HW limit the complexity that can be built into a system

To avoid limits imposed by the first and last of these, parallel processors can be used, each carrying out part of an overall computation. In other words, transistor density increases can be frozen as can the complexity of faster uniprocessor manufacturing, by moving to parallel processing. Although this forces the system size to grow, which in turn exacerbates latency issues, two of the three physical issues are controlled. The number of parallel units being used is often expressed as the *degree of parallelism*,  $n$ , see Fig. 1.

Parallelism also raises a new architectural issue: How does one interconnect the processors and the processors to memory? Ideally one would choose direct connection of each unit to all others (a crossbar switch), but this raises severe cost and design issues as the degree of parallelism grows. At the other extreme, the bus can be extended from within each processor to all others, a simple but low-performance idea. Between these extremes, one can choose a fast parallel ring, torus, or shuffle interconnect network pattern, each with many parallel data transmission paths and various performance and manufacturing trade-offs. For details and more references see [1, 3].

From the 1960s through the 1990s, a host of research and commercially available parallel systems were built, exploring a wide variety of architectural trade-offs. At the same time, beginning in the 1960s, several related approaches to computing emerged. Multiprocessing, the connection of whole computers to increase system throughput, began. The distinction can be captured by viewing *parallel computing* as turnaround computing – whose goal is the fast turnaround of one job at a time. In contrast, *multiprocessing* can be viewed as throughput computing – the goal being to complete a large volume of similar transactions quickly.

The third approach, *distributed computing* arose for a totally different reason [4]. Large companies bought multiple computer systems at different sites, and wanted to exchange results among them – e.g., financial information for the whole enterprise – via telephone line communications. Distributed computing in general puts less demand on communication than parallel computing or multiprocessing. By the late 1960s, this idea

**Parallel Computing. Fig. 1** Key parallel computation parameters

grew into the ARPANET among government contractors and agencies, and was followed by new concepts that led to the Internet.

At the HW technology level, transistor speeds increased continually and casualties developed – by the early 1990s ECL (emitter coupled logic) could not be pushed faster, and was supplanted by traditionally slower CMOS transistors. By the first decade of the twenty-first century, it became clear that silicon transistors, whose size continued to decrease (Moore's Law [5]) and whose power dissipation density concomitantly increased with clock speed, were hitting a “power wall.” The result was that clock speeds could no longer increase, even though densities could continue to grow, allowing more processors on a single semiconductor chip. Thus, parallel computing reached the mainstream, and by 2010 has become ubiquitous.

## Parallel Software Concepts

Over the decades of parallel architecture development, research into algorithms and parallel programming tools enjoyed broad growth. However, software (SW) application development is a very diverse subject, and parallel programming has not matured at the rate that parallel HW has arrived in the mainstream of computing. Roughly speaking, parallel application development suffers from all the problems inherent in sequential programming,

plus a number of additional problems arising from parallelism.

As is obvious from the release delays, security weaknesses, and other flaws in sequential applications, SW development methods are still maturing. Some decades after sequential computing HW reached its eventual complexity (except perhaps for cache hierarchy management), SW development remains labor intensive, with results that are error prone, and hard to test. Improving parallel SW development tools remains an important activity.

P

## Application Software Development

In 2010, various programming languages are able to capture any given algorithm in many forms. Some algorithms and applications are naturally parallel. For example, little dependence exists among tasks in multiprogramming and distributed computing, and any language that suits their problem domain will do. Other applications contain data and control dependences that appear to force sequential execution of program phases. While a continuum of ideas exists to deal with parallel programming, the following breakdown captures some key points, concluding with the unexploited parallelism remaining in useful parallel applications. This section is an introduction; more details appear in the following sections.

## Parallelization Methods

1. For some apparently nonparallel algorithms and programs, effective SW procedures lead to good parallel performance:
  - (a) Compilers can extract some parallelism from sequential constructs by language-level transforms [6].
  - (b) Parallel libraries allow developers to express parts of programs in parallel terms at the language level, without the need to understand the underlying parallel algorithms [7].
  - (c) For other program constructs, compilation is too hard and libraries are not available, so a language or algorithm change is necessary for compiler success, forcing the application developer to think through parallelism detail. Three programming models will be discussed in detail below as found in [8–10].

Thus, there are several ways to adjust some programs to be suitable for efficient parallel execution, but in other cases parallelism is harder to obtain.

## Parallelization Impediments

2. For the most difficult applications, algorithms and their programs, there are inherent, non-parallelizable issues:
  - (a) Data and control dependences arise that cannot practically be removed by a combination of compiler and run-time HW checks. For example, too much branching, or too many pointers or run-time parameter tests exist.
  - (b) Architecture-related clashes arise, e.g., there is too much nonoverlapped interprocessor communication or imbalance between the sizes of parallel tasks that waste parallel computation time, see Fig. 1.

In case 2, the best approach is to rethink the algorithms and program, and restructure the program or use entirely different algorithms. These steps can be very difficult and nonintuitive, unless a developer is specifically driven by the parallel architectural constraints imposed, understands parallel languages, and has a deep understanding of the underlying problem and various algorithms for solving it.

## Unexploited Parallelism in “Well-Parallelized” Applications

3. Consider the amount of “unexploited” parallelism remaining in an application that is already regarded as well parallelized for a given system. In other words, how far do parallel applications in use deviate from the perfect exploitation of parallelism in their algorithms? This question exposes language and compiler issues. Assume that an algorithm and program contain reduction operations in the form of Eq. 1, which sums the elements  $a_i$  of array  $a$  into scalar  $x$ . If the compiler cannot parallelize this,

$$x = 0; \quad \text{for all } i \quad (x = x + a_i) \quad (1)$$

then unexploited parallelism can be recovered by using a language (extension) that contains a parallel reduction operator. Much language research is directed toward filling such language gaps in ways that are easy to use in specific algorithms or application domains, e.g., games, image processing, and transaction processing.

Figure 1 summarizes several details that determine parallel system performance. The shaded areas represent useful work (their unequal lengths show that not all processor steps take the same amount of time), and the trees represent communication or synchronization, e.g., join/fork or message-passing patterns. Performance increases with the degree of parallelism and parallel-phase operations per processor, which increase the use of parallel resources. Performance decreases due to load imbalance and nonoverlapped communication, which waste resources relative to decreasing elapsed time in Eq. 2.

## System Architecture Performance Criteria

Let *computation time* be defined as a measure of the useful processing steps in a source program, i.e., corresponding to necessary steps in the original algorithms and their program counterparts. *Communication time* includes the total HW interconnect time and system SW overhead required in a program and its resulting computation to support the desired computation time.

Our overall objective is to *minimize total elapsed time*, in Eq. 2 (cf. Fig. 1).

$$\begin{aligned} \text{Total elapsed time} &= \text{Computation time} \\ &+ \text{Nonoverlapped communication time} \end{aligned} \quad (2)$$

In general, the diversity of parallel architectures, especially issues arising from major increases in processor count, change some of the inherent needs of algorithms to satisfy the constraints outlined above. Furthermore, each data size to which a given algorithm applies may force algorithm adjustments for machine size. Thus, for a given algorithm type, adaptations to machine parameters may be necessary.

As outlined above, algorithms, languages, run-time libraries, and architecture are closely linked in obtaining top performance. Good parallel performance across all types of problems can usually be obtained by an approach that includes all of these factors.

A universally important performance criterion that follows from Eq. 2 is shown in Eq. 3 (where *communication time* includes overlapped and nonoverlapped time).

$$\frac{\text{Computation time}}{\text{Communication time}} \geq 1 \quad (3)$$

Maintaining this inequality, averaged over time windows throughout a computation, means that the HW design and application SW running may be brought into balance by overlapping communication with meaningful computation.

The ratio can be used as a guideline in system and SW design. If the ratio of Eq. 3 is less than 1, increasing the numerator, while decreasing the denominator can reduce overall time and bring the HW use into balance. For example, if the ratio is less than 1, performance may be improved by using an algorithm with redundant operations that reduces the total data communication time. Such a trade-off causes no problems because the key ratio was too low to begin with.

## Parallel Performance

A successfully performing parallel computation must satisfy four basic requirements:

1. Algorithmic parallelism
2. Program parallelism
3. Data size and parallelism
4. Architecture balance and parallelism

These success requirements have many interpretations and interrelations, which are sketched below. They include mathematical issues at the algorithmic level, programming languages that well-suit important application areas, accommodating the data structures and

sizes that occur naturally, and then synthesizing these requirements into an architectural design that is well suited to efficient solution of the problems defined by the original applications. Many books discuss various aspects of performance for a range of algorithms and applications, ranging from broad coverage [11] to emphases on nonnumerical [12] to numerical [13] computations.

1. *Algorithmic parallelism*: The algorithms used must avoid dependences among operations that force one step to follow another. The essence of parallelism is to be able to do large numbers of operations simultaneously, and this must begin at the algorithm and data structure level. A simple case is an interactive program that has several sequential algorithms, each of which can be run simultaneously – e.g., a game may use three processors working independently on processing user input, readying the next frame, and displaying the current frame.

A more scalable algorithm that may require any number of processors is one that operates on arrays of many numbers, or files of many records. For example, if computing  $x_i$  requires  $a_i$  and  $b_i$ ,  $1 \leq i \leq n$ , as in Eq. 4, the process can be carried out for any number of values at once. If it requires  $x_{i-1}$ , as in Eq. 5, this is a linear recurrence, which

$$\text{for all } i (x_i = a_i + b_i) \quad (4)$$

$$x_0 = 0; \quad \text{for all } i (x_i = x_{i-1} + a_i) \quad (5)$$

appears to have sequential dependences but can be transformed and computed by reasonable parallel algorithms in  $O(\log_2 n)$  steps. On the other hand, nonlinear recurrences, e.g., Eq. 6 ( $1 \leq i \leq n$ ), usually present insurmountable mathematical problems

$$x_{-2} = 2; x_{-1} = 1; x_0 = 1; \quad \text{for all } i \left( x_i = \frac{a_i(x_{i-1})^2 x_{i-2}}{b_i x_{i-3}} \right) \quad (6)$$

for parallelization, so a different algorithm must be found.

2. *Program parallelism*: Given a set of parallel algorithms, expressing them effectively in an appropriate parallel language is relatively straightforward. However, the structure of an algorithm and architecture

will force the choice of language, as the following example illustrates.

*Game Example:* Consider the many algorithms necessary to support an interactive computer game. At the highest level, communication from the players must be coordinated with the internals of the game. These include a changing scene driven by the game logic as well as modifications made by players' actions. High-quality graphics depends on computationally intense solutions of complex physics equations for mechanical structures, fluid flow, cloth and hair motion, etc. An important consideration for game writers is how to use all of the computing power available to create appealing graphics and game experiences. Finally, each new frame must be composed and displayed. All of this must occur in real time.

Three *programming models* form the core of most programming languages and methods (cf. Fig. 1).

- (a) *Message passing* among communicating sequential (or parallel) processes may be the appropriate programming model at the highest level of game SW. Each process runs under independent control of the operating system on one or more processors, with the added feature that processes occasionally may send data to, and receive data from, one another. To keep the program logic valid, the system SW must provide for processes interrupting one another, and later expecting acknowledgements back from other processes. Communication delays are typical of performance problems in message-passing programs. A good exposition of MPI, a popular message-passing language for scalable systems, is found in [9].
  - (b) The *fork-join parallel* model matches well with the execution of high-level tasks internal to a game. Any number of tasks can be dispatched with fork statements to separate processors, in the form of threads, and when their independent work is finished, they combine in join statements. *Threads* share memory and may be controlled by each application without OS intervention in scheduling. The degree of parallelism is limited by the number of parallel tasks. For a description of OpenMP and its use in shared memory programming, see [8].
  - (c) *Data parallel languages*, embody a third type of program parallelism. They normally express a great deal of low-level parallelism in the data, e.g., application-specific array oriented languages can be used to express parallelism directly in the form required by an application algorithm. Equation 4 is an example, and may occur in rendering an image for display, where each pixel is computed independently of all others. Another example is movie making, where each frame can be rendered independently of the others. An introduction to Cuda and OpenCL, two recent data parallel languages, is given in [10].
3. *Data size and parallelism:* The degree of parallelism is also limited by data dependence and data size. The number of independent data structures and the size of each are indicators of the degree of available parallelism in a computation. A successful parallel computation requires data locality in that program references stay relatively confined to the data available in each processor – otherwise too much overhead time can be consumed, ruining parallel performance.
- The number of *parallel-phase operations per processor* must be sufficient to dominate the communication time per phase, see Fig. 1. Equation 3 can be used to explain the reason why. In parallel algorithms, communication among processors (or processor-memory communication) occurs with some frequency; in the easy case, the frequency is low. But as the frequency grows, so does the communication in any time window. Equation 3 says that as the communication time exceeds computation time, performance can suffer. If there is little data per processor, then the computation time window without communication is expected to be small. Thus a small numerator leads to a large denominator, driving the ratio to violate the inequality.
4. *Architecture balance and parallelism:* The architecture must have a sufficient number of processors, sufficiently fast global memory access, and interprocessor communication of data and control information that allows parallel scalability. As systems grow in degree of parallelism, the memory and communication systems define the success of a design.

Of course, these qualitative statements imply many difficult technical design choices (mentioned earlier) that must provide a good match to the programs and data sets to be run. In systems with low degrees of parallelism, including modern multicore chips, all of the processors generate addresses for a single, shared address space. This *shared-memory* parallelism (SMP) allows them to communicate quickly and simply via memory. But as the degree of parallelism increases and parallelism grows, *distributed-memory* parallel (DMP) systems are used.

Whether DMP clusters of smaller SMP systems occupy a single large computer room, or span different cities, large systems have nonuniform memory access time (NUMA), so called because of the very large range of overheads involved in communicating with local (SMP) and global (DMP) memory. These systems present greater programming challenges, in order to minimize and overlap communication and computation time (recall Eq. 2) and to schedule tasks properly (load balancing) to minimize wasted resources (cf. Fig. 1). The great variety in real-world computations has led designers down many successful paths from the 1980s to the present [14, 15].

## Parallel Program Correctness

Correctness is harder to determine for a parallel program than for a sequential program, and fixing bugs is concomitantly much harder. Whole new classes of bugs arise in parallel programs, for various reasons. A major problem that arises at the hardware level is *non-determinism* of execution. Because the system is large and some clocks may be out of sync, slight timing variations may exist from run to run of a given program.

Even if in sync, different interactions with the OS (e.g., on which processor a process is scheduled) or with other applications, or slightly different data-dependent execution paths can cause a program to execute in different ways each time it runs. These nondeterministic issues make error states nearly impossible to capture or recreate. This is obvious for reactive or interactive programs, whose inputs are difficult to recreate exactly (precisely when did a keystroke that triggered a process occur?).

In some parallel programs, synchronization points occur to coordinate the work of distinct processors, e.g.,

at *join* points and at the end of *data parallel* operations. These are necessary to ensure that the computations on all processors are complete for a given parallel phase of the overall program, before continuing. In some programming languages, message passing is used to send data and synchronize control of various processors. This is common in distributed memory machines. Software developers often find it hard to get the logic of such programs exactly right, given the variety of inputs some programs have, and the fact that multiple developers may have worked on a given section of code.

The logic of some programs may require *critical sections*, in which a data structure is accessed by only one computational process at a time. For example, if work tasks are being chosen from a queue, to assure that each task is assigned to only one processor, the task assignment algorithm would include a critical section. Software *locks* may be used to allow just one process at a time to execute a critical section.

When combinations of the above occur, various anomalies may arise, including program *deadlock*, in which, e.g., two processors halt, each waiting for the other. In what is perhaps the worst case, poorly synchronized programs actually do not halt, but spend so much time waiting for one another and occasionally proceeding, that the effect is to lead naïve developers to confuse a complex correctness bug with a performance problem. The result may be fruitless developer time spent using performance tools and techniques to find a correctness problem, which needs other approaches.

## Future

The era of ubiquitous parallel processing hardware has arrived, but the development of parallel application SW is lagging. In 2010, single chips contain eight shared memory processors (or “cores”). Distributed memory clusters of these, containing from 32 to over 100 K processors are the state of the art in server computers. The use of clustered systems ranges from scientific research and engineering design, to Internet search engine support.

While their clock speeds are frozen, the core count in future chips will continue to provide more performance, based on better architecture, parallel applications algorithms, and SW. Computers based on new technologies and principles (e.g., quantum or biological

principles) could change all of this in some application areas, but it is most likely that parallel SW and architectural issues will continue to dominate much of system design for many decades.

There is a seldom mentioned issue in parallelism. After the challenges of getting all current applications well parallelized are met, how does performance continue to grow? There are only two ways that more parallel processors can produce more performance: larger data sets, or more complexity in algorithms for today's applications. Both of these factors have driven much of computing in the past, but clearly there are limitations for some applications in the future. Those that cannot grow, will be frozen at a performance level, which is fine in some areas. However, application developers will be forced to work harder in the future to exploit parallelism than they did in the past, and new parallel applications will continue to arise.

This leads to a host of new and continuing problems to be solved in order to allow parallelism to continue to provide performance benefits. Parallel algorithm research will continue to provide important basic parallelism. SW researchers will design new development tools to aid the above, work on languages that prevent the commission of serious bug errors, and drive toward hardware support for easier ways to write correct programs or tools to aid in debugging. Architecture and HW research will provide faster systems in accordance with Eqs. 1 and 2. All of these efforts tend to increase the degree of parallelism while reducing parallel computation time; increasing the width and shrinking the length of Fig. 1.

### Synonyms

Algorithmic skeletons

### Definition

A parallel skeleton is a programming construct (or a function in a library), which abstracts a pattern of parallel computation and interaction. To use a skeleton, the programmer must provide the code and type definitions for various application-specific operations, usually expressed sequentially. The skeleton implementation takes responsibility for composing these operations with control and interaction code in order to effect the specified computation, in parallel, as efficiently as possible. Abstracting from parallelism in this way can greatly simplify and systematize the development of parallel programs and assist in their cost-modeling, transformation, and optimization. Because of their high level of abstraction, skeletons have a natural affinity with the concepts of higher-order function from functional programming and of templates and generics from object-oriented programming, and many concrete skeleton systems exploit these mechanisms.

### Discussion

Traditional tools for parallel programming have adopted an approach in which the programmer is required to *micromanage* the interactions between concurrent activities, using mechanisms appropriate to the underlying model. For example, the core of MPI is based around point-to-point exchange of data between processes, with a variety of synchronization modes. Similarly, threading libraries are based around primitives for locking, condition synchronization, atomicity,

and so on. This approach is highly flexible, allowing the most intricate of interactions to be expressed. However, in reality many parallel algorithms and applications follow well-understood patterns, either monolithically or in composition. For example, image processing algorithms can often be described as *pipelines*. Similarly, *parameter sweep* applications present a parallel scheduling challenge which is orthogonal to the detail of the application and parameter space.

### Programming with Skeletons

The term *algorithmic skeleton* stems from the observation that many parallel applications share common internal interaction patterns. The parallel skeleton approach proposes that such patterns be abstracted as programming language constructs or library operations, in which the implementation is responsible for implicitly providing the control “skeleton,” leaving the programmer to describe the application-specific operations that specialize its behavior to solve a particular problem. For example, a pipeline skeleton would require the programmer to describe the computation performed by each stage, while the skeleton would be responsible for scheduling stages to processors, communication, stage replication, and so on. Similarly, in a parameter sweep skeleton, the programmer would be required to provide code for the individual experiment and the required parameter range. The skeleton would decide upon (and perhaps dynamically adjust) the number of workers to use, the granularity of distributed work packages, communication mechanisms, and fault-tolerance. At a more abstract level, a divide-and-conquer skeleton would require the programmer to specify the operations used to divide a problem, to combine subsolutions, to decide whether a problem is (appropriately) divisible, and to solve indivisible problems directly. The skeleton would take on all other responsibilities, from whether to use parallelism at all, to details of dynamic scheduling, granularity, and interaction.

Thus, in contrast to the micromanagement of traditional approaches, skeletons offer the possibility of *macromanagement* – by selection of skeletons, the programmer conveys macro-properties of the intended computation. This is clearly attractive, provided that the skeletons offered are sufficiently comprehensive collectively, while being sufficiently optimizable individually and in composition. Sometimes a skeleton may

have several implementations, each geared to a particular parallel architecture, for example, distributed- or shared-memory, multithreaded, etc. Such customization has the potential for achieving high performance, portable across various target machines.

Application programmers gain from abstraction, which hides much of the complexity of managing massive parallelism. They are provided with a set of basic abstract skeletons, whose parallel implementations have a well-understood behavior and predictable efficiency. To express an application in terms of skeletons is usually simpler than developing a low-level parallel program for it.

This high-level approach changes the program design process in several ways. First, it liberates the user from the practically unmanageable task of making the right design decisions based on numerous, mutually influencing low-level details of a particular application and a particular machine. Second, by providing standard implementations, it increases confidence in the correctness of the target programs, for which traditional debugging is too hard to be practical on massively parallel machines. Third, it offers predictability instead of an *a posteriori* approach to performance evaluation, in which a laboriously developed parallel program may have to be abandoned because of inadequate efficiency. Fourth, it provides semantically sound methods for program composition and refinement, which open up new perspectives in software engineering (in particular, for reusability). And last but not least, abstraction, that is, going from the specific to the general, gives new insights into the basic principles of parallel programming.

An important feature of the skeleton-based methodology is that the underlying formal framework remains largely invisible to application programmers. The programmers are given a set of methods for instantiating, composing, and implementing diverse skeletons, but the development of these methods is delegated to the community of implementers.

In order to understand the spectrum of skeleton programming research, it is helpful to distinguish between skeletons that are predominantly data-parallel in nature (with an emphasis on transformational approaches), skeletons that are predominantly task-parallel or related to algorithmic classes, and the concrete skeleton-based systems that have embedded these concepts in real frameworks.

## Data-Parallel Skeletons and Transformational Programming

The formal background for data-parallel skeletons can be built in the functional setting of the Bird–Meertens formalism (BMF), in which skeletons are viewed as higher-order functions (functionals) on regular bulk data structures such as lists, arrays, and trees.

The simplest – and at the same time the “most parallel” – functional is *map*, which applies a unary function  $f$  to each element of a list, that is,

$$\text{map } f [x_1, x_2, \dots, x_n] = [f x_1, f x_2, \dots, f x_n] \quad (1)$$

*Map* has the following natural data-parallel interpretation: each processor of a parallel machine computes function  $f$  on the piece of data residing in that processor, in parallel with the computations performed in all other processors.

There are also the functionals *red* (reduction) and *scan* (parallel prefix), each with an associative operator  $\oplus$  as parameter:

$$\text{red}(\oplus)[x_1, x_2, \dots, x_n] = x_1 \oplus x_2 \oplus \dots \oplus x_n \quad (2)$$

$$\text{scan}(\oplus)[x_1, x_2, \dots, x_n] = [x_1, x_1 \oplus x_2, \dots, x_1 \oplus \dots \oplus x_n] \quad (3)$$

Reduction can be computed in parallel in a tree-like manner with logarithmic time complexity, owing to the associativity of the base operation. There are also parallel algorithms for computing the scan functional with logarithmic time complexity, despite an apparently sequential data dependence between the elements of the resulting list.

Individual functions are composed in BMF by means of backward functional composition  $\circ$ , such that  $(f \circ g)x = f(gx)$ , which represents the sequential execution order on (parallel) stages.

Special functions, called *homomorphisms*, possess the common property of being well-parallelizable in a data-parallel manner.

**Definition 1 (List Homomorphism)** A function  $h$  on lists is called a homomorphism with combine operation  $\otimes$ , iff for arbitrary lists  $x, y$ :

$$h(x + y) = (hx) \otimes (hy) \quad (4)$$

Definition 1 describes a class of functions, operation  $\otimes$  being a parameter, which is why it can be viewed as

defining a skeleton. Both map and reduction can obviously be obtained by an appropriate instantiation of this skeleton.

The key property of homomorphisms is given by the following theorem:

**Theorem 1 (Factorization)** *A function  $h$  on lists is a homomorphism with combine operation  $\otimes$ , iff it can be factorised as follows:*

$$h = \text{red}(\otimes) \circ \text{map } \phi \quad (5)$$

where  $\phi a = h[a]$ .

In this theorem, homomorphism has one more parameter beside  $\otimes$ , namely function  $\phi$ . The practical importance of the theorem lies in the fact that the right-hand side of the equation (5) is a good candidate for parallel implementation. This term consists of two stages. In the first stage, function  $\phi$  is applied in parallel on each processor (*map* functional). The second stage constructs the end result from the partial results in the processors by applying the *red* functional. Therefore, if a given problem can be expressed as a homomorphism instance then this problem can be solved in a standard manner as two consecutive parallel stages – map and reduction.

The standard two-stage implementation (5) may be time-optimal, but only under an assumption that makes it impractical: the required number of processors must grow linearly with the size of the data. A more practical approach is to consider a bounded number  $p$  of processors, with a data block assigned to each of them. Let  $[\alpha]_p$  denote the type of lists of length  $p$ , and subscript functions defined on such lists with  $p$ , for example,  $\text{map}_p$ . The partitioning of an arbitrary list into  $p$  sublists, called *blocks*, is done by the *distribution function*,  $\text{dist}(p) : [\alpha] \rightarrow [[\alpha]]_p$ . The following obvious equality relates distribution to its inverse, flattening:  $\text{red}(+) \circ \text{dist}(p) = \text{id}$ .

**Theorem 2 (Promotion)** *If  $h$  is a homomorphism w.r.t.  $\otimes$ , then*

$$h \otimes \text{red}(+) = \text{red}(\otimes) \circ \text{map } h \quad (6)$$

This general result about homomorphisms is useful for parallelisation via data partitioning: from (6), a

standard distributed implementation of a homomorphism  $h$  on  $p$  processors follows:

$$h = \text{red}(\otimes) \circ \text{map}_p h \circ \text{dist}(p) \quad (7)$$

Sometimes, it can be assumed that data is distributed in advance: either the distribution is taken care of by the operating system, or the distributed data are produced and consumed by other stages of a larger application.

The development of programs using skeletons differs fundamentally from the traditional process of parallel programming. Skeletons are amenable to formal transformation, that is, the rewriting of programs in the course of development, while ensuring preservation of the program's semantics. The transformational design process starts by formulating an initial version of the program in terms of the available set of skeletons. This initial version is usually relatively simple and its correctness is obvious, but its performance may be far from optimal. Program transformation rules are then applied to improve performance or other desirable properties of the program. The rules applied are semantics-preserving, guaranteeing the correctness of the improved program with respect to the initial version. Once rules for skeletons have been established (and proved by, say, induction), they can be used in different contexts of the skeletons' use without having to be reproved.

For example, in the SAT programming methodology [10] based on skeletons and collective operations of MPI, a program is a sequence of stages that are either a computation or a collective communication. The developer can estimate the impact of every single transformation on the target program's performance. The approach is based on reasoning about how individual stages can be composed into a complete program, with the ultimate goal of systematically finding the best composition. The following example of a transformation rule from [8] is expressed in a simplified C+MPI notation. It states that, if binary operators  $\otimes$  and  $\oplus$  are associative and  $\otimes$  distributes over  $\oplus$ , then the following transformation of a composition of the collective operations scan and reduction is applicable:

$$\left[ \begin{array}{l} \text{MPI\_Scan } (\otimes) ; \\ \text{MPI\_Reduce } (\oplus) ; \end{array} \right] \implies$$

```

 Make_pair;
 MPI_Reduce (f(\otimes , \oplus));
 if my_pid==ROOT then Take_first;

```

(8)

Here, the functions `Make_pair` and `Take_first` implement simple data arrangements that are executed locally in the processes, that is, without interprocess communication. The binary operator  $f(\otimes, \oplus)$  on the right-hand side is built using the operators from the left-hand side of the transformation.

Rule (8) and other, similar transformation rules have the following important properties: (1) they are formulated and proved formally as mathematical theorems; (2) they are parameterized in one or more operators, for example,  $\oplus$  and  $\otimes$ , and are therefore usable for a wide variety of applications; (3) they are valid for all possible implementations of the collective operations involved; (4) they can be applied independently of the parallel target architecture.

### Task- and Algorithm-Oriented Skeletons

In contrast to the data-parallel style discussed in the preceding section, there are many instances of skeletons in which the abstraction is best understood by reference to an encapsulated parallel control structure and/or algorithmic paradigm. These can be examined along a number of dimensions, including the linguistic framework within which the skeletons are embedded, the degree of flexibility and control provided through the API, the complexity of the underlying implementation framework and the range of intended target architectures.

While *map* is the simplest data-parallel skeleton, *farm* can be viewed as the simplest task-parallel skeleton. Indeed, in its most straightforward form, *farm* is effectively equivalent to *map*, calling for some operation to be applied independently to each component of a bulk data structure. More subtly, the use of *farm* often carries the implication that the execution cost of these applications is unpredictable and variable, and therefore that some form of dynamic scheduling will be appropriate – the programmer is providing a high-level, application-specific hint to assist the implementation. Typical *farm* implementations will employ centralized

or decentralized master–worker approaches, with internal optimizations which try to find an appropriate number of workers and an appropriate granularity of task distribution (trading interaction overhead against load balance). From the programmer’s perspective, all that must be provided is code for the operation to be applied to each task, and a source of tasks, which could be a data structure such as an array or a stream emerging from some other part of the program. The *bag-of-tasks* skeleton extends the simple *farm* with a facility for generating new tasks dynamically.

*Pipeline* skeletons capture the pattern in which a stream of data is processed by a sequence of “stages,” with performance derived from parallelism both between stages, and where applicable, within stages. Even such a simple structure allows considerable flexibility in both API design and internal optimization. For example, the simplest pipeline specification might dictate that each item in the stream is processed by each stage, that each such operation produces exactly one result, and that all stages are stateless. For such a pipeline, the programmer is required to provide a sequential function corresponding to each stage. More flexible APIs may admit the possibility of stateful stages, of stages in which the relationship between inputs and outputs is no longer one-for-one (e.g., filter stages, source, and sink stages), of bypassing stages under certain circumstances, and even of controlled sharing of state between stages. From the implementation perspective, internal decisions include the selection of the number of implementing processes or threads, allocation of operations to processes or threads, whether statically or dynamically, and correct choice of synchronization mechanism.

The *divide-and-conquer* paradigm underpins many algorithms: the initial problem is divided into a number of sub-instances of the same problem to be solved recursively, with subsolutions finally combined to “conquer” the original problem. For the situation in which the sub-instances may be solved independently the opportunities for parallelism are clear. Within this context, there is considerable scope to explore a skeleton design space in which constraints in the API are traded against performance optimizations within the implementation. A very generic API would simply require the programmer to provide operations for “divide” and “conquer,” together with a test determining whether an

instance should be solved recursively, and a direct solution method for those instances failing this test. Less-flexible APIs, could, for example, require the degree of division to be fixed (every call of divide returns the same number of sub problems), the depth of recursion to be uniform across all branches of divide tree, or even for some aspects of the “divide” or “conquer” operations to be structurally constrained. Each such constraint provides useful information, which can be exploited within the implementation.

Wavefront computations are to be found at the core of a diverse set of applications, ranging from numerical solvers in particle physics to dynamic programming approaches in bioinformatics. From the application perspective, a multidimensional table is computed from initial boundary information and a simple stencil that defines each entry as a function of neighboring entries. Constraints on the form of the stencil allow the table to be generated with a “wavefront” of computations, flowing from the known entries to the unknown, with consequent scope for parallelism. A *wavefront* skeleton may require the programmer to describe the stencil and the operation performed within it, leaving the implementation to determine and schedule an appropriate level of parallelism. As with *divide-and-conquer*, specific *wavefront* skeleton APIs may impose further constraints on the form of these components.

Branch-and-bound is an algorithmic technique for searching optimization spaces, with built-in pruning heuristics, and scope for parallelization of the search. Efficient parallelization is difficult, since although results are ultimately deterministic, the success of pruning is highly sensitive to the order in which points in the space are examined. This makes it both promising and challenging to the skeleton designer. With respect to the API, a *branch-and-bound* skeleton can be characterized by small number of parameters, capturing operations for generating new points in the search space, bounding the value of such a point, comparing bounds, and determining whether a point corresponds to a solution.

## Skeleton-Based Systems

Past and ongoing research projects have embedded selections of the above skeletons into a range of programming frameworks, targeting a range of platforms. The P3L language [15] was a notable early example in which skeletons became first-class language constructs,

together with sequential “skeletons” for iteration and composition. Subsequent projects within the Pisa group have taken similar skeletons into object-oriented contexts, with a focus on distributed and Grid implementations. In contrast, Muesli [3] allows data-parallel skeletons to be composed and called from within a layer which itself composes task-parallel skeletons, all within a C++ template-based library. Several systems have taken a functional approach. Hermann’s HDC [12] focuses exclusively on a collection of divide-and-conquer skeletons within Haskell, and implemented on top of MPI, while the Eden skeleton library [14] and related work [11] have implemented skeletons on top of both implicitly and explicitly parallel functional languages. The COPS project [2] presents a layered interface in which expert programmers can also have access to the implementation of the provided “templates,” all embedded in Java with both threaded and distributed RMI-based implementations. The SkeTo project offers a BMF-based collection of data-parallel skeletons for lists, matrices, and trees, implemented in C with MPI. Domain-specific skeletons are represented within the Mallba project [1] (focusing on combinatorial search) and Skipper and QUAFF projects (image processing). Higher-Order Components (HOCs) [5], Enhance [19], and Aspara [6] extend the idea of skeletons toward the area of distributed computing and Grids. HOCs implement generic parallel and distributed processing patterns, together with the required middleware support and are offered to the user via a high-level service interface. Users only have to provide the application-specific pieces of their programs as parameters, while low-level implementation details such as transfer of data across the grid are handled by the HOC implementations. HOCs have become an optional extension of the popular Globus middleware for Grids.

Skeleton principles are also evident in a number of other emerging parallel programming tools. Most notably, the MapReduce paradigm (related to, but distinct from the similarly named BMF skeletons) represents a pattern common to many applications in Google’s infrastructure. Emphasis in the original implementation was placed on load balancing and fault-tolerance within an unreliable massively parallel computational resource, a task strongly facilitated by the structurally constraining nature of the skeleton. Thain’s Cloud Computing Abstractions [18] implement

a range of distributed patterns with applications in Biometrics and Genomics. As with MapReduce, these are trivial to implement sequentially, and relatively straightforward on a reliable, homogeneous parallel architecture. The strength of the approach becomes apparent when ported to less predictable (or reliable) targets, with no additional effort on the part of the programmer. Finally, skeletal approaches can also be discerned in MPI's collective operations [9], where `MPI_Reduce` and `MPI_Scan` are parameterized by operations as well as data, and Intel's Threading Building Blocks [17], which in particular includes a *pipeline* skeleton.

## Parallel Tools Platform

GREGORY R. WATSON

IBM, Yorktown Heights, NY, USA

## Synonyms

[PTP](#)

## Definition

The Parallel Tools Platform (PTP) is an integrated development environment (IDE) for developing parallel programs using the C, C++, Fortran, and Unified Parallel C (UPC) languages. PTP builds on the Eclipse platform

by adding features such as advanced help, static analysis, parallel debugging, remote projects, and remote launching and monitoring. It also provides a framework for integrating other non-Eclipse tools into the Eclipse platform. The Parallel Tools Platform is not restricted to any particular programming model, but most tools to date are designed to support coarse-grained parallelism.

## Discussion

### Challenges

The challenges facing a developer writing parallel programs largely fall into the following three areas:

**Coding:** The programmer must translate the mathematical model of a problem into an algorithm that is implemented using a particular programming language and parallel programming model. This process of translation involves a large degree of effort, since there is often a significant mismatch between the model and an implementation that fully exploits the available parallelism.

**Testing and debugging:** Once an application program has been created, its correctness and accuracy must be validated. This involves a cycle of comparing the program output to known values using a variety of input data sets in order to verify that the results are correct. Coding errors, logic errors, and nondeterministic behavior all have to be addressed during this process, typically by employing an interactive debugger that allows program state to be inspected at key points during execution.

**Performance optimization:** A correctly functioning program may still not optimally utilize the available hardware resources. A variety of tools are typically employed to examine program behavior in order to identify bottlenecks and other performance related issues. These tools usually collect relevant information about the program execution, either directly, or in an aggregated form, and provide a means of analyzing and interpreting the data in order to identify actions that can be taken to improve performance. This is important for many situations when the speed of execution is time critical, such as in weather applications.

These activities are made significantly more difficult when applications are being developed for architectures that employ concurrent execution (or parallelism)

in order to achieve extremely high levels of performance. Parallel programming introduces many additional complexities that impact on all aspects of the development process. The nature of these complexities depends on the particular programming model employed, but includes issues such as deciding how the algorithm or data is to be partitioned, the need to deal with *communication* in addition to computation, and the inherent nondeterminism introduced by concurrent execution.

### Productivity

The quest to maximize productivity has received a much greater emphasis in recent years, where productivity is defined as both the speed and ease at which a correctly functioning application can be *developed* combined with the level of *performance* achieved by fully exploiting the available parallelism. Improving productivity is therefore dependent on a wide range of factors. One approach for improving the application development process, and that has seen wide success across a range of computing disciplines, is the use of an integrated development environment (IDE).

An IDE combines a core set of tools into a single package that provides a consistent user interface across a variety of systems and architectures. Many IDEs also provide a plug-in capability so that the core set of tools can be extended as new tools are developed or extra functionality is required. IDEs tend to improve developer productivity because the required tools are always available regardless of the environment, and also because they are integrated together, tools can share data and other information in order to streamline the developer workflow. Scientific computing is one of the few areas that have largely shunned the use of IDEs. Recently, however, the benefits of using an IDE for developing scientific programs have become more apparent to the community. This is probably because the scope of the programming task for the new generation of supercomputers is looking increasingly daunting, combined with an influx of new developers who have already had exposure to, and understand the advantages of, IDEs.

### Productive Parallel Programming

The goal of the Parallel Tools Platform is to address the challenges facing developers of parallel programs in a

manner that leads to improved productivity. The strategy employed by PTP to achieve this is to combine the productivity enhancements inherent in an integrated development environment with a number of key tools that specifically target the parallel application developers' capacity to deliver correct applications that are optimized for their target platforms.

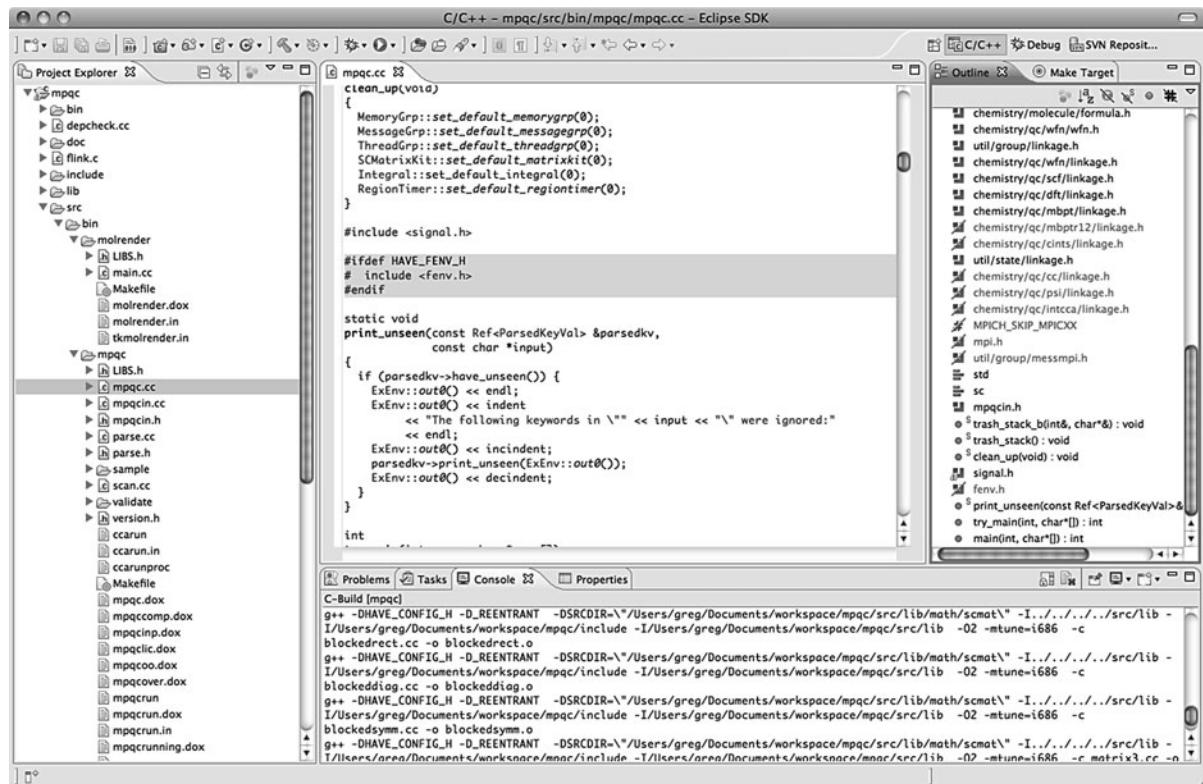

## C, C++, Fortran, and UPC Programming in Eclipse

The Eclipse platform is an open source, vendor neutral, portable, extensible platform for tool integration. It employs a plug-in architecture that allows tools to be integrated directly with the platform, and provides a range of core functionality that is suited to a variety of application development activities. This core functionality includes support for multi-developer projects, an integrated help system, multiple language support, project resource management, advanced editing features, incremental builds, and a range of other features. Eclipse functionality is extensible using the plug-in

mechanism, and there is a rich community of developers and a large number of both commercial and open source plug-ins available. The IDE is also highly portable, so it is available on a wide variety of hardware platforms.

The main interface provided by Eclipse is the *workbench* shown in Fig. 1. The workbench arranges *views* (text editors, project explorers, consoles, and other user interface components) into groupings known as *perspectives*. There is typically a perspective available for particular types of activities (coding, debugging, etc.) Eclipse also permits views to be shared between different perspectives. Along with a traditional menu bar, the workbench provides a toolbar containing a variety of actions that are associated with the currently active perspective. There is also a status bar and a range of other user interface decorations. Individual views may also have toolbars and menus that vary depending on context.

Eclipse provides a number of advanced coding and editing features that are common across any language

Parallel Tools Platform. Fig. 1 The eclipse workbench showing the C/C++ development perspective

that it supports. Many of these features rely on core functionality that is provided as standard in Eclipse, but is typically not available in other development environments. Such features include:

**Context-sensitive help:** In order to provide user assistance that is targeted to a particular context, this feature can deliver help documentation on demand (for example, when the user hits a key) or automatically display information such as prototype definitions or code snippets that pop up when the cursor is placed over a particular piece of text.

**Searching:** In addition to the usual string or pattern matching searches available in many editors, Eclipse allows searching on language elements (such as types, variables, functions etc.), the ability to limit searches to contexts (such as declarations, references, etc.), and to specify the scope of the search (such as a subset of the files in a project).

**Content assistance:** Reducing the amount of typing that a developer is required to do can be a powerful means of improving productivity. By inferring what the developer will type based on context and scope information, Eclipse's *code completion* makes suggestions using the first few letters of the language element currently being entered (e.g., a function name, variable name, etc.), via either manual or automatic activation. Frequently used snippets of code can also be saved as *code templates*. These templates can then be inserted into the text according to the current scope in the same manner as other code completions.

**Refactoring:** Improving code by changing its structure without changing behavior is a common, but error-prone, task in programming. By providing a range of common but sophisticated refactorings that can be automatically performed, Eclipse is able to prevent many of the errors that are introduced by manual changes. Typical refactorings include the ability to rename language elements, such as variables or functions, extract sections of code into a method or function, and automatically declare an interface, as well as many others.

**Wizards:** Another method of reducing the amount of repetitive work is to automate many of the common tasks that a developer must undertake. Eclipse provides a variety of wizards for activities such as creating new projects, classes, or files, importing projects into

Eclipse, exporting projects from Eclipse, and project conversion.

In addition to these powerful features, Eclipse provides support for application building, either using project supplied build scripts (for example Makefiles), or using an internal build system to track file dependencies and manage external tools such as compilers and linkers. The build support is also able to process errors and warnings generated by external tools, and map these back to messages displayed in the user interface, and markers that are inserted into the editor views.

The Eclipse C/C++ Development Tools (CDT) provide C, C++, and UPC language support, while the Parallel Tools Platform *Photran* feature adds Fortran support to Eclipse. Support for a wide range of other languages also available through a variety of Eclipse and third-party plug-ins.

## Code and Static Analysis for Parallel Programs

In addition to the advanced editing features that are a standard part of Eclipse, PTP adds a range of enhanced features that are specifically targeted toward parallel programming.

The first of these provides additional high-level help documentation for language elements used by common programming models, such as the message passing interface (MPI), the OpenMP Application Programming Interface, IBM's Low-level messaging Application Programming Interface (LAPI), and UPC. This documentation can be accessed using Eclipse's standard context sensitive help feature during coding, and will display prototype information along with a detailed description of the element.

Another feature provided by PTP is cataloging and navigation of MPI application programming interfaces and OpenMP pragma statements in a parallel program. This enables the developer to see the elements that have been used in the program at a single glance, and to navigate to the source code line that contains a selected element.

PTP also includes a Barrier Analysis tool that provides a more sophisticated analysis of MPI programs. This tool locates all calls to MPI *barrier* functions (synchronization points) in a program, and computes logical paths through the program to determine if it

is possible for a deadlock to occur. This can happen because all tasks must synchronize on an MPI barrier, but logic errors may enable one or more tasks to miss execution of the barrier. The advantage of this type of analysis is that it can be performed without the need to execute the program.

used to enter all the parameters necessary for a successful program launch. Run configurations are automatically saved so they can be easily used to relaunch an application during testing or debugging activities. PTP provides an extended run configuration for parallel programs that allows system-specific information about the parallel run to be supplied.

## Launching and Monitoring Parallel Programs

One hindrance to developer productivity is the seemingly basic ability to easily launch an application on a target parallel system. Most high-performance computing systems employ complex environments to monitor and control application launching. Many of these systems are also highly centralized assets that are tightly controlled, and they will typically restrict direct user access using a batch scheduler system. A developer's ability to interact with these systems will therefore be limited by their ability to deal with the additional complexity that this introduces. This is particularly the case where programs are being ported from one system to another, or where the developer has access to multiple systems and architectures.

PTP's approach to this issue is to provide a single, uniform interface that allows the developer to launch and monitor applications on a wide range of systems, without needing to understand the intricacies of each particular system. This is achieved through two features:

*Parallel runtime perspective:* This perspective provides a number of views that give the developer a snapshot of system activity at any particular time. Importantly, the views are independent of the type of system that is being targeted, so the developer does not need to be concerned with the underlying system details. The perspective is comprised of the *Resource Manager View*, which lists the systems that are available to the developer for launching and debugging applications, the *Machines View*, which shows the status of the system and its computing elements, and the *Jobs View*, which lists pending, running, and completed jobs on the system. A console is also available to display the program-generated output.  
*Parallel application run configuration:* This utilizes the standard Eclipse *Run Configuration* dialogs, which are

## Parallel Debugging

Developing complex parallel programs is a difficult task, and it is particularly challenging to ensure that they operate correctly. Finding errors in a parallel program is complicated because the many concurrent threads of execution make it difficult to observe the program operation in a deterministic manner. Managing large applications running on many processors may present a problem to the developer as well since the sheer volume of information may be overwhelming. The very act of debugging the program may also disturb its operation enough to make identifying the cause of an error impossible.

The PTP debugger attempts to address some of these issues. In particular, the debugger provides the basic functionality needed to step through the execution of the program examining variables and program state along the way, and an easy to use interface that enables the developer to quickly obtain pertinent information about an executing application. The debugger is invoked in the same manner as any other application launch, by clicking a button. Eclipse will automatically switch to the *Parallel Debug Perspective* when the debugging session is ready.

The Parallel Debugger Perspective comprises a number of views to facilitate the debugging task. The *Parallel Debug View* provides a high level view of the application, showing all the tasks currently executing. Debug operations on groups of processes, such as single stepping, can be performed using this view. The *Debug View* provides information about individual threads of execution, including a stack frame showing the current location. The *Variables View* shows the local variables from the currently selected stack frame in the Debug View, and can be used to inspect variables from a range of tasks. Other views are also available to inspect different aspects of the program state.

## Utilizing External Tools

Although PTP provides a range of tools for developing parallel programs, there are many other tools available that could be used to the developer's advantage if they were accessible from within the Eclipse environment. To facilitate this, PTP provides an external tools framework that allows non-Eclipse tools to be integrated in a manner that preserves the developer's workflow. The framework defines three main integration points during the application development workflow: *compile*, *execute*, and *analyze*. The *compile* integration point specifies how the normal build commands are to be modified during the build process to perform any tool-specific actions. An example of this might be to instrument the application to collect tracing or profiling information. The *execute* integration point specifies how the command used for launching of the application executable can be modified to perform any tool-specific actions. An example of this might be to pass the application executable to a tool that performs data collection during the execution. The *analyze* integration point allows an external tool to be launched once the program execution is complete, such as a tool to analyze performance data generated during execution.

In addition to these integration points, the external tools framework provides a *Feedback View* that enables externally generated information to be mapped back to source files and lines within the Eclipse environment. Eclipse can then display this information in the form of sortable tables, or by annotating the source code directly with markers or other forms of highlighting.

## Remote Development

To be an effective enhancement to conventional development processes, PTP needs to support a broad range of environments and systems. Many of these systems are scarce resources, so access is often tightly controlled from remote locations. Ideally, application developers for these systems need to be able to access these resources for testing, debugging, and performance optimization as if they were local. This enables the development process to be significantly streamlined, since the developer does not need to be concerned with copying executables and/or data files from system to system.

PTP addresses this requirement by adding a *Remote Development Tools (RDT)* feature. This enables a project

to be physically located on a remote machine, but allows access to the project and its source files for editing and building as if they were local. RDT takes care of all the activities necessary to make this process appear as transparent as possible to the developer. This can also be combined with PTP's ability to launch and debug programs on a remote target system, so the developer is able to take advantage of a fully remote enabled environment.

## The Parallel Tools Platform Today

PTP is an evolving project. Started in 2005, it has an active and growing developer community that spans a range of government, academic, and commercial organizations. The number of developers contributing to the project continues to increase, including the renowned National Center for Supercomputing Applications, which has recently begun to actively participate in PTP development.

Another promising development is the contribution of value-added components that enhance the functionality of PTP. Contributions have been made by the University of Oregon to add functionality to support their performance analysis tool, called Tuning and Analysis Utilities (TAU), the University of Utah to support their tool for formal verification of MPI programs, called In-situ Partial Order (ISP), and the University of Florida to support their tool for performance analysis of partitioned global-address-space (PGAS) programming models, called Parallel Performance Wizard (PPW).

PTP's main goal to date has been to demonstrate that Eclipse is a viable alternative for the development of scientific applications for large-scale computer systems. The list of features that are now available, and the growing developer and contributor community, demonstrate that this goal has been met.

## Future Directions

A comprehensive IDE for developing applications for a broad range of parallel platforms is a huge undertaking. PTP has begun by addressing many of the most pressing issues, such as programmer assistance, uniform access to remote systems, parallel debugging, and external tool integration. However there are still a large number of

issues that remain to be dealt with, and these will form the basis of much of the ongoing development over the coming years. Some of these issues include:

**Scalability:** Both application and systems sizes are increasing dramatically. The next generation of petascale systems will have hundreds of thousands of processing elements, and executions that exceed one million threads will be likely. The applications themselves are growing continuously, with millions of lines of code now becoming increasingly common. To continue to be effective, PTP will need to support such scales without unduly impacting developer productivity.

**Debugging paradigms:** Conventional debugging approaches have been successfully applied to parallel programs for some years. However, as program sizes increase, it is likely that these techniques will break down. One reason for this is that the sheer volume of information (for example, a million executing threads) is likely to overwhelm the developer. New debugging paradigms will need to be introduced that address this information overload, yet still allows the developer to accurately pinpoint the location of errors within a program.

**Static analysis tools:** Eclipse has an enormously powerful infrastructure available to the tool developer, and PTP has only really touched the surface of possible tools to exploit this. There is significant scope for much more powerful static analysis and refactoring tools that could have a very beneficial impact on developer productivity, and work is actively underway to enhance this capability.

**Remote development:** To be a truly effective remote development platform, PTP needs to support additional paradigms for developing applications remotely. In particular, the ability to work off-line and support for synchronizing with a remote repository are two areas that would enhance developer productivity significantly.

**Multi-core architectures:** The computing industry is beginning to see a real convergence between multi-core systems, which have already reached hundreds or even thousands of cores, and parallel architectures, which already employ multi-core programming elements. Many of the techniques used for parallel programming may also be beneficial for applications that wish to exploit multi-core technology. PTP is the logical home for exploring this convergence, and work is beginning to take place in this area.

## Bibliographic Notes and Further Reading

The idea of using computers to aid in the software engineering process extends back to the late 1960s; however, it was not until the 1980s that the market for computer-aided software engineering or CASE-based tools became significant (the term CASE was not coined until 1982). CASE covers a very broad area of software engineering practices, whereas integrated development environments, which are one class of CASE tools, tend to focus on the relatively small set of software engineering practices associated with the edit-build-test-debug development lifecycle.

There have been a number of papers describing the relationship between productivity and the use of IDEs, and the productivity and quality improvements that can be obtained by such environments is well documented [5, 6, 9, 10]. Their success is also reflected in the best practice use of IDEs for most commercial software development today.

Van De Vanter, et al. [11] have asserted that there are many reasons why existing developer tools are not going meet the productivity requirements of high performance computing: they are difficult to learn, they may not scale as machine sizes increase, they are different across different platforms, they are hard to develop or port to new platforms, they are often poorly supported, and they can be expensive.

The use of IDEs for parallel computing has also been explored before [1–4, 8], but all of these appear to have suffered from low levels of use, were academic research projects, or were too expensive to develop and maintain, and so have gradually died out. PTP is the first time that an open-source IDE has been tailored specifically for scientific and parallel computing [12].

The non-for-profit Eclipse Foundation was created in 2004 to oversee the stewardship of the open-source Eclipse platform. Since it was established, the Foundation membership has grown to exceed 150 organizations. Many of these companies use Eclipse as the core of a commercial product offering, after having abandoned their own proprietary IDE technology and switched to the Eclipse platform. Eclipse is widely used across many computing fields, and arguably has the largest number of users of any IDE in history. It is also now one of the largest open-source projects and there have been over two million downloads of the latest version alone [7].

## Parallelism Detection in Nested Loops, Optimal

ALAIN DARTE

École Normale Supérieure de Lyon, Lyon, France

### Synonyms

Detection of DOALL loops; Nested loops scheduling; Parallelization

### Definition

Loops are a fundamental control structure in imperative programming languages. Being able to analyze, transform, and optimize loops is a key feature for compilers to handle repetitive schemes with a complexity proportional to the program size and not to the number of operations it describes. This is true for the generation of optimized software as well as for the generation of hardware, for both sequential and parallel execution.

**Exploiting parallelism** is a difficult task that depends, among others, on the target architecture, on the structure of computations in the program, and on the way data are mapped, used, and communicated. In contrast, **detecting parallelism** that can be expressed as loops, i.e., transforming Fortran-like DO loops into DOALL loops (loops whose iterations are all independent) depends only on the dependences between computations in the program being analyzed. Intuitively, an algorithm is **optimal** for parallelism detection in loops, if it transforms the loops of a program so that each statement is surrounded, after transformation, by a maximal number of parallel (DOALL) loops. However, such a notion of optimality needs to be defined with care (see the discussion hereafter) to avoid inconsistent or inaccurate claims.

### Discussion

#### Optimal Parallelism Detection in Loops

How to define optimal parallelism detection in loops? An optimality criterion solely based on the *number of*

parallel loops – thus not on the number of iterations – has no meaning for loops with constant bounds as they can always be unrolled or strip-mined. For example, it is true that hyperplane scheduling can always be applied on  $n$  perfectly nested loops with constant bounds, resulting in a code with one outer sequential loop and  $(n - 1)$  parallel loops. However, it does not mean that it exhibits any parallelism as, for a purely sequential code, each parallel loop has then a single iteration. Similarly, an optimality criterion should not lead to inconsistencies due to the way loops are generated, e.g.,  $n$  nested loops with constant loop bounds can be fully unrolled leading to a code with no loop while applying loop tiling leads to  $2n$  loops.

One way to define **optimality** is **with respect to the execution time** of the parallelized code **on an ideal PRAM-like machine**, with an unlimited number of computation units, where any instruction takes a single unit of time. An algorithm for parallelism detection is then optimal if the corresponding code with DOALL loops has an optimal execution time for this ideal machine, which is the maximal length of a path in the dependence DAG (directed acyclic graph) obtained by fully unrolling the program. However, a full unroll of the code is too costly, often undesirable as it loses the loop structure, and sometimes impossible, e.g., when the loop bounds are parameterized. A more practical definition of optimality is to assume that each loop has a parameterized number of iterations, of order  $N$ , and to say that an algorithm is optimal if the execution time of the parallelized program on the ideal machine is  $O(N^d)$  where  $d$  is minimal. Optimality can then be proved by exhibiting a dependence path in the unroll program whose length is not  $O(N^{d-1})$ . A more accurate definition of optimality can be given by applying the same reasoning for each statement, considering that any other statement takes no time on the ideal machine, i.e., does not count in the length of a dependence path.

In general, algorithms for parallelism detection transform the code so that each statement is surrounded by the same number of loops before and after transformation. This is true, in particular, for algorithms based on unimodular transformations. In this case, one retrieves the intuitive notion of optimality which states that parallelism detection is optimal if each statement is surrounded, after transformation, by a maximal number of parallel loops. The only constraint that a

parallelism detection algorithm must respect is that the partial order of operations defined by the dependences in the program are preserved. How these dependences are computed and abstracted is not part of the algorithm, it is its input. In other words, the **optimality** of an algorithm can only be defined **with respect to the dependence abstraction** it uses. To show that it is optimal, one needs to exhibit a dependence path of the required length, not in the original program, but in its abstraction, i.e., a dependence path in an over-approximation of the actual dependence graph.

A more complete discussion on the definition of optimality for parallelism detection algorithms is provided in [10, 12, 13]. The rest of this essay, with large parts borrowed from [7], shows that it is possible to give, for each classic dependence abstraction (dependence level, uniform dependence vector, direction vector, dependence cone, dependence polyhedron), an algorithm which is optimal with respect to this abstraction. Moreover, this algorithm is a specialization of a more generic algorithm [13], inspired by the decomposition of Karp, Miller, and Winograd for checking the computability of a system of uniform recurrence equations [18]. Notice that the previous optimality criterion makes no distinction between an outer parallel loop and an inner parallel loop. If a parallel loop can always be pushed down, i.e., interchanged with inner loops, the converse is not true. However, detecting parallel loops that contain sequential loops and detecting permutable loops (the base for loop tiling) are two similar problems that can be achieved by variations of the algorithms mentioned hereafter. But optimality for these goals is more difficult to define. Here is a summary of the main optimality results:

*Dependence level* The algorithm of Kennedy and Allen [2] is optimal, which implies that loop distribution is sufficient to detect maximal parallelism for dependence levels.

*Uniform dependences* Hyperplane scheduling (as defined by Lamport [19]) is optimal, for perfectly nested loops, which implies that unimodular transformations with one outermost sequential loop is sufficient for uniform dependences.

*Direction vectors* An adaptation of the algorithm of Wolf and Lam [25] (which detects permutable loops) is optimal, which implies that unimodular

transformations (loop interchange, loop reversal, loop skewing) are sufficient for direction vectors.

*Dependence polyhedron* The algorithm of Darte and Vivien [13] is optimal, which implies that unimodular transformations, combined with loop distribution and loop shifting, are sufficient for dependence polyhedra.

*Affine dependences* The algorithm of Feautrier [16] is optimal among all affine transformations, but these transformations are not sufficient to detect maximal parallelism for affine dependences.

This essay is organized as follows. The first section recalls the model of system of uniform recurrence equations (SURE) and the link between the computability and scheduling problems of such a system. The second section shows how, thanks to a uniformization of dependence distance abstractions, the detection of parallelism in nested DO loops can be transferred to the model of SURE so as to derive optimality results. The last section illustrates yet another connection: the multi-dimensional scheduling techniques used to analyze a SURE and to detect parallelism in nested DO loops can also be used to prove the termination of some WHILE loops.

## The Organization of Computations in a System of Uniform Recurrence Equations

In 1967, Karp, Miller, and Winograd introduced a model (system of uniform recurrence equations or SURE) to describe a set of regular computations as mathematical equations [18]. The goal of their paper, entitled “The Organization of Computations for Uniform Recurrence Equations,” was to study the parallelism that such a description contains implicitly, motivated by “the recent [at this time] development of computers capable of performing many operations concurrently,” in particular for regular applications such as solving partial differential equations by finite-difference methods. This work was purely theoretical: the paper does not even have a conclusion section, which would possibly mention some applications. Nevertheless, it turned out to be very prophetic, when considering the large number of developments for which it served as foundations. For example, it has some connections with accessibility problems in vector addition systems and Petri nets. The developments of systolic arrays and of high-level synthesis from

systems of recurrence equations are directly inspired from it. Most scheduling methods developed for automatically parallelizing DO loops are based on it, directly or indirectly. As a by-product, the theory of unimodular transformations and the different parallelism detection algorithms [2, 13, 16, 19, 25] can be seen as extensions and/or specializations of the technique of Karp, Miller, and Winograd, adapted to specific dependence abstractions and objectives. Last but not least, it has also some connections with techniques to prove the termination of imperative programs, either with the insertion of counters or by the derivation of affine ranking functions [1, 5, 17, 22].

### Definition of a SURE

A SURE is a finite set of  $m$  equations of the form

$$a_i(p) = f_i(a_{i_1}(p - d_{i_1,i}), \dots, a_{i_m}(p - d_{i_m,i})) \quad (1)$$

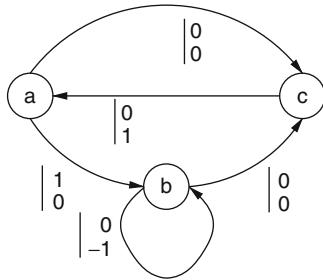

where  $p \in \mathbb{Z}^n$  is called an **iteration vector**,  $d_{i,j} \in \mathbb{Z}^n$  is called a **dependence vector**,  $f_i$  is a strict function with  $m_i$  arguments whose properties are not considered (only the structure of computations is analyzed, not what they do). The value  $a_i(p)$  has to be computed for all integral points  $p$  in a subset  $\mathcal{P}$  of  $\mathbb{Z}^n$ , called the **evaluation region**. Values are supposed to be given at  $p - d_{i,j} \notin \mathcal{P}$  (input variables) wherever required for the evaluation at  $p \in \mathcal{P}$ .

The value  $a_i(p)$  is said to depend on  $a_j(p - d_{j,i})$ , for  $1 \leq j \leq i_m$ . These dependence relations define a graph  $\Gamma$ , called the **expanded dependence graph** (EDG). Its set of vertices is  $\{1, \dots, m\} \times \mathcal{P}$  and there is an edge from  $(j, q)$  to  $(i, p)$  if  $a_i(p)$  depends on  $a_j(q)$ . A SURE can be equivalently defined by a weighted-directed multigraph  $G = (V, E, w)$ , called the **reduced dependence graph** (RDG), as follows:

- For each  $a_i$ , there is a vertex  $v_i$  in  $V$ .
- If  $a_i(p)$  depends on  $a_j(p - d_{j,i})$ ,  $G$  has an edge  $e = (v_j, v_i)$  in  $E$  from  $v_j$  to  $v_i$  with **weight**  $w(e) = d_{j,i}$ .

A SURE is then defined by an RDG  $G = (V, E, w)$  and an evaluation region  $\mathcal{P}$ . For example, the following system, to be evaluated for  $\mathcal{P} = \{(i, j) \mid 1 \leq i, j \leq N\}$ ,

$$\begin{cases} a(i, j) = c(i, j - 1) \\ b(i, j) = a(i - 1, j) + b(i, j + 1) \\ c(i, j) = a(i, j) + b(i, j) \end{cases}$$

**Parallelism Detection in Nested Loops, Optimal.** Fig. 1

Corresponding RDG for the SURE example

defines a SURE with three equations on a square of size  $N$ , corresponding to the RDG of Fig. 1.

### Computability: Definition and Properties

The definition of a SURE, either by Equation (1), or by the reduced dependence graph, is implicit: to compute a value  $a_i(p)$ , one must first compute all values that appear in the right-hand side of the definition of  $a_i(p)$ . These values are computed the same way, by evaluating the right-hand side of their definition, and so on. Thus, two questions arise:

*Computability problem* Does this recursive process end, i.e., are all values  $a_i(p)$  computable?

*Scheduling problem* If the system is computable, how to organize the computations?

A **schedule** is a function  $\theta$  from the vertices of the EDG  $\Gamma$  to  $\mathbb{N}$  such that  $\theta(j, q) < \theta(i, p)$  whenever  $(i, q)$  depends on  $(j, q)$ . A SURE is **computable** (or explicitly defined) if there exists a schedule. It is not computable if there exists a vertex  $(i, p)$  in the EDG  $\Gamma$  such that the length of a dependence path leading to it is unbounded. Then, either  $a_i(p)$  depends on itself (possibly through other computations) or it needs to wait “infinite” time before the complete evaluation of its right-hand side. In this case, because the in-degree in the EDG  $\Gamma$  is finite, there is an infinite path leading to  $(i, p)$ .

To make the analysis simpler, the following discussion focuses on (parametric) bounded evaluation regions. An RDG  $G$  is said computable if all SUREs defined from  $G$  on bounded evaluation regions are computable.

**Theorem 1** An RDG is computable if and only if (iff) it has no cycle of zero weight.

More precisely, the fact that  $G$  has no cycle of zero weight is a sufficient condition for a SURE defined from  $G$  to be computable, whatever the bounded evaluation region. However, it is a necessary condition only if the evaluation region is “sufficiently large” (see [9, 18]).

### The case of a single equation

A uniform recurrence equation (URE) is defined by an evaluation region  $\mathcal{P} \subseteq \mathbb{Z}^n$  and an RDG  $G$  with a single vertex, i.e., by a single equation  $a(p) = f(a(p - d_1), \dots, a(p - d_m))$ . Let  $D$  be the  $n \times m$  matrix whose columns are the dependence vectors. Consider the following sets:

$$T(D) = \{t \in \mathbb{Z}^m \mid tD \geq 1\}$$

$$Q(D) = \{q \in \mathbb{Z}^m \mid q \geq 0, q \neq 0, Dq = 0\}$$

and  $T_{\mathbb{Q}}(D)$  and  $Q_{\mathbb{Q}}(D)$  their rational relaxations.  $G$  is computable iff it has no cycle of zero weight, i.e.,  $Q(D)$  is empty. Farkas Lemma [23] shows the following result:

**Theorem 2**  $Q(D) = \emptyset \Leftrightarrow Q_{\mathbb{Q}}(D) = \emptyset \Leftrightarrow T_{\mathbb{Q}}(D) \neq \emptyset \Leftrightarrow T(D) \neq \emptyset$ .

This property shows that checking if an RDG is computable can be done in polynomial time by checking that  $T_{\mathbb{Q}}(D)$  is non empty, i.e., that the cone generated by the dependence vectors is strictly included in a half-space. Each  $t \in T(D)$  corresponds to a **separating hyperplane** and a schedule  $\theta_t$  defined by  $\theta_t(p) = t.p + K$  where  $t.p$  is the vector product and  $K = -\min_{p \in \mathcal{P}} t.p$ . Indeed, if  $q$  depends on  $p$ ,  $q = p + d_i$ , then  $\theta_t(q) = t.q + K = t.p + t.d_i + K > \theta_t(p)$ . Thus, an RDG is computable iff there is an **affine schedule**, i.e., a way of computing the URE by a regular schedule, whose definition does not depend on the evaluation region  $\mathcal{P}$ .

Given a vector  $t \in T_{\mathbb{Q}}(D)$ , the **latency** of the schedule  $\theta_t$ , i.e., the total number of sequential steps it induces, can be rounded to  $L(\theta_t) = \max_{p, q \in \mathcal{P}} t.(p - q)$ . Finding the “fastest” linear schedule means solving a min-max optimization problem  $L_{\min} = \min\{L(\theta_t) \mid t \in T_{\mathbb{Q}}(D)\}$ . If  $\mathcal{P}$  is a polytope  $\{p \mid Ap \leq b\}$ , then  $L(\theta_t) = \max\{t.(p - q) \mid Ap \leq b, Aq \leq b\}$ . The duality theorem of linear programming [23] leads to:

$$\begin{aligned} L(\theta_t) &= \max\{t.(p - q) \mid Ap \leq b, Aq \leq b\} \\ &= \min\{(t_1 + t_2).b \mid t_1, t_2 \geq 0, t_1 A = t, t_2 A = -t\} \\ L_{\min} &= \min\{(t_1 + t_2).b \mid t_1, t_2 \geq 0, t_1 A = -t_2 A = t, tD \geq 1\} \end{aligned}$$

Solving the previous linear program gives a way to produce a vector  $t$  in  $T_{\mathbb{Q}}(D)$  from which a fast schedule can be built. Its performance can be characterized as follows:

**Theorem 3** *If the evaluation region  $\mathcal{P}$  is sufficiently large, the difference between  $L_{\min}$  (the latency of the fastest affine schedule) and the longest dependence path in  $\Gamma$  (the latency of the fastest schedule) is bounded by a constant that does not depend on the domain size.*

Theorems 2 and 3 together show that only two cases can occur for a URE defined on bounded regions: either the URE is not computable as soon as the evaluation region is large enough, or there is an affine schedule. In the latter case, for a URE defined on polyhedra  $\{Ap \leq Nb\}$ , the length of the longest path is  $kN + O(1)$  for some positive rational  $k$  and an affine schedule with latency  $kN + O(1)$  can be derived. See more details in [9].

#### The case of several equations

For one equation, a vector  $q \in Q(D)$  can be interpreted directly as a cycle in the RDG since all edges are connected to the same vertex: they can be used in any order. For several equations, it is more difficult to express a cycle by linear constraints and to ensure that edges are traversed in a specific order. To detect cycles of zero weight in  $G = (V, E, w)$ , the key is to consider  $G'$  the subgraph of zero-weight multicycles (union of cycles), i.e., the subgraph of  $G$  generated by the edges that belong to a union of cycles whose total weight is zero. The following theorem identifies the links between  $G$  and  $G'$ .

**Theorem 4** (a)  $G$  contains a zero-weight cycle iff its subgraph  $G'$  does. (b)  $G$  contains a zero-weight cycle iff one of its strongly connected components (SCCs) does. (c) If  $G'$  is strongly connected,  $G$  has a zero-weight cycle.

These properties give the hint for solving the problem with a recursive search. To detect a zero-weight cycle in  $G$ , it is sufficient to consider each SCC of  $G'$ . If  $G'$  is empty,  $G$  has no zero-weight multicycle, thus no zero-weight cycle. If  $G'$  has more than one SCC, then  $G$  has a zero-weight multicycle if at least one SCC has a zero-weight cycle. It remains to solve the terminating case, i.e., when  $G'$  is strongly connected, in which case  $G$  has a zero-weight cycle. Finally, this leads to the decomposition of Karp, Miller, and Winograd.

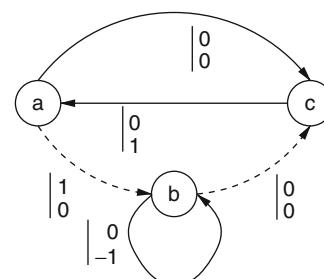

(Decomposition of Karp, Miller, and Winograd)  
Boolean KMW( $G$ ):

- Build the subgraph  $G'$  of zero-weight multicycles in  $G$ .
- Compute  $G'_1, \dots, G'_s$ , the  $s$  SCCs of  $G'$ .
  - If  $s = 0$ ,  $G'$  is empty, return TRUE.
  - If  $s = 1$ ,  $G'$  is strongly connected, return FALSE.
  - Otherwise return  $\wedge_i \text{KMW}(G'_i)$  (logical AND).

Then,  $G$  is computable iff  $\text{KMW}(G)$  returns TRUE.

Consider the SURE whose RDG is depicted in Fig. 1. The two edges  $(a, b)$  and  $(b, c)$  cannot belong to a zero-weight multicycle, since the weight of any multicycle that traverses them has a positive first component. The self-dependence on  $b$  and the cycle formed by the edges  $(a, c)$  and  $(c, a)$  define a zero-weight multicycle, thus  $G'$  is the subgraph of  $G$  obtained by deleting the two edges from  $(a, b)$  and  $(b, c)$  (see Fig. 2). It has two SCCs. For both, the subgraph of zero-weight multicycle is empty, thus the decomposition stops: both SCCs are computable, thus  $G'$  is computable, and finally  $G$  is computable too.

Let us now focus on the construction of the subgraph  $G'$ . The **cycle vector** associated to a cycle in  $G$  is a vector  $q$ , with  $|E|$  components, such that  $q_e$  is the number of times the edge  $e$  is traversed in the cycle. The **connection matrix** is a  $|V| \times |E|$  matrix  $C$  such that  $C_{v,e} = 1$  (resp.  $C_{v,e} = -1$ ) if the edge  $e$  leaves (resp. enters) vertex  $v$ , and  $C_{v,e} = 0$  otherwise. A vector  $q \geq 0$  such that  $Cq = 0$  represents a union of cycles, which is a cycle if the subgraph of  $G$  generated by the edges  $e$  such that  $q_e > 0$  is connected. Let  $W$  be the  $n \times |E|$  weight

Parallelism Detection in Nested Loops, Optimal. Fig. 2

As dotted lines, edges that do not belong to  $G'$

**matrix** whose columns are the edges weights of  $G$ . Then, the edges of  $G'$  are exactly the edges  $e$  for which  $v_e = 0$  in any optimal solution of the following linear program:

$$\min \left\{ \sum_e v_e \mid q \geq 0, v \geq 0, q + v \geq 1, Cq = 0, Wq = 0 \right\}$$

Now, to better understand what is behind this linear program, let us interpret its dual. After algebraic manipulations, it can be written as:

$$\max \left\{ \sum_e z_e \mid 0 \leq z \leq 1, t \cdot w(e) + \rho_{y_e} - \rho_{x_e} \geq z_e, \forall e \in E \right\}$$

where  $e$  goes from  $x_e$  to  $y_e$ . The complementary slackness theorem [23] shows interesting properties in the dual.

**Theorem 5** *For any optimal solution  $(z, t, \rho)$  of the dual:*

$$e \in G' \Leftrightarrow t \cdot w(e) + \rho_{y_e} - \rho_{x_e} = 0 \quad (2)$$

$$e \notin G' \Leftrightarrow t \cdot w(e) + \rho_{y_e} - \rho_{x_e} \geq 1 \quad (3)$$

**Theorem 5** shows how the constraints  $t \cdot D \geq 1$  obtained for linear scheduling in the case of a URE (remember the set  $T(D)$  in Theorem 2) can be generalized to the case of a SURE. For a URE,  $t$  was interpreted as a vector normal to a hyperplane that separates the space into two half-spaces, all dependence vectors being strictly in the same half-space. Here, the vector  $t$  defines (up to a translation given by the constants  $\rho$ ) a hyperplane which is a **strictly separating hyperplane** for the edges not in  $G'$ , see Inequality (3), and a **weakly separating hyperplane** for the edges in  $G'$ , see Equality (2). Furthermore, for each subgraph  $G$  that appears in the decomposition,  $t$  defines a hyperplane that is the “most often strict”: the number of edges, for which such a hyperplane is strict, is maximal (since  $\sum_e z_e$  is maximal). See more details in [11].

Define the **depth**  $d$  of  $G = (V, E, w)$  as the maximal number of recursive calls generated by the initial call  $KMW(G)$  (counting the first one), except if  $G$  is acyclic, in which case  $d = 0$ . The depth  $d$  is a measure of the parallelism described by  $G$ : it is related both to the length of the longest paths (intrinsic sequentiality) and to the minimal latency of particular schedules, called

shifted-linear **multi-dimensional schedules**, i.e., mappings from  $V \times \mathbb{Z}^n$  to  $\mathbb{Z}^d$ . The execution order is the lexicographic order  $\leq_{lex}$  on vectors of dimension  $d$ : the components of the schedule can be interpreted as hours, minutes, seconds, ..., described by nested loops starting from the outermost one.

For each  $v \in V$ , involved in  $d_v$  recursive calls, a sequence of vectors  $t_v^1, \dots, t_v^{d_v}$  and of constants  $\rho_v^1, \dots, \rho_v^{d_v}$  can be built by considering the dual program during the decomposition algorithm. The two sequences can be completed with zeros, if needed, to get sequences of length  $d$ .

**Theorem 6** *Let  $G = (V, E, w)$  be a computable, strongly connected RDG of depth  $d$ . If the evaluation region is a  $n$ -dimensional cube of size  $N$ , the mapping defined by  $\theta(v, p) = (t_v^1 \cdot p + \rho_v^1, \dots, t_v^{d_v} \cdot p + \rho_v^{d_v}, 0, \dots, 0)$  defines a multi-dimensional schedule with latency  $O(N^d)$ . Furthermore, the associated EDG  $\Gamma$  contains a dependence path of length  $\Omega(N^d)$ , whose projection onto  $G$  visits  $\Omega(N^{d_v})$  times each vertex  $v \in V$ .*

A dependence path of length  $\Omega(N^d)$  can be built in  $\Gamma$ , following the hierarchical structure of  $G'$ , by traversing order  $N$  times a cycle that visits all vertices of  $G$  and by plugging, during this traversal, each SCC of  $G'$  order of  $N$  times, in a recursive manner. Consider the example of Fig. 2 again. Go from  $a(1, 1)$  to  $a(1, N-1)$ , following  $(N-1)$  times the cycle between  $a$  and  $c$ . Then, go to  $b(2, N-1)$  following the edge  $(a, b)$ , and to  $b(2, 1)$  following  $(N-1)$  times the self-loop on  $b$ . Finally, go to  $c(2, 1)$  and  $a(2, 2)$  following the edges  $(b, c)$  and  $(c, a)$  once. This makes a path of length  $2(N-1)+1+(N-1)+2 = 3N$ . This pattern can be repeated  $(N-1)$  more times, leading to  $a(N, N)$ , for a path of length  $3N^2$ .

In terms of scheduling, solving the constraints of Theorem 5 shows that  $a(i, j)$  can be computed at time step  $(2i+1, 2j)$ ,  $b(i, j)$  at step  $(2i, -j)$ , and  $c(i, j)$  at step  $(2i+1, 2j+1)$ . Indeed, for the first level of the decomposition, the constraints amount to look for a vector  $t$  such that  $t \cdot (0, 1) = t \cdot (0, -1) = 0$  (for the two cycles of  $G'$ ) and  $t \cdot (1, 0) \geq 2$  (for the cycle  $(a, b, c, a)$  with two edges not in  $G'$ ), which leads, e.g., to  $t = (2, 0)$  and suitable constants  $\rho_a, \rho_b$ , and  $\rho_c$ . The second level leads to  $t = (0, 2)$  for  $a$  and  $c$ , and  $t = (0, -1)$  for  $b$ . This explicit schedule

corresponds to the code below. It is purely sequential (2-dimensional schedule, for a dependence of length order  $N^2$ , in a square of size  $N$ ). In general, if a statement is surrounded in the initial code by  $n$  loops and scheduled with a  $d$ -dimensional schedule, it will be surrounded by  $d$  sequential loops and  $(n - d)$  parallel loops in the resulting code.

```

DO i=1, N
 DO j=N, 1, -1
 b(i,j) = a(i-1,j) + b(i,j+1)
 ENDDO
 DO j=1, N
 a(i,j) = c(i,j-1)
 c(i,j) = a(i,j) + b(i,j)
 ENDDO
ENDDO

```

## Loop Transformations and Automatic Loop Parallelization

Linear programming methods, optimizations on polytopes, manipulations of integral matrices, are now commonly used in the field of automatic parallelization and program transformations, in particular for imperative codes with DO loops. The key is to represent, analyze, and transform loops without unrolling them, in an abstract way, thanks to polyhedral representations and transformations. This way, compilation methods can be developed with a complexity that depends on the (textual) size of the program and not on the number of operations it describes. DO loops are indeed, as SUREs, a condensed way for representing repetitive computations. Such an approach started in 1974 when Lamport introduced the hyperplane method [19] to parallelize perfectly nested loops. Similar techniques were applied for the automatic synthesis of systolic arrays from uniform recurrence equations. In 1988, Feautrier introduced PIP [14], a software tool for parametric (integer) linear programming, and he demonstrated its interest for dependence analysis [15], loop parallelization [16], code generation [4], etc. This work initiated many more developments based on polytopes for detecting dependences, scheduling computations,

mapping data and communications, generating code for computations and communications, etc.

The following presentation, borrowed from [10], recalls the link between the decomposition of Karp, Miller, and Winograd, and different algorithms for transforming (sequential) DO loops into DOALL loops, i.e., loops whose iterations can be computed in any order, in particular in parallel. These algorithms perform high-level source-to-source transformations, in the same way a user inserts parallelization directives in OpenMP. Exploiting the parallelism is another story, which requires data and communication optimizations, depending on the target architecture.

### Representation of DO Loops

Loop transformations apply to codes defined by nested loops, for which the control structure is simple enough to be captured with polytopes. Each loop has its own loop counter that takes, if the loop step is 1, any integer value from the lower to the upper bound, which are defined by affine expressions of the surrounding loop counters. The iterations of  $n$  perfectly nested loops can thus be represented by an **iteration domain**, set of all integer vectors in a polyhedron. When running the program, each statement  $S$  is executed for each value of the surrounding loop counters, represented by an **iteration vector**  $p$ . Such an execution is an **operation**, denoted  $S(p)$ .

Thus, as for SUREs, nested loops have an evaluation region, the iteration domain. However, unlike SUREs, the schedule is explicit and defines the semantics, while the dependences are implicit and must be pre-computed. Indeed, because each inner loop is scanned for each iteration of an outer loop, the operations  $S(p)$  are carried out in the predefined **sequential order**  $<_{seq}$ , given by the lexicographic order defined on iteration vectors plus the textual order:

$$S(p) <_{seq} T(q) \Leftrightarrow (\tilde{p} <_{lex} \tilde{q}) \text{ or } (\tilde{p} = \tilde{q} \text{ and } S <_{text} T)$$

where  $\tilde{p}$  and  $\tilde{q}$  are the vectors  $p$  and  $q$  restricted to the loop counters that surround both  $S$  and  $T$ . There is a **data dependence** from  $S(p)$  to  $T(q)$  (denoted  $S(p) \Rightarrow T(q)$ ) if both operations access the same memory location, at least one access is a write, and  $S(p) <_{seq} T(q)$ . As for SUREs, the relation  $\Rightarrow$  defines a partial order between operations, i.e., an **expanded**

**dependence graph** (EDG). To keep the program semantics, code transformations should preserve this partial order. In general, instead of representing all pairs  $(S(p), T(q))$  for which  $S(p) \Rightarrow T(q)$ , the dependences are approximated by a **reduced dependence graph** (RDG), with one vertex per statement, where the weight  $w(e)$  of each edge  $e$  describes a set  $D_e$  of **dependence distances**  $\tilde{q} - \tilde{p}$ , in a conservative way: if  $S(p) \Rightarrow T(q)$  in the EDG, then there exists  $e = (S, T)$  in the RDG such that  $\tilde{q} - \tilde{p} \in D_e$ . In other words, the RDG describes a superset of the EDG called **apparent dependence graph** (ADG). All loop transformations algorithms have to respect the dependences in the ADG. Thus, their properties, in particular their optimality for detecting parallelism, need to be analyzed with respect to the ADG (and not the EDG, which is not provided), i.e., with respect to the dependence abstraction used.

### Approximations of Distances: Dependence Level and Direction Vector

The simplest way to represent a dependence distance is to use the abstraction by dependence level. A dependence between  $S(p)$  and  $T(q)$  is **loop-independent** if it occurs for a fixed iteration of each loop surrounding both  $S$  and  $T$  (i.e.,  $\tilde{q} = \tilde{p}$ ). Otherwise, it is **loop-carried** and its **level** is the index of the first nonzero component of  $\tilde{q} - \tilde{p}$ . Then, all iterations of a loop  $L$  at depth  $k$  can be executed in any order, i.e.,  $L$  is parallel, if there is no dependence at level  $k$  in the RDG that corresponds to the code surrounded by  $L$ .

The main idea of Allen and Kennedy's parallelization algorithm [2] is to use loop distribution to reduce the number of statements within a loop, and thus the number of potential dependences. Briefly speaking, loop distribution separates, in different loops, the statements of the different SCCs of the RDG. Then, each SCC is treated separately and, according to the dependence levels, the outermost loop is marked as a DOALL or DOSEQ loop. Inner loops are treated the same way, recursively. Here is a sketch of the algorithm (different but equivalent to the original formulation). The initial call is  $AK(G, 1)$ , where  $G$  is the RDG with dependence levels.

A careful analysis [12] reveals that this algorithm is nothing but the decomposition of Karp, Miller, and Winograd, applied to an RDG with levels, except that parallel loops are generated at the outermost level,

---

(Algorithm of Allen and Kennedy)

$AK(G, k)$ :

- Remove from  $G$  all edges of level  $< k$ .
  - Compute the SCCs of  $G$ .
  - For each SCC  $C$  in topological order, do:
    - If  $C$  is reduced to a single statement  $S$ , with no edge, generate DOALL loops in all remaining dimensions, and generate code for  $S$ .
    - Else
      - Let  $l$  be the minimal dependence level in  $C$ .
      - Generate DOALL loops from level  $k$  to level  $l - 1$ , and a DOSEQ loop for level  $l$ .
      - Call  $AK(C, l + 1)$ .
- 

when possible. Indeed, if schedules are searched as in [Theorem 5](#), considering that  $w(e)$  corresponds to any distance vector represented by the dependence level of the edge  $e$ , then the only valid schedules are the elementary schedules that correspond to loop distribution/parallelization. This can also be understood with the uniformization principle mentioned in the next section. Moreover, using a proof technique similar to the one used in [Theorem 6](#), one can even prove the following optimality result.

**Theorem 7** *Allen and Kennedy's algorithm is optimal for parallelism extraction in an RDG labeled with dependence levels.*

Here, the optimality means the following. Let  $d_S$  be the number of DOSEQ loops generated around a statement  $S$ . Assume that each loop has order  $N$  iterations. Then, it is possible to build, in the ADG corresponding to the RDG, a dependence path that visits  $\Omega(N^{d_S})$  times the statement  $S$ . It is even possible to build a code, with the same RDG, whose EDG contains such a path. In other words, without any other information, there is no way to extract more parallelism.

Another popular dependence abstraction is the **direction vector** whose components belong to  $\mathbb{Z} \cup \{*, +, -\} \cup (\mathbb{Z} \times \{+, -\})$ . Its  $i$ th component is an approximation of the  $i$ th components of all possible distance vectors: it is equal to  $z+$  (resp.  $z-$ ) if all  $i$ th components are at least (resp. at most)  $z \in \mathbb{Z}$ . It is equal to  $*$  if the  $i$ th component may take any value and to  $z \in \mathbb{Z}$  if it takes the unique value  $z$ . The notation  $+$  (resp.  $-$ ) is a shortcut for  $1+$  (resp.  $(-1)-$ ). A dependence of level  $k$  corresponds

to a direction vector  $(0, \dots, 0, +, *, \dots, *)$  where  $+$  is the  $k$ -th component. Unlike the dependence level, the direction vector gives information on all dimensions of the distance vectors. But, it is still not powerful enough to express relations between different components.

When loops are perfectly nested and direction vectors are constant, loops are called **uniform**. Since dependences are directed according to the sequential order, the direction vector is always lexicopositive, its first nonzero component is positive, and [Theorem 2](#) applies: there is a linear schedule, and the code can always be rewritten with one outer sequential loop (which carries all dependences) surrounding parallel loops. Lamport's **hyperplane method** [19] is just a different way to build a linear schedule, without requiring linear programming. To reduce the number of sequential steps, [Theorem 3](#) can be applied too. Variants in which not all dependences are carried by the outermost loop lead, among others, to more subtle NP-complete retiming problems (see [8]).

Finally, a more powerful abstraction of dependence distances is to represent them by a **dependence polyhedron**, defined by a set of vertices, a set of rays, and a set of lines. A direction vector is a particular polyhedral representation. For example, the direction vector  $(2+, *, (-1)-, 3)$  defines the polyhedron with one vertex  $(2, 0, -1, 3)$ , two rays  $(1, 0, 0, 0)$  and  $(0, 0, -1, 0)$ , and one line  $(0, 1, 0, 0)$ . Thanks to a uniformization principle, an RDG with dependence polyhedra can be reinterpreted in terms of SUREs as recalled in the next section.

## Uniformization Principle: From Dependence Polyhedra to SUREs

Consider the following code example:

```
DO i=1, N
 DO j=1, N
 a(i,j) = a(i,j-1) + a(j,i)
 ENDDO
ENDDO
```

It has three dependences: a uniform flow dependence of distance  $(0, 1)$  from  $S(i, j)$  to  $S(i, j + 1)$ , a flow dependence from  $S(i, j)$  to  $S(j, i)$  if  $i < j$ , and an anti-dependence from  $S(j, i)$  to  $S(i, j)$  if  $j < i$ . The latter two dependences correspond to the same dependence

distances and can be combined. The uniform dependence has level 2 and the combined dependence has level 1, thus the algorithm of Allen and Kennedy cannot find any parallelism. The corresponding direction vectors are equal to  $(0, 1)$  and  $(+, -)$ . In the second dimension, the “ $1$ ” and the “ $-$ ” are incompatible and prevent the detection of parallelism. However, there is a linear schedule  $\theta(i, j) = 2i + j$ , which leads to a transformed code with one parallel loop:

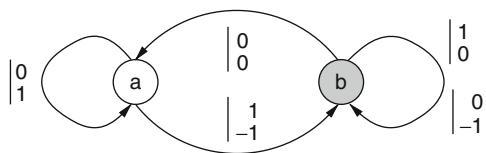

```
DO j = 3, 3N
 DOALL i=max(1, lceil (j-N)/2 rceil), min(N, lceil (j-1)/2 rceil)
 a(i,j-2i) = a(j-2i,i) + a(i,j-2i-1)
 ENDDOALL
ENDDO
```

To find this program transformation, one can notice that the set of distance vectors  $\{(j - i, i - j) \mid 1 \leq j - i \leq N - 1\}$  can be (over)-approximated by  $\mathcal{D} = \{(1, -1) + \lambda(1, -1) \mid \lambda \geq 0\}$ , i.e., a polyhedron with one vertex  $v = (1, -1)$  and one ray  $r = (1, -1)$ . Now, as for [Theorem 2](#), consider  $t$  such that  $t.d \geq 1$  for any dependence vector  $d$ . Thus,  $t.(0, 1) \geq 1$  and  $t.d \geq 1$  for all  $d \in \mathcal{D}$ . The latter inequality is equal to  $t.(1, -1) + \lambda t.(1, -1) \geq 1$  with  $\lambda \geq 0$ , which is equivalent to  $t.(1, -1) \geq 1$  and  $t.(1, -1) \geq 0$ , i.e.,  $t.v \geq 1$  and  $t.r \geq 0$ . Therefore, a valid linear schedule is defined by a vector  $t$  that satisfies the three inequalities  $t.u \geq 1$ ,  $t.v \geq 1$ ,  $t.r \geq 0$ , which leads, as desired, to  $t = (2, 1)$  and  $\theta(i, j) = 2i + j$ .

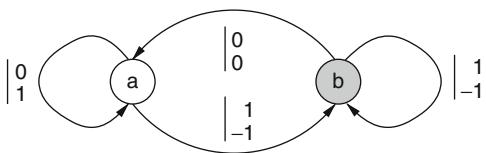

What is important here is the “uniformization” principle, which transforms an inequality on  $\mathcal{D}$  into uniform inequalities on  $v$  and  $r$ . In terms of dependence path, this amounts to consider an edge  $e$ , labeled by the distance vector  $p = v + \lambda r$ , as a path that uses once the “uniform” vector  $v$  and  $\lambda$  times the “uniform” vector  $r$ . Now, the dependence vectors are not necessarily lexicopositive anymore (e.g., a ray can be equal to  $(0, -1)$ ). Thus, the uniformized dependence graph looks more like the RDG of a SURE than the RDG of a uniform loop nest. However, the constraint imposed on a ray  $r$  is weaker, it is  $t.r \geq 0$  instead of  $t.r \geq 1$ , and  $t.l = 0$  for a line  $l$ . This freedom must be taken into account in the parallelization algorithm. This leads to the algorithm of Darte and Vivien, devoted to an RDG with dependence polyhedra [13]. The technique is simple, it consists in uniformizing the dependences so as to transform the initial RDG into the RDG of a SURE, with some new vertices emulating rays and lines. Despite the

fact that these new vertices must be considered in a special way, all results obtained for SUREs, such as Theorems 5 and 6, and the structure of the subgraph  $G'$ , can then be transferred to provide an optimal algorithm for parallelism detection in an RDG with dependence polyhedra. Furthermore, thanks to this uniformization principle, the algorithm can be specialized to a particular dependence abstraction, such as dependence level or direction vector, while keeping optimality with respect to the dependence abstraction. For the dependence level abstraction, it is the algorithm of Allen and Kennedy. For direction vectors and a single instruction (or block of instructions considered atomically), it leads to a variant of the algorithm of Wolf and Lam that would generate parallel loops instead of permutable loops (to find permutable loops, one needs to analyze the cone generated by the cycle weights, those in  $G'$  form the vector space of this cone).

Figures 3 and 4 depict the uniformized RDGs for the previous example when the non-uniform dependence is represented by a direction vector  $(+, -)$  and a dependence polyhedron along  $(1, -1)$ . In the first case, two self-loops on the new vertex  $b$ , of weight  $(1, 0)$  and  $(0, -1)$ , are introduced, resulting in a nonempty subgraph  $G'$ , and no parallelism. In the second case, the self-loop on  $b$  has weight  $(1, -1)$  and the RDG has no multicycle of zero weight, and thus contains some parallelism. Similarly, the graph of Fig. 1 is the uniformized

Parallelism Detection in Nested Loops, Optimal. Fig. 3  
Uniformized graph for direction vectors

Parallelism Detection in Nested Loops, Optimal. Fig. 4  
Uniformized graph for polyhedron vector

RDG for the following code, where  $b$  is the vertex introduced by the uniformization:

```
DO i=1, N
 DO j=1, N
 a(i,j) = c(i,j-1)
 c(i,j) = a(i,j) + a(i-1,N)
 ENDDO
ENDDO
```

### Going Beyond, with the Affine Form of Farkas Lemma

So far, the discussion focused, as in Theorem 6, on loop transformations based on multi-dimensional scheduling functions (with the lexicographic order) called shifted-linear, i.e., of the form  $\theta(v, p) = (t_v^1 \cdot p + \rho_v^1, \dots, t_v^{d_v} \cdot p + \rho_v^{d_v}, 0, \dots, 0)$  where, for all vertices of the same SCC encountered at depth  $i$  of the decomposition, the linear part  $t_v^i$  is the same. Different constants (similar to retiming [20]) can be used for different statements however. The fact that the linear part is the same made life easier. Indeed, to get valid scheduling functions, one had to solve inequalities of the form  $\theta(T, q) - \theta(S, p) \geq \epsilon$  ( $\epsilon = 0$  or  $1$  as in Theorem 5), i.e.,  $t_T(q-p) + \rho_T - \rho_S \geq \epsilon$ . If the dependence distance  $q-p$  is constant, one directly ends up with a system of linear inequalities. Otherwise, as just showed, the set of all  $q-p$  can be approximated by a polyhedron and linear inequalities involving the vertices, rays, and lines of this polyhedron are obtained.

Now, what if even more general functions are searched, i.e., affine functions with a different linear part for each statement? This is the approach of Feautrier [16]. With  $\theta(S, p) = t_S \cdot p + \rho_S$ , the constraints that need to be solved are then of the form  $t_T \cdot q - t_S \cdot p + \rho_T - \rho_S \geq \epsilon$  for all  $p$  and  $q$  such that  $S(p) \Rightarrow T(q)$ . The number of inequalities depends on the number of  $p$  and  $q$ , which is not practical. However, if the set of pairs  $(p, q)$  such that  $S(p) \Rightarrow T(q)$  can be described by a polyhedron, the **affine form of Farkas lemma** can be used to simplify the inequalities. This lemma states that  $c \cdot p \leq \delta$  for all vectors  $p$  in a polyhedron  $\{p \mid Ap \leq b\}$  iff  $c = y \cdot A$  for some vector  $y \geq 0$  such that  $y \cdot b \leq \delta$ . With this mechanism, an inequality involving all  $(p, q)$  in a polyhedron can be replaced by a finite set of inequalities.

The affine form of Farkas lemma is the key tool for writing inequalities in Feautrier's algorithm, which generates general multi-dimensional affine scheduling

functions. The skeleton of the algorithm itself is similar to the decomposition of Karp, Miller, and Winograd: trying to find a function for which as many dependences as possible are satisfied. As for previous algorithms, some optimality result can be formulated, but of a different nature. For affine dependences, i.e., if  $p$  is expressed as an affine function of  $q$ , for  $q$  in a polyhedron, whenever  $S(p) \Rightarrow T(q)$ , optimal parallelism detection requires more than affine functions, in particular index splitting, i.e., piecewise affine functions. Thus Feautrier's algorithm cannot be optimal with respect to the dependence abstraction it was designed for. However, among all affine functions, it can find one with the "right" parallelism extraction, in other words, the algorithm is optimal with respect to the class of functions it considers [24]. Extensions to detect outer parallel loops, to derive permutable loops for tiling, and to generate codes where not all dependences are carried have also been proposed, see, e.g., [3, 21].

### Multi-dimensional Affine Ranking Functions and Program Termination

Recall the graph of Fig. 1. It is the RDG of a SURE with three equations,  $a$ ,  $b$ ,  $c$ . Starting from such a description of repetitive computations, with explicit evaluation region, implicit schedule, and explicit dependences, an explicit schedule for it was derived. As seen in the previous section, this RDG can also be interpreted as the uniformized RDG of two Fortran-like nested loops where  $b$  is a dummy vertex added to emulate the  $(1, 0-)$  direction vector. In this case, from a description of repetitive computations, with explicit iteration domain and explicit initial schedule (the sequential order), dependences that were implicit are first computed and abstracted.

Then, another schedule is derived that respects the dependences and expresses, possibly, some parallelism. Now, consider the following C-like code example:

```

 $y = 0; x = 0;$
while ($x \leq N$ and $y \leq N$) {
 if (unknown) {
 $x = x + 1;$
 while ($y \geq 0$ and unknown) $y = y - 1;$
 }
 $y = y + 1;$
}

```

This code is yet another description of repetitive computations. Here, the schedule is explicit, it is the sequential schedule. However, loop counters are not specified, no iteration domain is specified, and the program may not terminate. The program is controlled by a parameter  $N$  and the integer variables  $x$  and  $y$  whose values are modified by the program. Now, the RDG of Fig. 1 depicts, not the dependences between computations, but how integer variables, implied in the program control, evolve. Each vertex corresponds to a state (program point + values of variables), edges represent transitions, i.e., modifications of variables. Again, this leads to a model of computations similar to the model of SUREs, for which the techniques and results previously exposed can be useful. In this example, the program can be proved to terminate, after performing  $O(N^2)$  operations.

### Integer Interpreted Automata and Invariants

The following presentation is borrowed from [1]. To prove the termination of an imperative program, a standard approach is to transform it into an **affine integer interpreted automaton**  $(\mathcal{K}, n, k_{init}, \mathcal{T})$  defined by (1) a finite set  $\mathcal{K}$  of control points, (2)  $n$  integer variables represented by a vector  $x$  of size  $n$ , (3) an initial control point  $k_{init} \in \mathcal{K}$ , and (4) a finite set  $\mathcal{T}$  of 4-tuples  $(k, g, a, k')$ , called **transitions**, where  $k \in \mathcal{K}$  (resp.  $k' \in \mathcal{K}$ ) is the source (resp. target) control point. The **guard**  $g : \mathbb{Z}^n \mapsto \mathbb{B} = \{\text{true}, \text{false}\}$  is a logical formula expressed with affine inequalities  $Gx + g \geq 0$  and the **action**  $a : \mathbb{Z}^n \mapsto \mathbb{Z}^n$  assigns, to each variable valuation  $x$ , a vector  $x'$  of size  $n$ , expressed by an affine expression  $x' = Ax + a$ .

The guard  $g$  in the transition  $t = (k, g, a, k')$  gives a necessary condition on variables  $x$  to traverse the transition  $t$  from  $k$  to  $k'$ , and to apply its corresponding action  $a$ . If, for two transitions going out of  $k$ , the guards describe non-disjoint conditions, the automaton expresses some non-determinism. To approximate non-affine or non-analyzable assignments in the program, the link between  $x$  and  $x'$  can be described by affine relations instead of functions, which introduces another form of non-determinism. Unlike for SUREs, this non-determinism can be unbounded, i.e., a single transition can give rise to an unbounded number of "successors"  $x'$  for a given  $x$ .

Unlike for DO loops and SUREs where the range of iteration vectors is explicitly defined, with the iteration domain and the evaluation region respectively, here, the set of all possible values for  $x$  at control point  $k$ , denoted  $\mathcal{R}_k$ , is implicit and hard to compute exactly. However, it is possible to over-approximate  $\mathcal{R}_k$  by an **invariant** at control point  $k$ , i.e., a formula true for all reachable states  $(k, x)$ . Polyhedral invariants can be computed with **abstract interpretation** techniques, widely studied since the seminal paper of Cousot and Halbwachs [6]. In this case,  $\mathcal{R}_k$  is over-approximated by the integer points within a polyhedron  $\mathcal{P}_k$ , which represents all the information on the variables at control point  $k$  that can be deduced from the program by state-of-the-art analysis techniques.

### Termination and Ranking Functions

Invariants can only prove partial correctness of a program. The standard technique for proving termination is to consider a **ranking function** to a well-founded set, i.e., a set  $\mathcal{W}$  with a (possibly partial) order  $\leq$  (the notation  $a < b$  means  $a \leq b$  and  $a \neq b$ ) with no infinite descending chain, i.e., no infinite sequence  $(x_i)_{i \in \mathbb{N}}$  with  $x_i \in \mathcal{W}$  and  $x_{i+1} < x_i$  for all  $i \in \mathbb{N}$ . More precisely, a ranking is a function  $\rho : \mathcal{K} \times \mathbb{Z}^n \rightarrow \mathcal{W}$ , from the automaton states to a well-founded set  $(\mathcal{W}, \leq)$ , whose values decrease at each transition  $t = (k, g, a, k')$ :

$$(x \in \mathcal{R}_k) \wedge (g(x) = \text{true}) \wedge (x' = a(x)) \\ \Rightarrow \rho(k', x') < \rho(k, x) \quad (4)$$

The ranking is said to be affine if it is affine in the second parameter (the variables). It is **one-dimensional** if its co-domain is  $(\mathbb{N}, \leq)$  and  **$d$ -dimensional** (or multi-dimensional of dimension  $d$ ) if its co-domain is  $(\mathbb{N}^d, \leq_d)$ , where the order  $\leq_d$  is the standard lexicographic order on integer vectors.

Obviously, the existence of a ranking function implies program termination for any valuation  $v$  at the initial control point  $k_{init}$ . A well-known property is that an integer interpreted automaton terminates for any initial valuation if it has a ranking function. Furthermore, if it terminates and has bounded non-determinism, there is a one-dimensional ranking function (but it is not necessarily affine). The problem is now very similar to the scheduling problem described for SUREs and for DO loops, except that dependences are considered in the opposite direction. In the same way, affine multi-dimensional ranking functions can be derived.

Considering rankings with  $d > 1$  is mandatory to be able to prove the termination of programs that induce a number of transitions, i.e., a trace length, more than linear in the program parameters. Considering rankings with a different affine function for each control point also extends the set of programs whose termination can be determined, compared, e.g., to shifted-linear rankings or to the technique of [5].

### A Greedy Complete Polynomial-Time Procedure

A ranking function  $\rho$  of dimension  $d$  needs to satisfy two properties. First, as  $\rho$  has co-domain  $\mathbb{N}^d$ , it should assign a nonnegative integer vector to each relevant state:

$$x \in \mathcal{P}_k \Rightarrow \rho(k, x) \geq 0 \text{ (component-wise)} \quad (5)$$

Second, it should decrease on transitions. Let  $\mathcal{Q}_t$  be the polyhedron giving the constraints of a transition  $t = (k, g, a, k')$ , i.e.,  $x \in \mathcal{P}_k$ ,  $g(x)$  is true, and  $x' = a(x)$ .  $\mathcal{Q}_t$  is built from the matrices  $A$  and  $G$ , and the vectors  $a$  and  $g$ . For an automaton whose actions are general affine relations,  $\mathcal{Q}_t$  is directly given by the action definitions. With  $\Delta_t(\rho, x, x') = \rho(k, x) - \rho(k', x')$ , Inequality (4) then becomes:

$$(x, x') \in \mathcal{Q}_t \Rightarrow \Delta_t(\rho, x, x') >_d 0 \quad (6)$$

which means  $\Delta_t(\rho, x, x') \neq 0$  and its first nonzero component is positive. If this component is the  $i$ -th, the **level** of  $\Delta_t(\rho, x, x')$  is  $i$ . A transition  $t$  is said to be (fully) **satisfied by the  $i$ -th component** of  $\rho$  (or **at dimension  $i$** ) if the maximal level of all  $\Delta_t(\rho, x, x')$  is  $i$ . To build a ranking  $\rho$ , the same greedy mechanism as in [5, 16, 18] can be used. The components of  $\rho$ , functions from  $\mathcal{K} \times \mathbb{Z}^n$  to  $\mathbb{N}$ , are built from the first one to the last one. For a component  $\sigma$  of  $\rho$  and a transition  $t$  not yet satisfied by one of the previous components of  $\rho$ , the following constraint is considered:

$$(x, x') \in \mathcal{Q}_t \Rightarrow \Delta_t(\sigma, x, x') \geq \epsilon_t \text{ with } 0 \leq \epsilon_t \leq 1 \quad (7)$$

and a ranking is selected for which as many transitions as possible have  $\epsilon_t = 1$ , i.e., are now satisfied. Again, inequalities such as (7) are captured thanks to the affine form of Farkas lemma. The algorithm itself has the same structure as the decomposition of Karp, Miller, and Winograd, and of Feautrier's algorithm.

(Generation of a multi-dimensional affine ranking)

- 1:  $i = 0; T = \mathcal{T}$ ;  $\triangleright$  Initialize  $T$  to all transitions
- 2: **while**  $T$  is not empty **do**
- 3:   Find a 1D affine function  $\sigma$  and values  $\epsilon_t$  such that all inequalities (5) and (7) are satisfied and as many  $\epsilon_t$  as possible are equal to 1;  
       $\triangleright$  This means maximizing  $\sum_{t \in T} \epsilon_t$
- 4:   Let  $\rho_i = \sigma ; i = i + 1$ ;  $\triangleright \sigma$  defines the  $i$ -th component of  $\rho$
- 5:   If no transition  $t$  with  $\epsilon_t = 1$ , **return** false  $\triangleright$  No multi-dimensional affine ranking.
- 6:   Remove from  $T$  all transitions  $t$  such that  $\epsilon_t = 1$ ;  
       $\triangleright$  The transitions have level  $i$
- 7: **end while;**
- 8:  $d = i$ ; **return** true;  $\triangleright d$ -dimensional ranking found

Since nonterminating programs exist, there is no hope of proving that a ranking function always exists. Moreover, there are terminating affine interpreted automata with no multi-dimensional affine ranking. Thus, what can be proved is only that, if a multi-dimensional affine ranking exists, the algorithm finds one, i.e., it is **complete** for the class of multi-dimensional affine rankings. Also, as the sets  $\mathcal{R}_k$  are over-approximated by the invariants  $\mathcal{P}_k$ , completeness has to be understood with respect to these invariants, which means that if the algorithm fails when an affine ranking exists, it is because invariants are not accurate enough.

**Theorem 8** *If an affine interpreted automaton, with associated invariants, has a multi-dimensional affine ranking function, then the greedy algorithm finds one. Moreover, the dimension of the generated ranking is minimal.*

## Conclusion

In [18], Karp, Miller, and Winograd introduced several new concepts and techniques that gave rise to important developments in the context of loop transformations and program analysis. The key is to represent a repetitive scheme of computations, even infinite, by a finite structure, the reduced dependence graph (and its variants). This allows a compiler to manipulate a program in a time that depends on the structure of the code but not on the number of operations that it describes. In other words, there is no need to unroll loops to understand what they do. Linear programming

techniques and polyhedral representations can be used to analyze and optimize such programs, in a parametric way.

This essay mentioned three related problems: determining if a system of uniform recurrence equations is computable, transforming DO loops so as to reveal parallel loops, and proving the termination of programs with IFs and WHILE loops, thanks to affine ranking functions. The link with program termination is still to be explored. Indeed, if the derivation of affine rankings is similar to the derivation of affine schedules, there are many subtle differences, in particular concerning the underlying iteration domains (invariants). One of the most challenging problems is to derive piecewise affine rankings to prove the termination of many more programs. For the detection of parallelism, deriving parallel codes with more data reuse and a better handling of memory transfers is still a challenge.

[Parallelization](#)

### Definition

Autoparallelization is the translation of a sequential program by a compiler into a parallel form that outputs the same values as the original program. For some authors, autoparallelization means only translation for multiprocessors. However, this definition is more general and includes translation for instruction level, vector, or any other form of parallelism.

## Discussion

### Introduction

The compilers of most parallel machines are autoparallelizers, and this has been the case since the earliest parallel supercomputers, the Illiac IV and the TI ASC, were introduced in the 1960s. Today, there are autoparallelizers for vector processors, VLIW processors, microprocessor vector extensions, and multiprocessors.

Autoparallelization is for productivity. Autoparallelizers, when they succeed, enable the programming of parallel machines with conventional languages such as Fortran or C. In this programming paradigm, code is not complicated by parallel constructs and the obfuscation typical of manual tuning.

Inserting explicit parallel constructs and tuning is not only time-consuming but also produces non-portable, machine-dependent code. For example, codes written for multiprocessors and those for SIMD machines have different syntax and organization. On the other hand, with the support of autoparallelization, conventional codes could be portable across machine classes.

Explicit parallelism introduces opportunities for program defects that do not arise in sequential programming. With autoparallelization, the code has sequential semantics. There is no possibility of deadlock and programs are determinate. The downside is that it is not possible to implement asynchronous algorithms, although this limitation does not affect the vast majority of applications.

### Requirements for Autoparallelization

A parallelizing compiler must analyze the program to detect implicit parallelism and identify opportunities for restructuring transformations, and then apply a sequence of transformations.

Detection of implicit parallelism can be accomplished by (1) computing the dependences to determine where the sequential order of the source program can be relaxed, and (2) analyzing the semantics of code segments to enable the selection of alternative parallel algorithms.

The transformation process is restricted by the information provided by this analysis and is guided by heuristics supported by static prediction of execution time or program profiling.

### Dependence Analysis

The dependence relation is a partial order between operations in the program that is computed by analyzing variable and array element accesses. Executing the program following this partial order guarantees that the program will produce the same output as the original code. For example, in

```
for (i=0; i < n; i++) {a[i] += 1;}
for (j=0; j < n; j++) {b[j] = a[j]*2;}
```

corresponding iterations of the first and the second loop must be executed in the specified order. However, these pairs of iterations do not interact with other pairs and therefore do not have to execute in the original order to produce the intended result. Only corresponding iterations of these two loops are ordered. By determining what orders must be enforced, dependence analysis tells us which reordering is valid and what can be done in parallel: two operations that are not related by the partial order resulting from the dependence analysis can be reordered or executed in parallel with each other.

Dependence analysis can be done statically, by a compiler; or dynamically, during program execution.

Static analysis is discussed next, while dynamic analysis is discussed below under the heading of “Runtime Resolution”.

How close the dependences generated by static dependence analysis are to the minimum number of ordered pairs required for correctness depends on the information available at compile time and the algorithms used for the analysis. The loops above are examples of loops that can be analyzed statically with total accuracy because (1) all the information needed for an accurate analysis is available statically, and (2) the subscript expressions are simple, so that most analysis algorithms can analyze them accurately. Accuracy is tremendously important because when the set of dependences computed by a test is not accurate, spurious dependences must be assumed and this may preclude valid transformations including conversion into parallel form.

There are numerous algorithms for dependence analysis that have been developed through the years. They typically trade off accuracy for speed of analysis. For example, some fast tests do not make use of information about the values of the loop indices, while others require them. Ignoring the loop limits works well in some cases. The loops above are an example of this situation. The value of  $n$  in these loops is not required to do an accurate analysis. However, in other cases, knowledge of the loop limits is needed. Consider the loop

```
for (i=10; i<15; i++) {a[i] += a[i-8];}
```

The loop limits, 10 and 14, are necessary to determine that no ordering needs to be enforced between loop iterations since, for these values, the iterations do not

interact with each other. A test that ignores the loop limits will report that (some) iterations in this loop must be executed in order.

Some of the most popular dependence tests require for accuracy that the subscript expressions be affine expression of the loop indices and the values of the coefficients and the constant be known at compile time. For example, a test that requires knowledge of the numerical values of coefficients would have to assume that iterations of the loop

```
if (m > 0) {
 for (i=0; i < n; i+=2){
 a[m*i] += a[m*i+1];
 }
}
```

must be executed in order, while a test with symbolic capabilities would be able to determine that the iterations do not have to be executed in any particular order to obtain correct results. [Table 1](#) presents the main characteristics of a few dependence tests.

When the needed information is not available at compile time or the analysis algorithm is inaccurate, the decision can be postponed to execution time (see “Transformations for Runtime Resolution” below). For example, the loop

```
for (i=0; i < n; i++) {a[i+k] += a[i];}
```

can be transformed into an array operation as long as k is negative, but the compiler will not know that this is the case if k happens to be a function of the input to the program or if the value propagation analysis conducted by the compiler cannot decide that k is negative. A similar situation arises in the loop

```
for (i=0; i < n; i++) {a[m[i]] += a[i];}
```

where m[i] must be  $\leq i$  or  $\geq n$  and all the m[i]’s be different for a transformation into vector operation to be

valid. But this will only be known to the compiler, if it can propagate array values and these values are available in the source code. Otherwise, dependences must be assumed or the analysis postponed to execution time.

## Semantic Analysis

Semantic analysis identifies operators or code sequences that have a parallel implementation. A good example is the analysis of array operations. For example, in the Fortran statement

```
a(1:n) = sin(a(2:n+1))
```

the n evaluations of sin can proceed in parallel since their parameters do not depend on each other.

Although array operations like this can be interpreted as parallel operations, most Fortran 90 compilers at the time of the writing of this entry do not parallelize directly array operations, but instead translate them into loops which are analyzed by later passes for parallelization. So, in effect, they rely on semantic analysis.

The compiler can also apply semantic analysis to sequence of statements with the help of a database of patterns. For example,

```
for (i=0; i < n; i++) {s+=a[i];}
```

cannot be parallelized by relying exclusively on dependence analysis, because this analysis will only state the obvious: that each iteration requires the result of the previous one (the values of sum) to proceed. However, accumulations like this can be parallelized, if assuming that + is associative is acceptable, and are frequently found in real programs. Therefore, this pattern is a natural candidate for inclusion in this database.

Other frequently found patterns include: finding the minimum or maximum of an array, and linear recurrences such as

```
x[i]=a[i]*x[i-1]+b[i]
```

**Parallelization, Automatic. Table 1** Characteristics of a few dependence tests

| Test name     | # of loop indices in subscript | Subscript expressions must be affine? | Uses loop bounds? | Ref. |
|---------------|--------------------------------|---------------------------------------|-------------------|------|
| ZIV           | 0 (constant)                   | Y                                     | N/A               | [5]  |
| SIV           | 1                              | Y                                     | Y                 | [5]  |
| GCD           | Any                            | Y                                     | N                 | [2]  |
| Banerjee      | Any                            | Y                                     | Y                 | [2]  |
| Access Region | Any                            | N                                     | Y                 | [9]  |

Some compilers have been known to recognize more complex patterns such a matrix–matrix multiplication.

Once the compiler knows the type of operation, it can choose to replace the code sequence with a parallel version of the operation.

## Program Transformations

Program transformations are used to

1. Reduce the number of dependences
2. Generate code for runtime resolution, that is, code that at runtime decides whether to execute in parallel
3. Schedule operations to improve locality or parallelism

### Transformations for Reducing the Number of Dependences

This class of transformations aims at reducing the number of ordered pairs to improve parallelism and enable reordering. Induction variable substitution and privatization are two of the most important examples in this class. Induction variables are those that assume values that form an arithmetic sequence. Their computation creates a linear order that must be enforced. In addition, using induction variables in subscripts hinders the dependence analysis of other computations. For example, the loop

```
for (i=0; i<n; i++) {j+=2; a[j]=a[j]*2;}
```

cannot be parallelized in this form since  $j+=2$  must be executed in order. Furthermore, dependence analysis cannot know that each iteration of the loop accesses a different element unless it knows that  $j$  takes a different value in each iteration. Fortunately, in this example, as in most cases, the induction variable can be eliminated to increase parallelism and improve accuracy of analysis. Thus, here  $j$  may be represented in terms of the loop index and forward substituted:

```
for (i=0; i<n; i++) {a[j+2*i+1]=a[j+2*i+1]*2;}
```

The effect of this transformation is that the chain of dependences resulting from the  $j++$  statement goes away with the statement. Also, the removal of the increment makes  $j$  a loop invariant and this enables an accurate dependence analysis at compile time.

The identification of induction variables was originally developed for strength reduction, which replaces

operations with less expensive ones. A typical strength reduction is to replace multiplications with additions. For parallelism, the replacement goes in the opposite direction. For example, additions are replaced by multiplications as shown in the last example. Induction variable identification relies on conventional compiler data-flow analysis.

Privatization can be applied when the  $a$  variable is used to carry values from one statement to another within the one iteration of the loop. For example, in

```
for(i=0; i<n; i++) {a=b[i]*2; c[i] = a*c[i]}
```

the use of a single variable,  $a$ , in all iterations demands that the iterations be executed in order to guarantee correct results because,  $a$  should not be reassigned until its value has been obtained by the second statement of the loop body. The privatization transformation simply makes  $a$  private to the loop iteration and thus eliminates a reason to execute the iterations in order.

An alternative to privatization is expansion. This transformation converts the scalar into an array and has the same effect on the dependence as privatization. For the previous loop, this would be the result:

```
for (i=0; i<n; i++) {
 a1[i]=b[i]*2;
 c[i]=a1[i]*c[i]
}
a=a1[n-1];
```

Privatization is applied when generating code for multiprocessors, and expansion is necessary for vectorization. The main difficulty with expansion is the increase in memory requirements. While privatization increases the memory requirements proportionally to the number of processors, expansion does so proportionally to the number of iterations, a number that is typically much higher.

However, expansion can be applied together with a transformation called stripmining to reduce the amount of additional memory.

Privatization and expansion require analysis to determine that the variable being privatized or expanded is never used to pass information across iterations of the loop. This analysis can be done using conventional data flow analysis techniques.

### Transformations for Runtime Resolution

In its simplest form, runtime resolution transformations generate if statements to select between a parallel or serial version of the code. For example,

```
do i=m,n
 a(i+k)=a(i)*2
end do
```

as discussed above, can be vectorized if  $k \leq 0$ . The compiler may then generate a two-version code

```
if (k<=0) then
 a(k+m:k+n) += a(m:n)
else
 do i=m,n
 a(i+k)=a(i)*2
 end do
end if
```

Two-version code can be also be used in other situations. Thus, if the loop contains an assignment statement that accesses memory through pointers in the right- and left-hand sides, such as the loop

```
for (i=0; i <n; i++) {*(a+i)=*(b+i)+2;}
```

the if statement should check that address a is either less than address b or greater than address  $(b+n-1)$ .

More complex runtime resolution would be needed for loops like

```
for (i=0; i <n; i++) {a[m[i]]+=a[i];}
```

where the  $m[i]$ 's must be  $\leq i$  or  $\geq n$  and all distinct for vectorization to be possible, or  $m[i]$  either =  $i$  or outside the values in the iteration space and all distinct for transformation into a parallel loop. In

```
for (i=0; i <n; i++) {a[m[i]]+=a[q[i]];}
```

the  $m[i]$ 's and  $q[i]$ 's must be such that  $m[i] \leq q[i]$  and the  $m[i]$ 's all distinct for vectorization, or  $m[i] \neq q[j]$  whenever  $i \neq j$  for parallelization. Two-version loops can be generated also in this case, but the if condition is somewhat more complex as it must analyze a collection of addresses. In this last case, the technique is called inspector-executor. Another approach to runtime resolution is speculation, which attempts to execute in parallel and optimistically expects that there will be no conflicts between the different components executing in parallel. During the execution of the speculative parallel code or at the end, the memory references are checked to make sure that the parallel execution was correct.

If it was not, the execution is undone and the components executed at a later time either in the right order or again speculatively, in parallel.

Run time resolution is also used to check for profitability, i.e., that parallel execution will make execution faster. For example, if the number of iterations of a parallel loop is not known at compile time, runtime resolution can be used to decide whether to execute a loop in parallel as a function of the number of iterations. Also, runtime resolution can be used to guarantee that vector operations are only executed if the operands are or can be properly aligned in memory when this is required for performance. For example, SSE vector operations sometimes perform better when the operands are aligned on double word boundaries.

### Scheduling Transformations

An important class are the transformations that schedule the execution of program operations or partition these operations into groups. To enforce the order, the compiler typically uses the barriers implicit in array operations or multiprocessor synchronization instructions. One such transformation is stripmining. It partitions the iterations of a loop into blocks by augmenting the increment of the loop index and adding an inner loop as follows:

```
for (i=0; i <n; i++) {a[i]=a[i]+1;}

↓

for (i=0; i < (n/q)*q; i+=q) {
 for(j=i; j < i+q, j++) {
 a[j]=a[j]+1;
 }
}

for (i=(n/q)*q; i < n, i++) {a[i]=a[i]+1;}
```

Stripmining is useful to enhance locality and reduce the amount of memory required by the program. In particular, it can be used to reduce the memory consumed by expansion. If the goal is vectorization and the size of the vector register is  $q$ , this transformation will not reduce the amount of parallelism.

Another type of loop partitioning transformation is that developed for a class of autoparallelizing compilers targeting distributed memory operations. These compilers, including High-Performance Fortran and Vienna Fortran, flourished in the 1990s but are no longer used. The goal of partitioning was to organize loop iterations groups so that each group could

be scheduled in the node containing the data to be manipulated.

An important sequencing transformation is loop interchange, which changes the order of execution by exchanging loop headers. This transformation can be useful to reduce the overhead when compiling for multiprocessors and to enhance memory behavior by reducing the number of cache misses. For example, the loop

```
for (i=0; i < (n/q)*q; i+=q)
 for(j=i; j< i+q, j++) {
 a[j]=a[j]+1;
 }
```

can be correctly transformed by loop interchange into

```
for (j=0; j<n; j++)
 for(i=0; i<n, i++) {
 a[i][j]=a[i-1][j]+1;
 }
```

The outer loop of the original nest cannot be executed in parallel. If nothing else is done, the only option of the compiler targeting a multiprocessor is to transform the inner loop into parallel form and while this could lead to speedups, the result would suffer of the parallel loop initiation overhead once per iteration of the outer loop. Exchanging the loop headers makes the iteration of the outer loop independent so that the outer loop can be executed in parallel and the overhead is only paid once per execution of the whole loop. Furthermore, the resulting loop has a better locality since the array is traverse in the order it is stored, so that the elements of the array in a cache line are accessed in consecutive order, improving in this way spatial locality.

A third example of sequencing transformation is instruction level parallelization. Consider, for example, a VLIW machine with a fixed point and a floating point unit. The sequence

```
r1=r2+r3
r4=r4+r5
f1=f1+f2
f3=f4+f5
```

contains two fixed point operations (those operating on the r registers) and two floating point operations. Exchanging the second and the third operation is necessary to enable the creation of two (VLIW) instructions each making use of both computational units.

In some cases, the partitioning and sequencing of the operations is not completely determined at compile time. For example the sum reduction

```
for (i=0; i <n; i++) { s+=a[i]; }
```

once identified as such by semantic analysis, may be transformed into a form in which subsets of iterations are executed by different threads and the elements of a are accumulated into different variables, one per thread of execution. These variables are then added to obtain the final sum. The number of these threads can be left undefined until execution time. In OpenMP notation, this can be represented as follows:

```
#pragma omp parallel
{ float sp=0;
#pragma omp for
for (i=0; i <n; i++) {
 sp+=a[i];
}
#pragma omp single
{s+=sp;}
```

or, more simply,

```
#pragma omp parallel for reduction (+: sum)
for (i=0; i <n; i++) {
 sp+=a[i];
}
```

It should be pointed out that in this example, it has been assumed that floating point addition is associative, but because of the finite precision of machines, it is not. In some cases, it is correct to do this transformation, even if the result obtained is not exactly the same as that of the original program.

However, this is not always the case and transformations like this require authorization from the programmer. [Table 2](#) contains a list of important transformations not discussed above.

## Autoparallelization Today

Most of today's compilers that target parallel machines are autoparallelizers. They can generate code for multiprocessors and vector code. Although autoparallelization techniques have become the norm, the few empirical studies that exist as well as anecdotal evidence indicate that these compilers often fail to generate high-quality parallel code. There are two reasons for this. First, sometimes the compiler fails to find parallelism due to limitations of its dependence/semantic analysis or transformation modules. In other cases, it is unable to generate good quality code because of limitations in

**Parallelization, Automatic. Table 2** An incomplete list of transformations for autoparallelization

| Name                | Description                                                                                                     | Example of use                                           |
|---------------------|-----------------------------------------------------------------------------------------------------------------|----------------------------------------------------------|
| Alignment           | Reorganizes computation so that values produced in one iteration are consumed by the same iteration             | Reduce synchronization costs                             |
| Distribution        | Partitions a loop into multiple loops                                                                           | Separates sequential from parallel parts                 |
| Fusion              | Merges two loops                                                                                                | Reduce parallel loop initiation overhead                 |
| Skewing             | Partitions the set of iterations into groups that are not related by dependences (i.e. are not ordered)         | Enhance parallelism                                      |
| Node Splitting      | Breaks a statement into two                                                                                     | Reduce dependence cycles and thus enable transformations |
| Software pipelining | Reorders and partitions the executions of operations in a loop into groups that are independent from each other | Enhance instruction level parallelism                    |
| Tiling              | Partitions the set of iterations of a multiply nested loop into blocks or tiles                                 | Enhance locality                                         |
| Trace scheduling    | Reorder and partition the executions of operations in a loop into groups that are independent from each other   | Enhance instruction level parallelism                    |
| Unroll and Jam      | Partitions the set of iterations of a multiply nested loop into blocks or tiles with reuse of values            | Enhance locality                                         |

its profitability analysis. That is, the compiler incorrectly assumes that transforming into parallel form would slow the program down.

To circumvent these limitations, compilers accept directives from programmers to help the analysis or guide the transformation and code generation process. A few vectorization directives for the Intel C++ compiler and IBM XLC compiler are shown in Table 3. The programmer can also influence the result by modifying the program into a form that can be recognized by the compiler.

Despite their limitations, autoparallelizers today contribute to productivity by

1. Saving labor. As mentioned, manual intervention in the form of directives or rewriting is typically necessary, but programmers can often rely on the autoparallelizing compiler for some sections of code and in some cases the whole program.

2. Portability. Sequential code complemented with directives is portable across classes of machines with the support of compilers. Portability is after all one of the purposes of compilers and autoparallelization brings this capability to the parallel realm.
3. As a training mechanism. Programmers can learn about what can and cannot be parallelized by interacting with an autoparallelizer. Thus, the compiler report to the programmer is not only useful for manual intervention, but also for learning.

## Future Directions

Autoparallelization has only been partially successful. As previously mentioned, in many cases today's compilers fail to recognize the existence of parallelism, or having recognized the parallelism, incorrectly assume that transforming into parallel form is not profitable. Although autoparallelization is useful and

**Parallelization, Automatic. Table 3** Vectorization directives for the IBM (XLC) and Intel (ICC) compilers

| Vectorization directive                                                          | Purpose                                                                                                                                            |
|----------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>#pragma vector always (ICC)</code>                                         | Vectorize the following loop whenever dependences allow it, disregarding profitability analysis                                                    |
| <code>#pragma nosimd (XLC)</code>                                                | Preclude vectorization of the following loop                                                                                                       |
| <code>#pragma novector (ICC)</code>                                              |                                                                                                                                                    |
| <code>_assume_aligned (A, 16); /ICC</code><br><code>_alignx(16, A); (XLC)</code> | The compiler is told to assume that the vector (A in the examples) start at addresses that are a multiple of a given constant (16 in the examples) |

effective when guided by user directives, there is clearly much room for improvement. Research in the area has decreased notably in the recent past, but it is likely that there will be more work in the area due to the renewed interest in parallelism that multicores have initiated. Two promising lines of future studies are

1. Empirical evaluation of compilers to improve parallelism detection, code generation, compiler feedback, and parallelization directives. Evaluating compilers using real applications is necessary to make advances in autoparallelization of conventional languages. Although there has been some work done in this area, much more needs to be done. This type of work is labor intensive since the best and perhaps the only way to do it is for an expert programmer to compare what the compiler does with the best code that the programmer can produce. This process is likely to converge since code patterns repeat across applications [8]. These costs and risks are worthwhile given the importance of the topic and the potential for an immense impact on productivity.
2. Study programming notations and their impact on autoparallelization. Higher level notations, such as those used for array operations, tend to facilitate the task of a compiler while at the same time improving productivity. Language-compiler codesign is an important and promising direction not only for autoparallelization but for compiler optimization in general.

## Bibliographic Notes And Further Reading

As mentioned in the introduction, work on autoparallelization started in the 1960s with the introduction of Illiac IV and the Texas Instrument Advanced Scientific Computer (ASC). The Paralyzer, an autoparallelizer for Illiac IV developed by Massachusetts Computer Associates, is discussed in [10].

This is the earliest description of a commercial autoparallelizer in the literature. Since then, there have been numerous papers and books describing commercial autoparallelizers. For example, [11] describes an IBM vectorizer of the 1980s, [3] discusses Intel's vectorizer for their multimedia extension, and [13] describes the IBM XLC compiler autoparallelization features.

Many of the autoparallelization techniques were developed at universities. Pioneering work was done by David Kuck and his students at the University of Illinois [6, 7]. The field has benefited from the contributions of numerous researchers. The contributions of Ken Kennedy and his coworkers [1] at Rice University have been particularly influential.

There have been only a few papers evaluating the effectiveness of autoparallelizers. In [8], different vectorizing compilers are compared using a collection of snippets, and in [4] the effectiveness of parallelizing compilers is discussed using the Perfect Benchmarks.

More information on autoparallelization, can be found in the related entries or in books devoted to this subject [2, 5, 12, 14]. Reference [5] contains a discussion of compiler techniques for High-Performance Fortran.

## Parallelization, Basic Block

UTPAL BANERJEE

University of California at Irvine, Irvine, CA, USA

## Synonyms

Parallelization

## Definition

A *basic block* in a program is a sequence of consecutive operations, such that control flow enters at the beginning and leaves at the end without halt. *Basic block parallelization* consists of techniques that allow execution of operations in a basic block in an overlapped manner without changing the final results.

## Discussion

### Introduction

The operations in a basic block are to be executed in the prescribed sequential order. This execution order imposes a *dependence structure* on the set of operations, based on how they access different memory locations. A new order of execution is *valid* if whenever an operation  $B$  depends on an operation  $A$  in the block, execution of  $B$  in the new order does not start until after the execution of  $A$  has ended. The basic assumption is that executing the operations in any valid order will not change the final results expected from the basic block.

To reduce the total execution time of the block, one needs to find a new valid order where operations are overlapped. Among all such orders, one must choose only those that are compatible with the physical resources of the given machine. Even when the simultaneous processing of two or more operations is permissible by dependence considerations alone, there may not be enough resources available to process them simultaneously.

There are many algorithms for basic block parallelization. This essay presents four of them: two for a hypothetical machine with unlimited resources, and two for a machine with limited resources. It starts with a section on basic concepts, and after developing the algorithms, ends with a simple example that compares

the actions of all four on a given basic block. References to more algorithms are given in the bibliographic notes.

## Basic Concepts

By an *operation* one means an atomic operation that a machine can perform. An *assignment operation* reads one or more memory locations and writes one location. It has the general form:

$$A : \quad x = E$$

where  $A$  is a label,  $x$  a variable, and  $E$  an expression. Such an operation reads the memory locations specified in  $E$ , and writes the location  $x$ . A *basic block* in a program is a sequence of assignment operations, where flow of control enters at the top and leaves at the bottom. There are no entry points except at the beginning, and no branches, except possibly at the end. The object of study in this essay is a basic block of  $n$  operations. The set of those operations is denoted by  $\mathcal{B}$ . There is a mapping  $c : \mathcal{B} \rightarrow \{0, 1, 2, \dots\}$  that gives the cycle times of the operations.

An operation  $B$  in the block *depends* on another operation  $A$ , and one writes  $A \delta B$ , if  $A$  is executed before  $B$ , and one of the following holds:

1.  $B$  reads the memory location written by  $A$ .
2.  $B$  writes a location read by  $A$ .
3.  $A$  and  $B$  both write the same location.

An operation  $B$  is *indirectly dependent* on an operation  $A$ , and one writes  $A \bar{\delta} B$ , if there exists a sequence of operations  $A_1, A_2, \dots, A_k$ , such that

$$A = A_1, A_1 \delta A_2, \dots, A_{k-1} \delta A_k, A_k = B.$$

Two operations  $A$  and  $B$  are *mutually independent* if  $A \bar{\delta} B$  and  $B \bar{\delta} A$  are both false. The *dependence graph* of the basic block is a directed acyclic graph, such that the nodes correspond to the operations, and there is an edge from a node  $A$  to a node  $B$  if and only if  $A \delta B$ . Thus,  $A \bar{\delta} B$  means there is a directed path from the node  $A$  to the node  $B$  in the dependence graph.

A new execution order for the operations in  $\mathcal{B}$  is *valid* if whenever  $A, B$  in  $\mathcal{B}$  are such that  $A \delta B$ ,  $B$  is executed after  $A$  in the new order. If the prescribed sequential order of execution for  $\mathcal{B}$  is changed to any valid order, the results would still be the same. The goal is to find a valid execution order where operations

are overlapped as much as possible. However, any such order must also be compatible with the resources of the given machine.

Control steps for execution of the basic block are numbered  $1, 2, 3, \dots$ . *Scheduling* an operation in the block means assigning a control step to it where it can start executing. An *instruction* for a given machine is a set of operations that the machine can perform simultaneously. An instruction may be empty. *Scheduling* the basic block means creating a sequence of  $m$  instructions  $(I_1, I_2, \dots, I_m)$ , where  $I_k$  starts in control step  $k$ , such that

1. Each instruction consists of operations in  $\mathcal{B}$ , and each operation in  $\mathcal{B}$  appears in exactly one instruction.
2. The operations in each instruction are pairwise mutually independent.
3. If an operation  $B$  in an instruction  $I_k$  depends on an operation  $A$  in an instruction  $I_j$ , then  $j + c(A) \leq k$ .
4. In any control step, the given machine has enough resources to process simultaneously all operations being executed.

Such a sequence of instructions is a *schedule* for the basic block. A schedule for the block can be specified indirectly by scheduling each individual operation. Then all operations starting in control step  $k$  constitute the instruction  $I_k$ .

The *weight* of a path  $(A_1, A_2, \dots, A_k)$  in the dependence graph for the basic block  $\mathcal{B}$  is the expression  $[c(A_1) + c(A_2) + \dots + c(A_k)]$ . A path is *critical* if it has the greatest possible weight among all paths in the graph. Let  $T_0$  denote the weight of a critical path. Then, any schedule for  $\mathcal{B}$  will need at least  $T_0$  cycles to finish.

For each operation  $A \in \mathcal{B}$ , the set of all immediate predecessors (in the dependence graph) is denoted by  $\text{Pred}(A)$  and the set of all immediate successors by  $\text{Succ}(A)$ :

$$\text{Pred}(A) = \{B \in \mathcal{B} : B \bar{\delta} A\}, \quad \text{Succ}(A) = \{B \in \mathcal{B} : A \bar{\delta} B\}.$$

The number of members of a set  $S$  is denoted by  $|S|$ .

## Unlimited Resources

In this section, it is assumed that the given machine has an unlimited supply of resources (functional units, registers, etc.). Consequently, operations in the basic block

can be scheduled subject only to the dependence constraints between them. The two algorithms considered in this section complete the execution of  $\mathcal{B}$  in exactly  $T_0$  cycles.

The ASAP algorithm schedules an operation *as soon as possible* so that the basic block can be processed in the shortest possible time. It creates a simple function  $\ell : \mathcal{B} \rightarrow \{1, 2, \dots\}$  such that  $\ell(A)$  is the earliest possible step when  $A$  can start executing. The ALAP algorithm schedules an operation *as late as possible* within the constraint of executing  $\mathcal{B}$  in the shortest possible time. It creates a function  $L : \mathcal{B} \rightarrow \{1, 2, \dots\}$  such that  $L(A)$  is the latest possible step when  $A$  can start executing. The *ASAP label* of  $A$  is  $\ell(A)$  and its *ALAP label* is  $L(A)$ . It is clear that  $\ell(A) \leq L(A)$  for each operation  $A$ . The range of consecutive integers from which the control step for  $A$  may be chosen is  $\{\ell(A), \ell(A) + 1, \dots, L(A)\}$ .

### ASAP Algorithm

The goal of the ASAP algorithm (Fig. 1) is to compute the ASAP label  $\ell$  for each operation in the given basic block  $\mathcal{B}$ . If  $A$  and  $B$  are two operations such that  $A \delta B$ , then after starting  $A$ , one must wait at least until  $A$  has finished before starting  $B$ . This means one must have  $\ell(B) \geq \ell(A) + c(A)$ .

**Algorithm 1** Given a basic block  $\mathcal{B}$ , its dependence graph, and a machine with unlimited resources, this algorithm computes the ASAP label  $\ell$  of each operation, and the total number  $m$  of instructions needed to replace  $\mathcal{B}$ . For each  $A \in \mathcal{B}$ , the sets  $\text{Pred}(A)$  and  $\text{Succ}(A)$  are assumed to be known.

```

 $m \leftarrow 1$
 $V \leftarrow \mathcal{B}$
for each operation $A \in V$ do
 $\text{Pcount}(A) \leftarrow |\text{Pred}(A)|$
 $\ell(A) \leftarrow 1$
endfor
while $V \neq \emptyset$ do
 for each operation $A \in V$ do
 if $\text{Pcount}(A) = 0$ then
 for each $B \in \text{Succ}(A)$ do
 $\text{Pcount}(B) \leftarrow \text{Pcount}(B) - 1$
 $\ell(B) \leftarrow \max\{\ell(B), \ell(A) + c(A)\}$
 endfor
 $V \leftarrow V - \{A\}$
 $m \leftarrow \max\{m, \ell(A)\}$
 endif
 endfor
endwhile
```

Parallelization, Basic Block. Fig. 1 The ASAP algorithm

An operation is scheduled only after all its predecessors have been scheduled. An integer-valued function  $\text{Pcount}$  on  $\mathcal{B}$  is defined as follows: at any point in the algorithm,  $\text{Pcount}(A)$  is the number of immediate predecessors of an operation  $A$  that have not been scheduled yet.

Initially, all operations are assigned the control step 1, that is,  $\ell(A)$  is initialized to 1 for each  $A \in \mathcal{B}$ . Operations  $A$  for which  $\text{Pcount}(A) = 0$  keep this value of  $\ell(A)$ ; they have been scheduled. If  $\text{Pcount}(A) = 0$  and  $B$  is a successor of  $A$ , then reduce  $\text{Pcount}(B)$  by 1, and increase  $\ell(B)$  to  $[\ell(A) + c(A)]$  if it is smaller. The operations whose  $\text{Pcount}$  is now zero keep their ASAP label; they have been scheduled. This process continues until all operations in  $\mathcal{B}$  have been scheduled.

The earliest control step where an operation  $B$  can start is given by

$$\ell(B) = \max_{A \in \text{Pred}(B)} [\ell(A) + c(A)].$$

The total number of cycles needed to execute the block  $\mathcal{B}$  is

$$\max_{A \in \mathcal{B}} [\ell(A) + c(A)] - 1$$

which is clearly equal to the weight  $T_0$  of a critical path in the dependence graph. The total number of instructions needed to replace the basic block is given by  $m = \max_{A \in \mathcal{B}} \ell(A)$ .

### ALAP Algorithm

The goal of the ALAP algorithm (Fig. 2) is to compute the ALAP label  $L$  for each operation in the given basic block  $\mathcal{B}$ . The entire block has to be completed in the shortest possible time in such a way that each operation starts as late as possible. For each operation  $A$ , let  $f(A)$  denote the number of cycles from the point when  $A$  is scheduled to start to the point when execution of the entire block has been completed. The idea then is to minimize  $f(A)$  for each  $A$ . When operation  $A$  starts,  $[L(A) - 1]$  cycles have already elapsed. Hence, the total number of cycles  $T$  needed to complete  $\mathcal{B}$  is  $[L(A) - 1 + f(A)]$ , so that

$$L(A) = T + 1 - f(A). \quad (1)$$

The ALAP algorithm first computes  $T$ , and  $f(A)$  for each  $A$ , and then evaluates  $L(A)$  from this equation. If  $A$  and  $B$  are two operations such that  $A \delta B$ , then after starting  $A$ , one must wait at least until  $A$  has finished

**Algorithm 2** Given a basic block  $\mathcal{B}$ , its dependence graph, and a machine with unlimited resources, this algorithm computes the ALAP label  $L$  of each operation, and the total number  $m$  of instructions needed to replace  $\mathcal{B}$ . For each  $A \in \mathcal{B}$ , the sets  $\text{Pred}(A)$  and  $\text{Succ}(A)$  are assumed to be known.

```

 $T \leftarrow 0$
 $V \leftarrow \mathcal{B}$
for each operation $A \in V$ do
 $\text{Scount}(A) \leftarrow |\text{Succ}(A)|$
 $f(A) \leftarrow 0$
endfor
while $V \neq \emptyset$ do
 for each operation $A \in V$ do
 if $\text{Scount}(A) = 0$ then
 $f(A) \leftarrow f(A) + c(A)$
 $T \leftarrow \max\{T, f(A)\}$
 for each $B \in \text{Pred}(A)$ do
 $\text{Scount}(B) \leftarrow \text{Scount}(B) - 1$
 $f(B) \leftarrow \max\{f(B), f(A)\}$
 endfor
 $V \leftarrow V - \{A\}$
 endif
 endfor
endwhile
for each operation $A \in V$ do
 $L(A) \leftarrow T + 1 - f(A)$
endfor
 $m \leftarrow \max_{A \in \mathcal{B}} L(A)$

```

Parallelization, Basic Block. Fig. 2 The ALAP algorithm

before starting  $B$ . This means  $L(B) \geq L(A) + c(A)$ , or  $f(A) \geq f(B) + c(A)$  by (1). Thus, the minimum possible value for  $f(A)$  is

$$f(A) = c(A) + \max_{B \in \text{Succ}(A)} f(B).$$

An operation is scheduled only after all its successors have been scheduled. An integer-valued function  $\text{Scount}$  on  $\mathcal{B}$  is defined as follows: at any point in the algorithm,  $\text{Scount}(B)$  is the number of immediate successors of an operation  $B$ , that have not been scheduled yet.

Initialize  $T$  to 0, and  $f(A)$  to 0 for each  $A \in \mathcal{B}$ . If an operation  $A$  has  $\text{Scount}(A) = 0$ , then  $f(A)$  is increased by  $c(A)$  to reach  $f(A) = 0 + c(A) = c(A)$ . This operation has now been scheduled. The value of  $T$  is also increased to  $f(A)$  if  $T < f(A)$ . If  $\text{Succ}(A) = 0$  and  $B$  is a predecessor of  $A$ , then reduce  $\text{Scount}(B)$  by 1, and increase  $f(B)$  to  $f(A)$  if  $f(B) < f(A)$ . The operations  $A$  for which  $\text{Scount}(A)$  is now zero are handled next. This process continues until all operations in  $\mathcal{B}$  have been

processed. When the final value of  $f(A)$  for each operation  $A$  and the final value of  $T$  are known, the ALAP labels are found from the equation  $L(A) = T + 1 - f(A)$ .

The total number of cycles needed to execute the block is  $T = \max_{A \in \mathcal{B}} f(A)$  which is equal to the weight  $T_0$  of a critical path in the dependence graph. The total number of instructions needed to replace the basic block is given by  $m = \max_{A \in \mathcal{B}} L(A)$ .

## Limited Resources

In this section, the reality is acknowledged that any given machine has limited amount of functional resources. While scheduling the operations in the basic block  $\mathcal{B}$ , one now needs to worry about the potential resource conflicts between two operations, in addition to the dependence constraints that may exist between them. For simplicity, a pipelined implementation is assumed for each multi-cycle operation. Register allocation is not treated here; it should be done either before or after scheduling.

## List Scheduling

*List Scheduling* employs a greedy approach to schedule as many operations as possible among those whose predecessors have been scheduled. Each operation is assigned a priority. Operations that are ready to be scheduled are placed on a *ready list* ordered by their priorities. At each control step, the operation with the highest priority is scheduled first. If there are two or more operations with the same priority, then a selection is made at random. List scheduling encompasses a family of different algorithms based on the choice of the priority function. In the algorithm described here (Fig. 3), the priority of an operation  $A$  is defined by the difference  $\mu(A) = L(A) - \ell(A)$  between its ALAP and ASAP labels, called the *mobility* of the operation. An operation with a lower mobility has a higher priority.

First, Algorithm 1 and Algorithm 2 are used to find the ASAP and ALAP labels of each operation in the given basic block. Operations without predecessors are placed on a ready list  $\mathcal{S}$  and arranged in the order of increasing mobility. They are taken from the ready list and scheduled one by one subject to the availability of machine resources. After one round, if there is still an operation  $A$  left over in  $\mathcal{S}$ , then its ASAP label is increased by 1 without exceeding its ALAP label. This will reduce the mobility of  $A$ , if it is not already zero.

**Algorithm 3** Given a basic block  $\mathcal{B}$ , its dependence graph, and a machine with limited resources, this algorithm finds a schedule for  $\mathcal{B}$ . For each  $A \in \mathcal{B}$ , the sets  $\text{Pred}(A)$  and  $\text{Succ}(A)$  are assumed to be known.

```

 $V \leftarrow \mathcal{B}$
 $k \leftarrow 1$
for each operation $A \in V$ do
 Compute the labels $\ell(A)$ and $L(A)$ by Algorithm 1 and Algorithm 2
endfor
while $V \neq \emptyset$ do
 $S \leftarrow$ all operations in V whose predecessors have finished
 executing before control step k
 for each $A \in S$ do
 $\mu(A) \leftarrow L(A) - \ell(A)$
 endfor
 Arrange the operations of S in a sequence $(A_{r_1}, A_{r_2}, \dots, A_{r_{|S|}})$
 in the increasing order of their mobilities
 Create an empty instruction \mathbf{I}_k
 for $i = 1$ to $|S|$ do
 if A_{r_i} does not have resource conflicts with operations in \mathbf{I}_k then
 Put A_{r_i} in \mathbf{I}_k
 $V \leftarrow V - \{A_{r_i}\}$
 $S \leftarrow S - \{A_{r_i}\}$
 endif
 endfor
 $k \leftarrow k + 1$
 for each $A \in S$ do
 $\ell(A) \leftarrow \min\{\ell(A) + 1, L(A)\}$
 endfor
endwhile

```

Parallelization, Basic Block. Fig. 3 List scheduling algorithm

### Linear Analysis

The Linear Algorithm (Fig. 4) checks the operations of the basic block *linearly* in their order of appearance, and puts them into instructions observing dependence constraints and avoiding resource conflicts.

Arrange the operations in the block in their prescribed sequential order:  $A_1, A_2, \dots, A_n$ . For an easy description of the algorithm, it is convenient to assume that a control step could be any integer. Start with a sequence of empty instructions  $\{\mathbf{I}_k : -\infty < k < \infty\}$  arranged in an imaginary vertical column. The operations  $A_1, A_2, \dots, A_n$  are taken in this order and put in instructions one by one. At any point, all operations already scheduled are in a range of instructions  $(\mathbf{I}_t, \mathbf{I}_{t+1}, \dots, \mathbf{I}_b)$ , where  $t \leq 1$  and  $b \geq 1$ . The value of  $t$  keeps decreasing and the value of  $b$  keeps increasing. At the end of the algorithm, the final sequence  $(\mathbf{I}_t, \mathbf{I}_{t+1}, \dots, \mathbf{I}_b)$  can be renumbered to get a sequence of instructions  $(\mathbf{I}'_1, \mathbf{I}'_2, \dots, \mathbf{I}'_m)$ , where  $m = b - t + 1$ .

Both  $t$  and  $b$  are initialized to 1. The first operation  $A_1$  is put in instruction  $\mathbf{I}_1$ . Suppose operations  $A_1, A_2, \dots, A_{i-1}$  have already been scheduled, and the time has come to schedule  $A_i$ , where  $2 \leq i \leq n$ . Let  $k$  denote the smallest integer  $\geq t$ , such that all predecessors of  $A_i$  finish executing before control step  $k$ . If  $A_i$  has no predecessors, then  $k = t$ . Otherwise, if a predecessor  $A_r$  is in an instruction  $\mathbf{I}_j$ , where  $t \leq j \leq b$ , then  $k \geq j + c(A_r)$ . The exact value of  $k$  is found by taking the maximum of all such expressions.

So, operation  $A_i$  can be put in instruction  $\mathbf{I}_k$  without violating any dependence constraints. If  $k \leq b$ , start checking the instructions  $\mathbf{I}_k, \mathbf{I}_{k+1}, \dots, \mathbf{I}_b$ , in this order, for potential resource conflicts. If an instruction is there in this range with which  $A_i$  does not conflict, then put  $A_i$  in the first such instruction. Otherwise,  $A_i$  conflicts with all instructions in the range and  $k = b + 1$ . If  $k > b$  was true before the checking could start, then its value did not change. At this point, if  $A_i$  had no predecessors

**Algorithm 4** Given a basic block  $(A_1, A_2, \dots, A_n)$  of  $n$  operations, its dependence graph, and a machine with limited resources, this algorithm finds a schedule for the block. At any point in the algorithm, all scheduled operations lie in the sequence of instructions  $(\mathbf{I}_t, \mathbf{I}_{t+1}, \dots, \mathbf{I}_b)$ , where  $t \leq 1$  and  $b \geq 1$ .

```

 $t \leftarrow 1$
 $b \leftarrow 1$
Put the operation A_1 in instruction \mathbf{I}_1
for $i = 2$ to n do
 $k \leftarrow$ earliest control step $\geq t$ before which all predecessors of A_i finish executing
 while $k \leq b$ and A_i has a resource conflict with operations in \mathbf{I}_k do
 $k \leftarrow k + 1$
 endwhile
 if $k \leq b$ then
 put A_i in \mathbf{I}_k
 else
 if $\text{Pred}(A_i) = \emptyset$ then
 Put A_i in \mathbf{I}_{t-1}
 $t \leftarrow t - 1$
 else
 Put A_i in \mathbf{I}_k
 $b \leftarrow k$
 endif
 endif
endfor

```

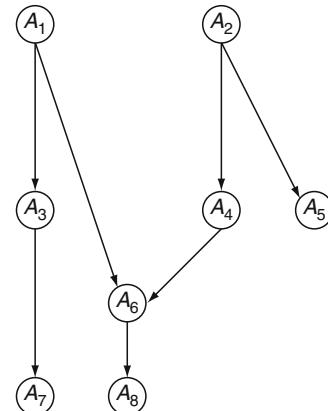

Parallelization, Basic Block. Fig. 4 The linear algorithm

in the first place, then put it at the top in instruction  $\mathbf{I}_{t-1}$  and decrease  $t$  to  $t - 1$ . If  $A_i$  had predecessors, then put it in instruction  $\mathbf{I}_k$  and increase  $b$  to  $k$ . The process ends when all operations in the given basic block have been scheduled.

### An Example

Consider a basic block  $\mathcal{B}$  consisting of eight operations  $A_1, A_2, \dots, A_8$  arranged in this order. The dependence graph of  $\mathcal{B}$  is given in Fig. 5. The type, cycle time, the immediate predecessors, and the immediate successors of each operation are listed in Table 1. It is assumed that the cycle time of an addition is 1, and that of a multiplication is 4. The four algorithms described in this essay are applied to  $\mathcal{B}$  one by one. The list scheduling and linear algorithms are customized for a machine with one adder and one multiplier. Note that the critical path in the dependence graph is  $A_2 \rightarrow A_4 \rightarrow A_6 \rightarrow A_8$ . Since its weight is  $T_0 = 10$ , the total number of cycles taken by each algorithm to process  $\mathcal{B}$  must be at least 10.

*ASAP Algorithm.* At the beginning, the ASAP label  $\ell(A_i)$  of each operation  $A_i$  is initialized to 1. Operations  $A_1$  and  $A_2$  have no predecessors. They keep their ASAP labels, that is, they are scheduled to start in control step 1. Since  $A_3$  and  $A_6$  are successors of  $A_1$ , and

Parallelization, Basic Block. Fig. 5 Dependence graph of basic block  $\mathcal{B}$

$A_4$  and  $A_5$  are successors of  $A_2$ , their ASAP values are increased as follows:

$$\begin{aligned}
 \ell(A_3) &\leftarrow \max\{\ell(A_3), \ell(A_1) + c(A_1)\} = \max\{1, 2\} = 2 \\
 \ell(A_6) &\leftarrow \max\{\ell(A_6), \ell(A_1) + c(A_1)\} = \max\{1, 2\} = 2 \\
 \ell(A_4) &\leftarrow \max\{\ell(A_4), \ell(A_2) + c(A_2)\} = \max\{1, 5\} = 5 \\
 \ell(A_5) &\leftarrow \max\{\ell(A_5), \ell(A_2) + c(A_2)\} = \max\{1, 5\} = 5.
 \end{aligned}$$

**Parallelization, Basic Block. Table 1** Details of the basic block of example 1

| OP A  | Type | c(A) | Pred(A)    | Succ(A)    | $\ell(A)$ | f(A) | L(A) | $\mu(A)$ |
|-------|------|------|------------|------------|-----------|------|------|----------|
| $A_1$ | +    | 1    |            | $A_3, A_6$ | 1         | 6    | 5    | 4        |
| $A_2$ | *    | 4    |            | $A_4, A_5$ | 1         | 10   | 1    | 0        |
| $A_3$ | +    | 1    | $A_1$      | $A_7$      | 2         | 2    | 9    | 7        |
| $A_4$ | +    | 1    | $A_2$      | $A_6$      | 5         | 6    | 5    | 0        |
| $A_5$ | +    | 1    | $A_2$      |            | 5         | 1    | 10   | 5        |
| $A_6$ | +    | 1    | $A_1, A_4$ | $A_8$      | 6         | 5    | 6    | 0        |
| $A_7$ | +    | 1    | $A_3$      |            | 3         | 1    | 10   | 7        |
| $A_8$ | *    | 4    | $A_6$      |            | 7         | 4    | 7    | 0        |

After  $A_1$  and  $A_2$  have been scheduled, operations  $A_3$ ,  $A_4$ , and  $A_5$  do not have any predecessors remaining to be scheduled. So, they can be scheduled in steps determined by their current ASAP values. Since  $A_7$  is a successor of  $A_3$  and  $A_6$  a successor of  $A_4$ , their ASAP values are increased as follows:

$$\begin{aligned}\ell(A_7) &\leftarrow \max\{\ell(A_7), \ell(A_3) + c(A_3)\} = \max\{1, 3\} = 3 \\ \ell(A_6) &\leftarrow \max\{\ell(A_6), \ell(A_4) + c(A_4)\} = \max\{2, 6\} = 6.\end{aligned}$$

After  $A_3$  and  $A_4$  have been scheduled, operations  $A_7$  and  $A_6$  do not have any predecessors remaining to be scheduled. So, they can be scheduled in steps determined by their current ASAP values. Since  $A_8$  is a successor of  $A_6$ , its ASAP value is increased as follows:

$$\ell(A_8) \leftarrow \max\{\ell(A_8), \ell(A_6) + c(A_6)\} = \max\{1, 7\} = 7.$$

After  $A_6$  has been scheduled, operation  $A_8$  does not have any predecessors remaining to be scheduled. So,  $A_8$  keeps its current ASAP value, and is scheduled to start in step 7. All the ASAP values are shown in Table 1.

The total number of control steps taken to execute  $\mathcal{B}$  is

$$\max_{1 \leq i \leq 8} [\ell(A_i) + c(A_i)] - 1 = 10.$$

The total number of instructions in the schedule is  $\max_i \ell(A_i) = 7$ . The instructions are  $(I_1, I_2, \dots, I_7)$ , where  $I_4$  is empty, and

$$\begin{aligned}I_1 &= \{A_1, A_2\}, I_2 = \{A_3\}, I_3 = \{A_7\}, \\ I_5 &= \{A_4, A_5\}, I_6 = \{A_6\}, I_7 = \{A_8\}.\end{aligned}$$

*ALAP Algorithm.* At the beginning,  $T$  is initialized to 0, and  $f(A_i)$  is initialized to 0 for each  $A_i$ . Since  $A_5$ ,  $A_7$ ,

and  $A_8$  have no successors,  $f(A_5)$ ,  $f(A_7)$ , and  $f(A_8)$  are increased as follows:

$$\begin{aligned}f(A_5) &\leftarrow f(A_5) + c(A_5) = 0 + 1 = 1 \\ f(A_7) &\leftarrow f(A_7) + c(A_7) = 0 + 1 = 1 \\ f(A_8) &\leftarrow f(A_8) + c(A_8) = 0 + 4 = 4.\end{aligned}$$

These operations have now been scheduled. The value of  $T$  is increased to 4. Since  $A_2$  is a predecessor of  $A_5$ ,  $A_3$  of  $A_7$ , and  $A_6$  of  $A_8$ , their  $f$  values are increased as follows:

$$\begin{aligned}f(A_2) &\leftarrow \max\{f(A_2), f(A_5)\} = \max\{0, 1\} = 1 \\ f(A_3) &\leftarrow \max\{f(A_3), f(A_7)\} = \max\{0, 1\} = 1 \\ f(A_6) &\leftarrow \max\{f(A_6), f(A_8)\} = \max\{0, 4\} = 4.\end{aligned}$$

Since  $A_3$  has no successors remaining to be scheduled,  $f(A_3)$  is changed as follows:

$$f(A_3) \leftarrow f(A_3) + c(A_3) = 1 + 1 = 2.$$

$A_3$  is now scheduled. The value of  $T$  remains unchanged at 4. Since  $A_1$  is a predecessor of  $A_3$ ,  $f(A_1)$  is increased as follows:

$$f(A_1) \leftarrow \max\{f(A_1), f(A_3)\} = \max\{0, 2\} = 2.$$

Since  $A_6$  has no successors remaining to be scheduled,  $f(A_6)$  is changed as follows:

$$f(A_6) \leftarrow f(A_6) + c(A_6) = 4 + 1 = 5.$$

$A_6$  is now scheduled. The value of  $T$  is increased from 4 to 5. Since  $A_1$  and  $A_4$  are predecessors of  $A_6$ , their  $f$  values are increased as follows:

$$\begin{aligned}f(A_1) &\leftarrow \max\{f(A_1), f(A_6)\} = \max\{2, 5\} = 5 \\ f(A_4) &\leftarrow \max\{f(A_4), f(A_6)\} = \max\{0, 5\} = 5.\end{aligned}$$

Now  $A_1$  and  $A_4$  do not have any successors remaining to be scheduled. Their  $f$  values are increased again as follows:

$$\begin{aligned}f(A_1) &\leftarrow f(A_1) + c(A_1) = 5 + 1 = 6 \\f(A_4) &\leftarrow f(A_4) + c(A_4) = 5 + 1 = 6.\end{aligned}$$

These two operations are now scheduled. The value of  $T$  is increased from 5 to 6. Since  $A_2$  is a predecessor of  $A_4$ ,  $f(A_2)$  is increased from 1 to  $f(A_4)$  or 6.

Since  $A_2$  now has no successors remaining to be scheduled,  $f(A_2)$  is increased again by  $c(A_2)$  to 6 + 4, or 10. The value of  $T$  is also increased from 6 to 10. Now that the value of  $T$  (total number of cycles), and the value of  $f(A_i)$  for each  $A_i$  are known, the ALAP labels are computed from the equation  $L(A) = T+1-f(A)$ . The values of  $f(A_i)$  and  $L(A_i)$  for each  $A_i$  are shown in Table 1.

The total number of instructions in the schedule is  $\max_i L(A_i) = 10$ . The instructions are  $(I_1, I_2, \dots, I_{10})$ , where  $I_2, I_3, I_4, I_8$  are empty, and

$$\begin{aligned}I_1 &= \{A_2\}, \quad I_5 = \{A_1, A_4\}, \quad I_6 = \{A_6\}, \\I_7 &= \{A_8\}, \quad I_9 = \{A_3\}, \quad I_{10} = \{A_5, A_7\}.\end{aligned}$$

*List Scheduling Algorithm.* Initially,  $V$  has all 8 operations. The initial value of the mobility of each operation is listed in Table 1. At step 1,  $S = \{A_1, A_2\}$ . The operations are arranged in the order  $(A_2, A_1)$ , since  $\mu(A_2) < \mu(A_1)$ . Both operations can be put in instruction  $I_1$ , since there is no resource conflict between them. At step 2,  $S = \{A_3\}$ . So,  $A_3$  goes into  $I_2$ . Similarly,  $A_7$  goes into  $I_3$ . At step 4,  $S = \emptyset$ . At step 5,  $S = \{A_4, A_5\}$ . The operations are arranged in this order, since  $\mu(A_4) < \mu(A_5)$ . Only  $A_4$  can be put into  $I_5$ . Take  $A_4$  out of  $S$  and decrease  $\mu(A_5)$  to 4. At step 6,  $S = \{A_5, A_6\}$ . The operations are arranged in the order  $(A_6, A_5)$ , since  $\mu(A_6) < \mu(A_5)$ . Only  $A_6$  can be put into  $I_6$ . Decrease  $\mu(A_5)$  to 3. At step 7,  $S = \{A_5, A_8\}$ . The operations are arranged in the order  $(A_8, A_5)$ , since  $\mu(A_8) < \mu(A_5)$ . Both operations can be put in instruction  $I_7$  since there is no resource conflict between them. The total number of instructions in the schedule for  $B$  is 7. Those instructions are  $(I_1, I_2, \dots, I_7)$ , where

$$\begin{aligned}I_1 &= \{A_1, A_2\}, \quad I_2 = \{A_3\}, \quad I_3 = \{A_7\}, \quad I_4 = \emptyset, \\I_5 &= \{A_4\}, \quad I_6 = \{A_6\}, \quad I_7 = \{A_5, A_8\}.\end{aligned}$$

Total number of cycles =  $[7 + \max\{c(A_5), c(A_8)\} - 1] = 10$ .

*Linear Algorithm.* Initially,  $t = b = 1$ . Put operation  $A_1$  in instruction  $I_1$ . Since  $A_2$  has no predecessors and does not conflict with  $A_1$ , put  $A_2$  also in  $I_1$ . Operation  $A_3$  has only one predecessor, namely,  $A_1$ . Since  $c(A_1) = 1$ ,  $A_3$  can be put in instruction  $I_2$ . Increase  $b$  to 2. The sole predecessor of  $A_4$  is  $A_2$  and  $c(A_2) = 4$ . Hence,  $A_4$  can go into instruction  $I_5$ . Increase  $b$  to 5. Operation  $A_5$  also has  $A_2$  as its only predecessor. But,  $A_5$  cannot go into  $I_5$ , since it conflicts with  $A_4$ . So, put  $A_5$  in  $I_6$  and increase  $b$  to 6. Operation  $A_6$  has two predecessors:  $A_1$  and  $A_4$ . The earliest instruction that can take  $A_6$  without violating dependence constraints is  $I_6$ . But  $I_6$  already has  $A_5$  and it conflicts with  $A_6$ . So, put  $A_6$  in  $I_7$  and increase  $b$  to 7. Now it is easy to see that  $A_7$  can go into  $I_3$  and  $A_8$  into  $I_8$ . Increase  $b$  to 8.

The total number of instructions in the schedule for  $B$  is 8. Those instructions are  $(I_1, I_2, \dots, I_8)$ , where

$$\begin{aligned}I_1 &= \{A_1, A_2\}, \quad I_2 = \{A_3\}, \quad I_3 = \{A_7\}, \quad I_4 = \emptyset, \\I_5 &= \{A_4\}, \quad I_6 = \{A_5\}, \quad I_7 = \{A_6\}, \quad I_8 = \{A_8\}.\end{aligned}$$

Total number of cycles =  $[8 + c(A_8) - 1] = 11$ .

## Bibliographic Notes and Further Reading

Basic block parallelization was first studied in the context of microprogramming. The book by Agerwala and Rauscher [1] gives a good introduction to microprogramming. The theory of job scheduling in operations research turned out to be a rich source of algorithms for the microprogramming research community [3, 4, 7]. For linear analysis and list scheduling as covered in this entry, a good place to start is the paper by Landskov and others [8]. (The algorithms presented above try to factor in explicitly the cycle times of operations.) Other standard references are [2, 5, 6, 10].

Only two algorithms are given in this entry for the limited resource case; there are many more. For example, for Force-directed Scheduling, see [9].

The ten references listed here constitute a small percentage of what is available.

## Definition

PARDISO, short for “PARallel DIrect SOLver,” is a thread-safe software library for the solution of large

sparse linear systems of equations on shared-memory multicore architectures. It is written in Fortran and C and it is available at [www.pardiso-project.org](http://www.pardiso-project.org). The solver implements an efficient supernodal method, which is a version of Gaussian elimination for large sparse systems of equations, especially those arising, for example, from the finite element method or in nonlinear optimization. It is the only sparse solver package that supports all kinds of matrices such as complex, real, symmetric, nonsymmetric, or indefinite. PARDISO can be called from various environments including MATLAB (via MEX), Python (via pypardiso), C/C++, and Fortran. PARDISO version 4.0.0 was released in October 2009.

## Discussion

### Introduction

The solution of large sparse linear systems lies at the heart of many calculations in computational science and engineering and is also of increasing importance in computations in the medical imaging and financial sectors. Today, systems of equations with millions to hundreds of millions of unknowns are solved. To do this within reasonable time requires efficient use of powerful parallel computers and advanced combinatorial and numerical algorithms based on direct or approximate direct factorizations. To date, only very limited software for such large systems is generally available. The PARDISO software addresses this issue.

In this chapter, some important combinatorial aspects and main algorithmic features for solving sparse systems will be reviewed. The algorithmic improvements of the past 20 years have reduced the time required to factor general sparse matrices by almost three orders of magnitude. Combined with significant advances in the performance to cost ratio of computing hardware during this period, current sparse solver technology makes it possible to solve those problems quickly and easily, which might have been considered by far too large until recently. This chapter discusses the basic and the latest developments for sparse direct solution methods that have lead to modern *LU* decomposition techniques.

The PARDISO development started in the context of a PhD Project [12] at ETH Zurich in Switzerland.

The first aim was to improve parallel sparse factorization methods for highly ill-conditioned matrices arising in the semiconductor device simulation area. The close collaboration with the simulation community resulted in a large amount of test cases and industrial use of the solver.

The library version of PARDISO is publicly released since March 2004. Ongoing research projects resulted in the current version 4.0.0, available since October 2009. This new version also includes novel state-of-the-art incomplete factorization-type preconditioners. The results of the research have appeared in several scientific journals, including the paper “On Large Scale Diagonalization Techniques for the Anderson Model of Localization” in the SIGEST section of the SIAM Review Journal [13].

It is the purpose of this chapter to describe the main combinatorial and numerical algorithms used in an efficient parallel solver.

### Sparse Gaussian Elimination in PARDISO

To introduce the notations, the LU-factorization of a nonsymmetric matrix  $A$  with pivoting is described. A simple description of the algorithm for solving sparse linear equations by sparse Gaussian elimination in PARDISO is as follows:

- Compute the triangular factorization  $P_r D_r P_f A P_f^T = L U$ . Here  $D_r$  and  $D_c$  are diagonal matrices to equilibrate the system,  $P_f$  is a permutation matrix that minimizes the number of nonzeros in the factor, and  $P_r$  and  $P_c$  are permutation matrices. Premultiplying  $A$  by  $P_r$  reorders the rows of  $A$ , and premultiplying  $A$  by  $P_c$  reorders the columns of  $A$ .  $P_r$  and  $P_c$  are chosen to enhance sparsity, numerical stability, and parallelism.  $L$  is a unit lower triangular matrix with  $L_{ii} = 1$  and  $U$  is an upper triangular matrix.
- Solve  $AX = B$  by evaluating

$$X = A^{-1}B = (P_f^{-1}D_r^{-1}P_r^{-1}LUP_c^{-1}D_c^{-1}P_f^{-T})^{-1}B,$$

$$X = P_f^T D_c P_c U^{-1} L^{-1} P_r D_r P_f B.$$

This is done efficiently by multiplying from right to left in the last expression: the rows of  $B$  are permuted with  $P_f$  and scaled by  $D_r$ . Multiplying  $P_r B$  means permuting the rows of  $D_r B$ . Multiplying  $L^{-1}(P_r D_r B)$  means solving triangular systems of equations with

$n_r$  right-hand sides with matrix  $L$  by substitution. Similarly, multiplying  $U^{-1}(L^{-1}(P_r D_r P_f B))$  means solving triangular systems with  $U$ .

For symmetric indefinite matrices, PARDISO performs a numerical factorization into  $LDL^T$ , in which the factorization is also stabilized by extended numerical pivoting techniques. In addition to the complete factorization, advanced support for incomplete inverse-based factorization preconditioners, in which the factors are computed approximately, are also included in PARDISO.

The efficient computation of the  $LU$  decomposition is of utmost importance in Gaussian elimination. Typically, a compact representation of the elimination tree can be used to derive all information concerning fill-in and numerical dependencies. In particular, the fact that pivoting and the factorization must be interlaced requires a completely different treatment than in the case without pivoting. Consider the situation when computing the  $LU$  decomposition column by column.

---

for  $k = 1, \dots, n$

update column  $k$  of  $L$  and  $U$  via the equation  $A_{1:n,k}$   
 $= L_{1:n,1:k-1} U_{1:k-1,k} - L_{1:n,k} u_{kk}$

1. step. solve  $L_{1:k-1,1:k-1} U_{1:k-1,k} = A_{1:k-1,k}$
2. step.  $L_{k:n,k} := A_{k:n,k}$   
 for  $i < k$  such that  $u_{ik} \neq 0$   
 $L_{k:n,k} := L_{k:n,k} - L_{k:n,i} u_{ik}$
3. step.  $u_{kk} = l_{kk}$   
 $L_{k:n,k} = L_{k:n,k} / u_{kk}$

---

Note that it is easy to add pivoting after step 2 by interchanging  $l_{kk}$  with some sufficiently large  $|l_{mk}|$ , where  $m \geq k$  before  $u_{kk}$  is defined. The art of efficiently computing column  $k$  of  $L$  and  $U$  consists of how the sparse forward solve  $L_{1:k-1,1:k-1} U_{1:k-1,k} = A_{1:k-1,k}$  in step 1 is efficiently implemented and, a fast update of  $L_{k:n,k}$  in step 2.

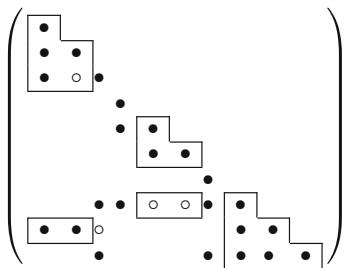

The dense  $LU$  decomposition as it is described so far can be implemented in a way that it makes heavily use of level-3 BLAS. One important aspect that allows raising efficiency and speeding up the sparse numerical factorization will be discussed now. It is the recognition

of an underlying block structure with dense submatrices caused by the factorization and the fill. The block structure allows to collect parts of the matrix in dense blocks and to treat them commonly using higher levels of BLAS. As a consequence of the LU decomposition, parts of the triangular factors can be encountered that are dense or become dense by the factorization. This key structure in sparse Gaussian elimination is based on supernodal representation of the columns and rows in the factors  $L$  and  $U$ . A sequence  $k, k+1, \dots, k+s-1$  of  $s$  subsequent columns in  $L$  that form a dense lower triangular matrix is called a supernode.

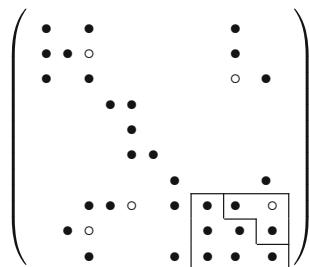

To illustrate the use of supernodes, Figs. 1 and 2 illustrate the underlying dense block structure.

Supernodes in PARDISO are stored in rectangular dense matrices. Beside the storage scheme as dense matrices, the nonzero row indices for these blocks need only be stored once. Next, the use of dense submatrices allows the usage of level-3 BLAS routines. To understand this, one can easily verify that the update process

$$L_{k:n,k} := L_{k:n,k} - L_{k:n,i} u_{ik}$$

**PARDISO. Fig. 1** Supernodes in  $L$ , symmetric case  
("○" denotes fill-in)

**PARDISO. Fig. 2** Supernodes in  $L + U$ , general case  
("○" denotes fill-in)

that computes  $L_{k:n,k}$  in the algorithm can easily be extended to the block case. Assuming that columns  $1, \dots, k+s-1$  are collected in  $p$  supernodes with column indices  $\mathcal{K}_1, \dots, \mathcal{K}_p$ . Apparently, the column set is  $\mathcal{K}_p = \{1, \dots, k+s-1\}$ . Then updating  $L_{k:n,\mathcal{K}_p}$  can be rewritten as

$$L_{k:n,\mathcal{K}_p} := L_{k:n,\mathcal{K}_p} - L_{k:n,i} U_{\mathcal{K}_i, \mathcal{K}_p},$$

where the sum has to be taken over all  $i$  in the block version of the elimination tree. Depending on whether one would like to compute the diagonal block  $L_{\mathcal{K}_p, \mathcal{K}_p}$  as full or as lower triangular matrix one is able to use level-2 BLAS or even level-3 BLAS subroutines. This allows exploiting machine-specific properties, such as caches to accelerate the computation.

As discussed above, dynamic pivoting has been a central tool by which nonsymmetric sparse linear solvers gain stability. Therefore, improvements in speeding up direct factorization methods were limited to the uncertainties that have arisen from using pivoting. Certain techniques, like the column elimination tree [2], have been useful for predicting the sparsity pattern despite pivoting. However, in the symmetric case, the situation becomes more complicated since only symmetric reorderings, applied to both columns and rows, are required, and no a priori choice of pivots is given. This makes it almost impossible to predict the elimination tree in a sensible manner, and the use of cache-oriented level-3 BLAS is impossible.

With the introduction of symmetric maximum weighted matchings [16] as an alternative to complete pivoting [3], it is now possible to treat symmetric indefinite systems similarly to symmetric positive definite systems. This allows to predict fill using the elimination tree, and thus allows to set up the data structures that are required to predict dense submatrices (also known as supernodes). This in turn means that one is able to exploit level-3 BLAS applied to the supernodes. Consequently, the classical Bunch–Kaufman pivoting approach needs to be performed only inside the supernodes.

This approach has recently been successfully implemented in symmetric indefinite version of PARDISO [16]. As a major consequence of this novel approach, the sparse indefinite solver has been improved to become almost as efficient as its symmetric positive counterpart.

Finally, iterative refinement is the last option to test and enhance the precision of the solution. To encourage the use of  $L$  and  $U$  as preconditioner in solving continuously dependent families of problems, PARDISO also offers a CG and CGS branch.

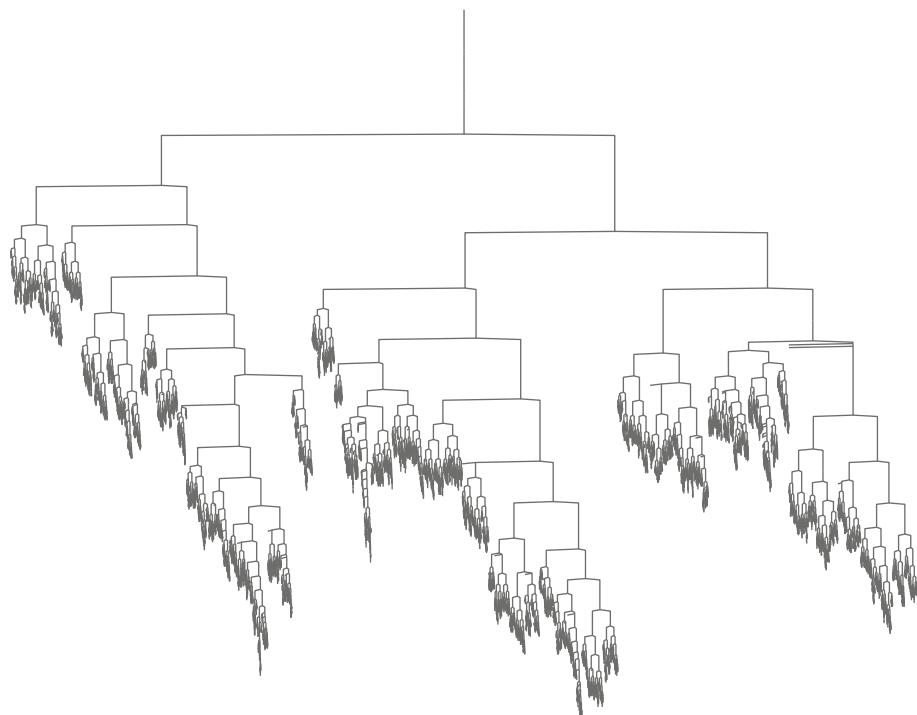

## Reordering Algorithms and Software in PARDISO

The efficiency of a direct solver depends strongly on the order in which the variables of the matrix are eliminated. This largely determines the computational amount of work executed during the numerical factorization and hence the overall time for the solution. Furthermore, the elimination order of the variables also determines the number of entries in the computed factors and the amount of main storage required. Experiments have shown that the multiple minimum degree (MMD) algorithm of J. Liu [8] is very well suited for 2D problems, but nested dissection type orderings do a much better job on larger problems from 3D discretizations. Thus, the ordering METIS package from Karypis and Kumar [7] and a constrained minimum fill-in orderings developed by Schenk and Gärtner [12] have

been added to PARDISO. In a somewhat more loosely coupled way, orderings from other packages such as approximate minimum degree [1] can also be used.

## Parallelization Strategies in PARDISO

Parallelism can be expressed by the elimination tree: different branches are independent (see Fig. 3). The length of each vertical line is proportional to the size of a dense diagonal block. The height counted in levels characterizes the longest chain of sequentially depending steps. Memory writes should be minimized and asynchronous scheduling is possible in PARDISO on SMP and NUMA architectures. It is used to reduce load balance requirements. Hence, the small amount of synchronization data is passed towards the root (or to the right in  $L$ ,  $U$ ), while the numerical data is read from the left of the actual supernode. Especially large supernodes close to the root of the elimination tree are split into panels to increase the number of parallel tasks. PARDISO uses METIS by default to generate nested dissection permutations and maps all sparse computations on dense matrix operations to achieve level-3 BLAS performance for the numerical factorization. Scheduling

PARDISO. Fig. 3 Typical elimination tree with a MMD reordering

distinguishes two levels in the elimination tree to reduce synchronization events: updates within the lower level are conflict free, hence must not be synchronized. In PARDISO, complete lower level subtrees of the elimination are mapped onto a single core of the multiprocessing architecture. The columns and rows associated with this complete subtree are factorized independently with respect to other subtrees. The nodes near the root of the elimination tree normally involve more computation than supernodes further away from the root. In practical examples more than 75% of the floating-point computations are performed on the supernodes close to the root of the tree. Unfortunately, the number of independent supernodes near the root of the tree is small, and so there is less parallelism to exploit. For example, the root in Fig. 3 has only two neighboring nodes and hence only two processors would perform the corresponding work while the other processors remain idle. The introduction of the panels and the execution of partial updates as tasks for supernodes close to the root increases the parallelism.

An additional constraint that has to be taken into account is that PARDISO is designed to solve a wide range of application problems including symmetric and nonsymmetric matrices, and numerical pivoting is performed within the numerical factorization. This means that only a static analysis of the sparsity pattern and a static allocation of supernodes to cores could be very inefficient if numerical pivoting is required. As a solution, a novel left-right looking factorization has been implemented that uses a dynamic allocation of threads during the numerical factorization. This has the benefit of enabling the linear scalability of the code to perform well on multicore architectures with up to 16 cores. The parallel execution in PARDISO does not change the constant in the leading order of the complexity bound compared with that of the sequential algorithm.

### Approximate Sparse Gaussian Factorization in PARDISO

The solver also includes a novel preconditioning solver [13]. The preconditioning approach for symmetric indefinite linear system is based on maximum weighted matchings and algebraic multilevel incomplete  $LDL^T$  factorization. These techniques can be seen as a complement to the alternative idea of using more complete

pivoting techniques for the highly ill-conditioned symmetric indefinite matrices. In considering how to solve the linear systems in a manner that exploits sparsity as well as symmetry, a diverse range of algorithms is used that includes preprocessing the matrix with symmetric weighted matchings, solving the linear system with Krylov subspace methods, and accelerating the linear system solution with multilevel preconditioners based upon incomplete inverse-based factorizations.

### General Software Issues in PARDISO

The PARDISO package was originally designed for structurally symmetric matrices arising in the semiconductor device simulation area, but, in the newer version, all other types of matrices such as real and complex symmetric, real or complex nonsymmetric systems, or complex Hermitian systems are permitted. The PARDISO software is written in C and Fortran. However, in recognition that some users prefer a Matlab or Python programming environment, an appropriate interface has been developed for these programming languages.

It requires OpenMP threading capabilities and makes heavy use of level-3 BLAS and LAPACK subroutines. For the parallel version of PARDISO, a single-threaded version of level-3 BLAS and LAPACK routines is used. PARDISO has been ported to a wide range of computers from previous generations of vector-computers such as Cray or NEC, to all kind of multicore architectures including Intel, AMD, IBM, SUN, and SGI [15] and also to recent throughput manycore processors such as GPUs from NVIDIA [14].

The PARDISO package has an excellent performance relative to other parallel sparse solvers. An extensive evaluation of the performance of the numerical factorization in comparison to a wide range of other sparse direct linear solver packages is given by Gould, Hu, and Scott [4]. Other independent comparisons can be found in [5]. PARDISO is currently heavily used in linear and nonlinear optimization solvers. Recent results can be found in [17]. The current version of the solver and a manual including several examples is available at [www.pardiso-project.org](http://www.pardiso-project.org).

### Example

The example illustrates the complexity gap between numerical factorization and solution in the sparse direct

solution process. As shown in [Table 1](#), the numerical factorization is the most time-consuming phase. This is demonstrated on a 3D eigenvalue problem. The symmetric eigenvalue problem  $Ax = \lambda Bx$  is chosen with up to  $3.5 \times 10^6$  unknowns to be close to the size limits of a today's 128 GB SMP machines.

The eigenvalue problem is solved by inverse iteration, polynomial acceleration, a few different spectral shifts, and the same number of factorizations. On average, five eigenvalues are computed per factorization. The spectral shifts can be chosen to result in

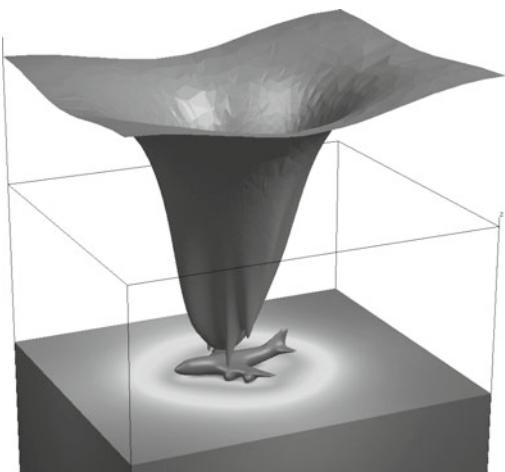

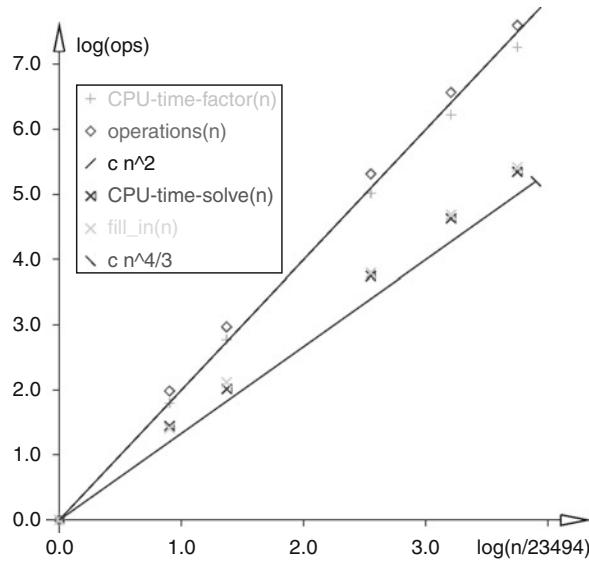

**PARDISO. Table 1** The serial computational complexity of the various phases of solving a sparse system of linear equations arising from 2D and 3D constant node-degree graphs with  $n$  vertices

| Phase                   | Dense    | 2D complexity | 3D complexity |
|-------------------------|----------|---------------|---------------|
| Reordering:             | –        | $O(n)$        | $O(n)$        |
| Symbolic factorization  | –        | $O(n \log n)$ | $O(n^{4/3})$  |
| Numerical factorization | $O(n^3)$ | $O(n^{3/2})$  | $O(n^2)$      |
| Triangular solution     | $O(n^2)$ | $O(n \log n)$ | $O(n^{4/3})$  |

highly ill-conditioned but sufficiently regular sparse linear systems. The symmetric indefinite linear systems are solved by the Bunch-Kaufman pivoting. The quadratic complexity of the sparse direct factorization is shown in [Fig. 4](#).

## Future Research Directions

Clearly, the quadratic complexity bound is limiting the problem size in 3D for sparse direct methods. However, from the user perspective, the robustness and the nearly achieved black box behavior are very convenient. The emergence of multicore architectures and scalable petascale architectures does not change both points. Instead, it motivates the development of novel algorithms and techniques that emphasize both concurrency and robustness for the solution of sparse linear systems. Since direct solvers do not generally scale to large problems and machine configurations, efficient application of preconditioned iterative solvers are warranted but involve more a priori knowledge. These hybrid solvers must optimize parallel performance, processor (serial) performance, as well as memory requirements, while being robust across specific classes of applications and systems.

**PARDISO. Fig. 4** Unstructured tetrahedral meshes with  $n = 23'494, 57'869, 92'328, 300'608, 579'150$  and  $996'557$  tetrahedra for a discrete Laplace problem. The left graphic shows the measured times for the numerical factorization and the solution, the number of floating-point operations, and the complexity bounds. The first eigenvector is shown in the right graphic. The selfsimilar tetrahedral meshes are generated by TetGen, <http://www.tetgen.org>

The research groups at Purdue University and University of Basel are currently developing a new parallel solver PSPIKE [10] that combines the desirable characteristics of direct methods (robustness) and effective iterative solvers (low computational cost), while alleviating their drawbacks (limited scalability, memory requirements, lack of robustness). The hybrid solver is based on the general sparse solver PARDISO and the Spike family of hybrid solvers [11]. The resulting PSPIKE algorithm is an extension of PARDISO to distributed-memory architectures. Results can be found in, for example, [10].

## PASM Parallel Processing System

HOWARD JAY SIEGEL, BOBBY DALTON YOUNG  
Colorado State University, Fort Collins, CO, USA

### Definition

PASM was a partitionable mixed-mode parallel system designed and prototyped in the 1980s at Purdue University to study three dimensions of dynamic reorganization: mixed-mode parallelism, partitionability, and flexible interprocessor communications.

### Discussion

#### Introduction

PASM was a partitionable mixed-mode parallel system designed and prototyped in the 1980s at Purdue University [20, 21]. Research was conducted about numerous software, hardware, parallel algorithm, and application aspects of PASM.

In the 1980s, two of the dominant organizations for parallel machines were “SIMD” and “MIMD” [8]. Be forewarned that our use of the term “SIMD” is more general than the way it is used with current multi-core systems, where it refers to operating on subfields of a long data word within a single processor. We will use the following definition: An SIMD (single instruction stream, multiple data stream) machine consists

of N processor-memory pairs, an interconnection network, and a control unit. The *control unit* broadcasts a sequence of instructions to the N processors that execute these instructions in lockstep (this is the “single instruction stream”). All “enabled” (active) processors execute the same instruction at the same time, but each processor does it on its own data. The operands for these instructions are fetched from the local memory associated with each processor (the fetching of operands from the collection of local memories form the “multiple data streams”). The *interconnection network* supports inter-processor communication. Thus, the SIMD definition used here assumes a collection of separate processors operating in lockstep, with all enabled processors following the same single instruction stream, but each processor operating on its own local data, resulting in multiple data streams. Examples of SIMD systems that have been constructed are Illiac IV [6], MasPar MP-1 and MP-2 [5], and MPP [4].

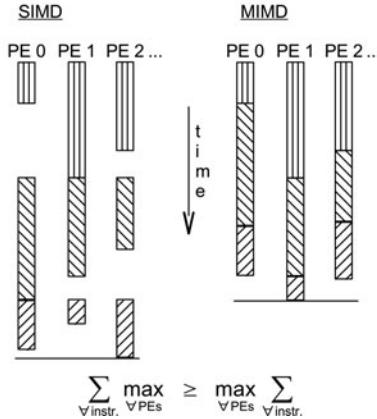

A *multiple-SIMD* system can be structured as a single SIMD machine or as two or more independent SIMD machines of various sizes. The Thinking Machines CM-2 [23] and original design of the Illiac IV [3] are examples of MSIMD systems.

The *MIMD* (multiple instruction stream, multiple data stream) mode of parallelism [8] uses N independent processor-memory pairs that can communicate via an interconnection network (i.e., a multicomputer). Each processor fetches its own instructions and its own operands from its local memory; thus, there are “multiple instruction streams” and “multiple data streams.” The nCUBE 2 [9] and IBM RP3 [15] are examples of MIMD systems that have been constructed. One mode of operation possible for MIMD is *SPMD* (single program, multiple data stream), where all processors independently execute the same program on different data sets [13].

A *mixed-mode* system can dynamically change between the SIMD and MIMD modes of parallelism at instruction-level granularity with negligible overhead. This allows different modes of parallelism to be used to execute various portions of an algorithm. Because the mode of parallelism has an impact on performance (see Fig. 1), a mixed-mode system may outperform a single-mode machine with the same number of processors for a given algorithm. A *partitionable mixed-mode* system can dynamically restructure to form independent

- SIMD Advantages**
- Ease of programming and debugging
    - SIMD: single program, PEs operate synchronously
    - MIMD: multiple interacting programs, PEs operate asynchronously
  - Overlap loop control with operations
    - SIMD: control unit does increment and compare while PEs “compute”
    - MIMD: same processor does both
  - Overlap operations on common data
    - SIMD: control unit performs operations that all PEs need (e.g., common local array addresses) while PEs “compute”
    - MIMD: same processor does all
  - Reduced inter-PE transfer overhead
    - SIMD: “send” and “receive” automatically synchronized
    - MIMD: need explicit synchronization and identification protocol
  - Minimal synchronization overhead
    - SIMD: implicit in program
    - MIMD: need explicit statements (e.g., semaphores)
  - Less program memory space required
    - SIMD: store one copy of program
    - MIMD: each PE stores own copy
  - Minimal instruction decoder cost
    - SIMD: decoder in control unit
    - MIMD: decoder in each PE

- MIMD Advantages**
- More flexible
    - No constraints on operations that can be performed concurrently
  - Conditional statements more efficient
    - SIMD: “then” and “else” execution serialized
    - MIMD: each PE executes as if uniprocessor
  - No SIMD control unit cost
  - Variable-time instructions more efficient
    - Assume there is a block of instructions where the execution time of each instruction is data dependent
    - SIMD: waits for slowest PE to execute each instruction (“sum of maxes”)
 
$$T_{\text{SIMD}} = \sum_{\forall \text{ instr. } \forall \text{ PEs}} \max(\text{instr. time})$$
    - MIMD: waits for slowest PE to execute block of instructions (“max of sums”)
 
$$T_{\text{MIMD}} = \max_{\forall \text{ PEs}} \sum_{\forall \text{ instr. }} (\text{instr. time})$$
  - Example: execution of three instructions in SIMD mode and MIMD mode

**PASM Parallel Processing System.** Fig. 1 Trade-offs between the SIMD and MIMD modes of parallelism [2]. Processing Elements (PEs) are processor-memory pairs. Examples of variable-time instructions are floating-point operations on the prototype’s Motorola MC68000 processors, and function calls (such as floating-point trigonometric operations) on current GPUs

or communicating submachines of various sizes, where each submachine can independently perform mixed-mode parallelism (e.g., TRAC [10]).

PASM is a PArtitionable-SIMD/MIMD system concept that was developed at Purdue University as a design for a large-scale partitionable mixed-mode machine based on commodity microprocessors [21]. PASM used a flexible multistage interconnection network for interprocessor communication. Thus, PASM could be dynamically reorganized along these three dimensions: partitionability, mode of parallelism, and connections among processors. This ability to be reorganized

allowed the system to match the computational structure of a problem, and also provided for fault tolerance in many situations. This fault tolerance is a form of robustness [1, 17], where the robust behavior requirement is continued system operation given the uncertainty of any single component failure, and quantified as the portion of the system that can still be used after a fault occurs.

A small-scale prototype was completed in 1987 as a proof-of-concept machine for the PASM design ideas, and was still running in 1995, with over 36,000 hours of execution time logged (Fig. 2) [20]. It was used

**PASM Parallel Processing System. Fig. 2** A photograph of the completed PASM prototype circa 1987 and some of the PASM team. *Left to right: Pierre Perrot (Technician), Tom Casavant (Professor), Wayne Nation (PhD Student), H.J. Siegel (Professor, team leader)*

for research and in a parallel programming course at Purdue. The goal of the PASM research team was to design, develop, and build a unique research tool for studying the combined three dimensions of dynamic reorganization mentioned above: mixed-mode parallelism, partitionability, and flexible interprocessor communications.

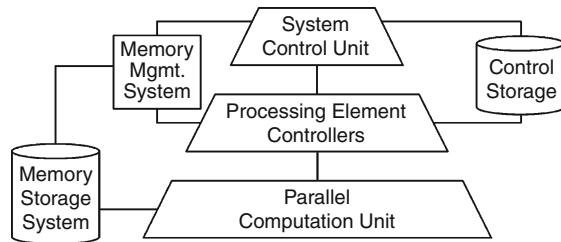

An overview of the organization of PASM is given in section “►The Overall PASM Organization.” Section “►The Parallel Computation Unit” describes the processing elements, memory, and interconnection network in the Parallel Computation Unit. The Memory Storage and Memory Management Systems are discussed in section “►The Memory Storage and Management Systems.” Section “►Using the PASM System” mentions some PASM prototype software tools and application studies. We conclude in section “►Conclusions” with a list of advantages of the PASM approach. A list of PASM-related publications is available at <http://hdl.handle.net/10217/34662>.

### The Overall PASM Organization

The PASM concept was a distributed-memory machine with a computational engine consisting of processor-memory pairs referred to as *PEs* (Processing Elements). The PASM design concepts could support at least 1,024 PEs. The small-scale prototype built at Purdue University (30 Motorola MC 68,000 processors, 16 in

the computational engine) supported experimentation with all three dimensions of reconfigurability mentioned earlier, and produced insights not observed from earlier simulations and theoretical studies.

The PASM system concept consists of six basic components shown in Fig. 3. The *System Control Unit* is the overall system coordinator and is the part of PASM with which the user directly interacts. The *Q PE Controllers (PECs)* serve as the PE control units in SIMD mode and may coordinate the PEs in MIMD mode. The *Parallel Computation Unit* contains the  $N = 2^n$  PEs, physically numbered 0 to  $N - 1$ , and the interconnection network used by the PEs. The *Memory Storage System* provides secondary storage for the PEs, and consists of  $N/Q$  secondary storage devices, each with an associated processor for file management. It is used to store data files for SIMD mode and both program and data files for MIMD mode. The *Memory Management System* contains multiple processors for controlling the transferring of files between the Memory Storage System and the PEs. *Control Storage* consists of a secondary storage device and an associated file server processor. It supports the PECs and the System Control Unit by holding all code and data used by these components, including the instructions to be broadcast to the PEs from the PECs in SIMD mode. The PASM prototype had a total of 30 processors:  $N = 16$  PEs,  $Q = 4$  PECs,  $N/Q = 4$  Memory Storage System processors, four Memory Management

**PASM Parallel Processing System.** Fig. 3 The high-level architectural organization of the PASM design concept

System processors, the Control Storage processor, and the System Control Unit.

The tasks to be performed by the System Control Unit include support for program development, job scheduling, general system coordination, management of system configuration and partitioning, assignment of user jobs to submachines, and connection to the host computer network. The hardware needed to combine and synchronize the PECs and PEs to form SIMD submachines of various sizes resides in the System Control Unit. Its functions include combining information from multiple PECs when collective conditionals, discussed in the next section, are performed. It also is responsible for coordinating the loading of the PE memories from the Memory Storage System with the loading of the PEC memories from the Control Storage.

We now describe how the PECs are connected to the PEs, and how this connection scheme is used to form independent mixed-mode submachines. The organization we use provides an efficient PEC/PE interface and supports the partitioning of the PE Interconnection Network.

The PECs, shown in Fig. 4, are the multiple control units required to form a multiple-SIMD system. There are  $Q = 2^q$  PECs, physically numbered from 0 to  $Q - 1$ . Each PEC controls a fixed group of  $N/Q$  PEs in the Parallel Computation Unit. A PEC and its associated PEs form a *PEC Group*. PEC  $i$  is connected to the  $N/Q$  PEs whose low-order  $q$  bits of their PE physical number have the value  $I$  (for reasons discussed in section “►The Parallel Computation Unit”). In an  $N = 1,024$  system,  $Q$  may be 32; for the  $N = 16$  prototype,  $Q = 4$ . Figure 5 shows the composition of the physical number of a PE.

The memory units in each PEC are double-buffered so that computation and memory I/O can be overlapped

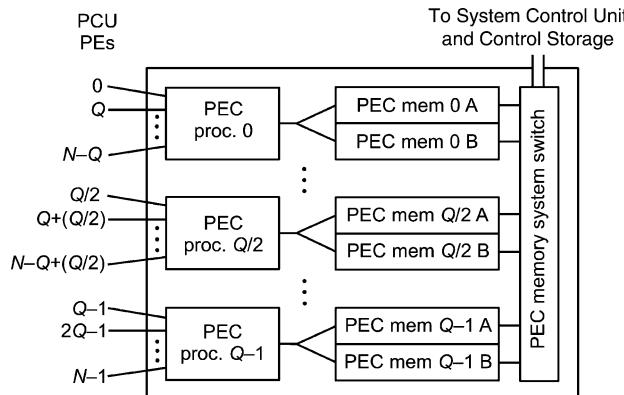

(see Fig. 4). For example, the PEC processor can execute a job in one memory unit while the next job is preloaded into the other memory unit from PEC secondary storage (the Control Storage). In MIMD mode, a PEC fetches from its memory the instructions and data used to coordinate the operation of its PEs. In SIMD mode, a PEC fetches the instructions and common PE data from its memory units. In general, in SIMD mode, control-flow instructions are executed in the PEC, and data processing instructions are broadcast to the PEC’s group of PEs.

*Submachines* are formed by one or more PEC Groups. The partitioning rule in PASM is that the numbers of all PEs in a submachine of size  $2^p$  must agree in their  $n - p$  low-order bit positions (for the reasons discussed in section “►The Parallel Computation Unit”). The  $p$  high-order bits of the physical number of a PE correspond to the PE’s logical number within the partition. Thus, a submachine containing  $R = 2^r$  PEC Groups ( $R^*N/Q = 2^p$  PEs), where  $0 \leq r \leq q$ , is formed by combining the PEs connected to the  $R$  PECs whose addresses agree in their  $q - r$  low-order bits. The PECs within a submachine of  $R^*N/Q$  PEs are logically numbered from 0 to  $R - 1$ . For  $R > 1$ , the logical number of a PEC is the high-order  $r$  bits of its physical number. Similarly, the PEs assigned to a submachine are logically numbered from 0 to  $(R^*N/Q) - 1$  (0 to  $2^p - 1$ ). The logical number of a PE is the high-order  $r + n - q = p$  bits of its physical number (see Fig. 5). There is a maximum of  $Q$  submachines, each of size  $N/Q$ .

Each submachine can operate as an independent mixed-mode system. PEs can switch between modes as often as desired; however, all PEs in a submachine must be in the same mode (SIMD or MIMD) at any point in time.

When a submachine is operating in SIMD mode, the  $R$  PECs must execute and broadcast the same instructions, and all PEs in the submachine must be synchronized. The PECs are given the same instruction simply by loading the memory units of the  $R$  PECs with the same program. The PEs are synchronized by providing a small amount of special circuitry in the System Control Unit that coordinates instruction broadcasts among these PECs.

Some advantages of this fixed PE to PEC mapping as compared with a dynamic PE to PEC interconnection (e.g., a crossbar switch [14]) include reducing

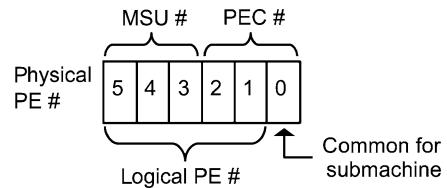

**PASM Parallel Processing System. Fig. 4** PASM Processing Element Controllers (PECs), and how they are connected to the Parallel Computation Unit (PCU) Processing Elements (PEs)

PEC/PE interface hardware, eliminating the overhead of maintaining a record of PE to PEC assignments, scheduling only  $Q$  PECs instead of  $N$  PEs, allowing the partitioning of the PE interconnection network into independent subnetworks (section “► [The Parallel Computation Unit](#)”), and supporting the structure of the efficient parallel primary to secondary memory connections (section “► [The Memory Storage and Management Systems](#)”). The main disadvantage to this approach is that the size of each submachine must be a power of two, with a minimum of  $N/Q$  PEs. However, for PASM’s intended experimental environment, flexibility at a “reasonable” cost is the goal, not maximum PE utilization.

## The Parallel Computation Unit

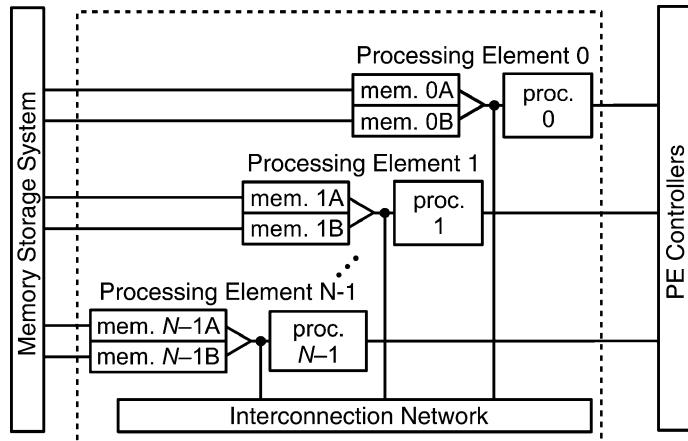

The Parallel Computation Unit, shown in [Fig. 6](#), contains  $N = 2^n$  PEs and an interconnection network. Similar to the double-buffering for the PECs, two memory units are used in each PE so that computation and memory I/O can be overlapped. For example, the PE processor can execute a job in one memory unit while the next job is preloaded into the other memory unit from PE secondary storage (the Memory Storage System). These memory units compose the primary memory of the system. In SIMD or MIMD mode, each PE can perform indirect memory addressing using its own PE logical number or local data.

Consider how PASM switches dynamically between the SIMD and MIMD modes of parallelism in our implemented prototype ([Fig. 7](#)). In MIMD mode, a PE processor fetches instructions from its local memory by

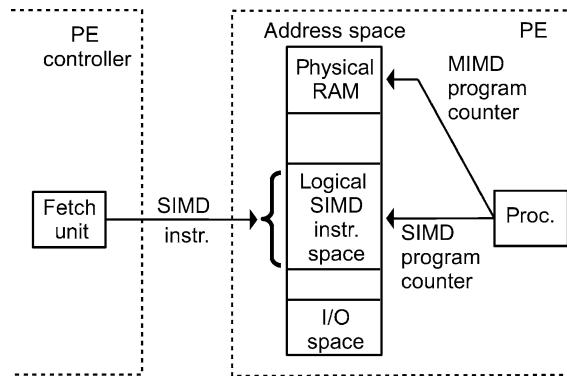

**PASM Parallel Processing System. Fig. 5** Physical number of a Processing Element (PE) for a system where  $N = 64 = 2^6$  PEs,  $Q = 8 = 2^3$  Processing Element Controllers (PECs), and  $N/Q = 8 = 2^3$  Memory Storage Units (MSUs). The PE is in a submachine of size  $R^*N/Q = 4$  PEC Groups (corresponding to  $32 = 2^5$  PEs). For this example, the physical numbers of all PEs in this submachine agree in bit position 0

placing its program counter value on the address bus and latching the data placed on the data bus by the memory device holding that instruction word. A PE is forced into SIMD mode by executing a jump to the “logical” SIMD instruction space, which is not a physical space. [Figure 7](#) illustrates the address space of a PE, showing the logical SIMD instruction space, physical RAM, and I/O space. Logic in the PE detects read accesses to the logical SIMD instruction space, and any such access sends a SIMD instruction request to the PE’s PEC. The SIMD instruction is issued by the submachine’s PECs only after all the PEs of a submachine have requested the instruction (recall the System Control Unit has special hardware to synchronize the PECs that are part of the same submachine). The instructions are sent by the submachine PECs’ Fetch Units to the PEs ([Fig. 7](#)). All enabled PEs in the submachine

PASM Parallel Processing System. Fig. 6 The PASM Parallel Computation Unit

PASM Parallel Processing System. Fig. 7 How the Processing Element (PE) logical address space in the PASM prototype is used to support mixed-mode computation

then execute the instruction simultaneously, each PE on its own data. Thus, all the PEs of the submachine are synchronized when a SIMD instruction is broadcast. The PE continues to access instructions from the SIMD instruction space until an instruction is broadcast that causes each PE to jump to an instruction in its physical RAM (Fig. 7), changing to MIMD mode. Such flexibility in mode switching allows mixed-mode programs to be written that change modes at instruction-level granularity with negligible overhead. The SIMD instruction fetch mechanism also can be used to support a form of MIMD “barrier synchronization” [20].

Masking schemes are used in SIMD mode to enable and disable PEs. The PASM system uses PE-address

masks (originated by the PASM project [21]) and data-conditional masks. A *PE-address mask* enables a set of PEs based solely on the logical addresses (numbers) of PEs; it does not depend on local PE data. A PE-address mask has  $n$  positions, where each position contains either a 0, 1, or X (“don’t care”). A PE is enabled only if the binary representation of its number matches the mask. For example, for  $N = 64$ ,  $[5\{X\}0]$  is equivalent to  $[XXXXX0]$  and enables all even-numbered PEs. A *negative PE-address mask* enables all PEs whose addresses do not match the mask. For example, for  $N = 64$ ,  $[4\{X\}2\{0\}] = [XXXXX0]$  enables all PEs whose numbers are not multiples of four. PE-address masks are a convenient notation for enabling PEs in a large-scale parallel machine, and proved very useful in image processing applications.

*Data-conditional masks* enable PEs based on some condition that is dependent on local PE data. The resulting data condition may be true in some PEs and false in other PEs. An example use of data-conditional masking is the *where* statement, the SIMD counterpart to the *if-then-else* statement. When the segment

```
where <data-condition> do <where-part>
elsewhere <else-part>
```

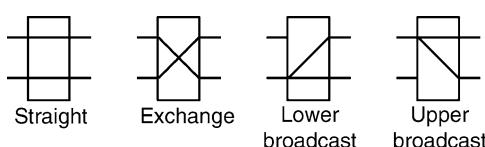

is executed, each PE independently evaluates the *<data-condition>*. The PEs where the condition evaluates true execute the *<where-part>*, and the PEs where the condition evaluates to false are idle. Next, the PEs where the condition evaluates to false

execute the `<else-part>`, and the PEs where the condition evaluates true are idle. This type of masking is used in many SIMD machines (e.g., CM-2, MP-1). Data-conditional and PE-address masks can be used together.

There are situations in which the combined conditional status of all enabled PEs in a SIMD submachine is needed, e.g., `if-none`, `if-any`, and `if-all1`. For example, if the PEs of a submachine are each examining a portion of an image to find certain objects, it may be necessary to know whether any of the PEs have found such an object. Because PASM is a partitionable system, operations such as these require conditional results to be communicated from the PEs to their PECs and subsequently combined among the PECs comprising a SIMD submachine. These operations are efficiently supported by providing a small amount of additional circuitry in the System Control Unit that combines PEC Group results according to the current system partitioning.

The *Interconnection Network* allows PEs to communicate with each other. As described earlier, the partitioning rule in PASM requires that the physical numbers of all PEs in a submachine of  $2^p$  PEs agree in their  $n - p$  low-order bit positions (see Fig. 5). Thus, the  $p$  high-order bits of a PE's physical number form its logical number within a submachine of  $2^p$  PEs. The low-order partitioning rule was chosen for PASM so that either the multistage cube [18] or the augmented data manipulator (ADM) [18] networks could be used. However, the multistage cube was selected because of its comparative cost-effectiveness.

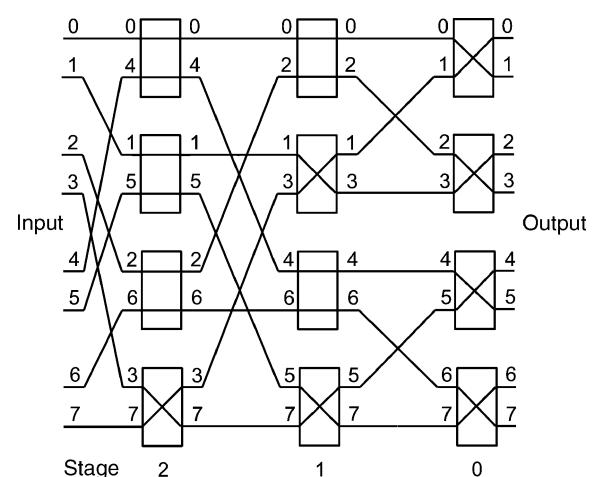

The *multistage cube network* has  $N$  input ports,  $N$  output ports, and contains  $n = \log_2 N$  stages of  $N/2$  two-input/two-output *interchange boxes*. Each interchange box can be set to one of the four states shown in Fig. 8. The network can be used in both the SIMD and MIMD modes of parallelism.

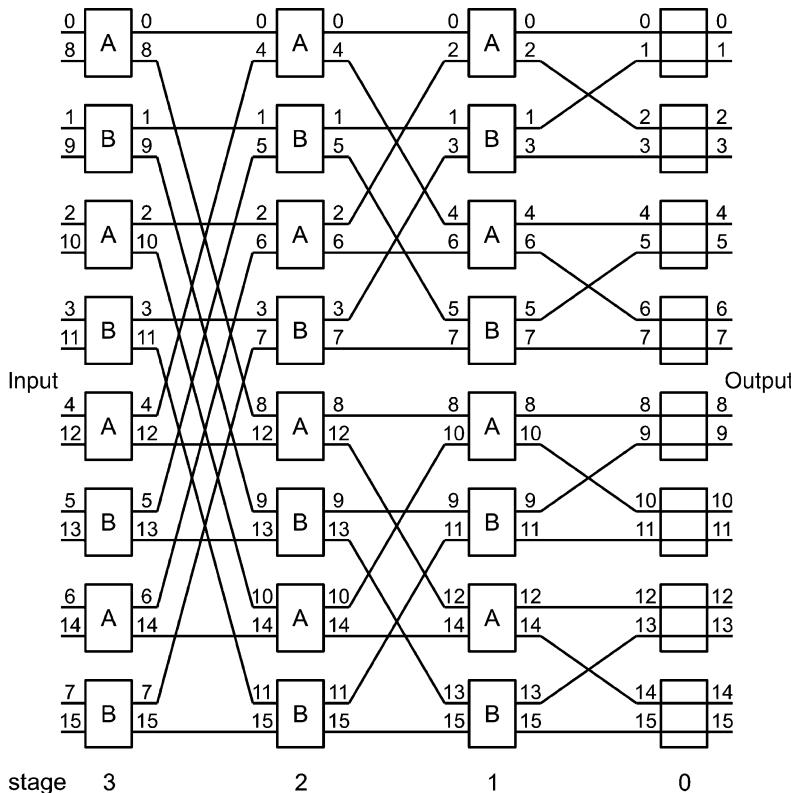

**PASM Parallel Processing System. Fig. 8** The four valid states of a multistage cube network interchange box

Figure 9 shows the multistage cube network for  $N = 8$ . PE  $i$  is connected to network input port  $i$  and output port  $i$ . The stages are numbered consecutively from  $n - 1$  at the input stage to 0 at the output stage. The upper interchange box output label is the same as the upper input, and the lower interchange box output label is the same as the lower input. The interconnection pattern between stages is such that at stage  $j$  the two links whose labels differ only in bit  $j$  are connected to the same interchange box. Figure 9 shows the network set for a “permutation” connection ( $\text{input } i \rightarrow \text{output } (i + 1) \bmod 8$ ) for an  $N = 8$  multistage cube network. The network can be controlled in a distributed fashion using routing tags for specifying permutations, one-to-one connections (e.g., PE  $a$  to PE  $b$ ), one PE to many multicast connections, and combinations of these [18].

A network is *partitionable* if it can be divided into independent subnetworks of smaller sizes that have all the properties of the original network [18]. In general, a size  $N$  multistage cube network can be partitioned into multiple subnetworks of different sizes, where the size of each subnetwork is a power of two. For example, Fig. 10 shows an  $N = 16$  network partitioned into two subnetworks by setting the interchange boxes in stage 0 to straight. Because stage 0 is straight, even-numbered inputs cannot reach odd-numbered outputs, and odd

**PASM Parallel Processing System. Fig. 9** A multistage cube network for  $N = 8$  Processing Elements (PEs) set to perform the “permutation” of sending data from PE  $i$  to PE  $(i + 1) \bmod N$  for  $0 \leq i < N$

**PASM Parallel Processing System. Fig. 10** A multistage cube network for  $N = 16$  Processing Elements (PEs) partitioned into two independent subnetworks, each of size eight. Subnetwork A consists of the even-numbered input and output ports, and subnetwork B the odd

inputs cannot reach even outputs. The two resulting subnetworks are subnetwork *A*, which contains physical ports 0, 2, ..., 14, and subnetwork *B*, which contains physical ports 1, 3, ..., 15. Because each of these subnetworks is an independent multistage cube network (of size  $N/2 = 8$ ), either or both subnetworks may be further partitioned by forcing all interchange boxes in stage 1 of the subnetwork to be straight. This process can be applied recursively.

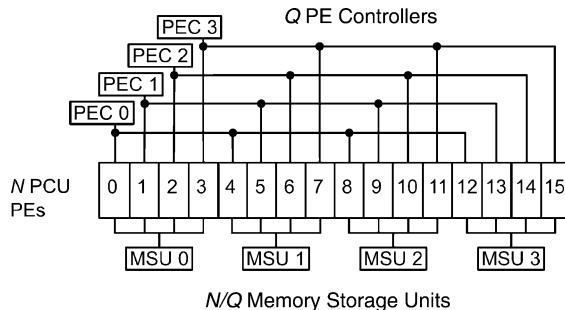

The *Extra Stage Cube network* [18] (designed as a part of the PASM project) is a single-fault tolerant variation of the multistage cube network. There is an extra stage of interchange boxes at the input, labeled stage  $n$ . Links whose labels differ in the 0th bit position are paired at these extra stage boxes in the same way that they are at stage 0. This Extra Stage Cube network fault-tolerant variation has all of the useful properties described above for the multistage cube, and was constructed in the PASM prototype. It is robust in the sense

that it can still provide all of the capabilities of a fully functional multistage network despite the failure of any single network component.

# The Memory Storage and Management Systems

The Memory Storage System (Fig. 6) is the secondary storage for the Parallel Computation Unit, storing data files in SIMD mode and both program and data files in MIMD mode (programs for SIMD mode are stored in the Control Storage). The Memory Storage System is comprised of  $N/Q$  independent *Memory Storage Units* (MSUs), numbered from 0 to  $(N/Q) - 1$ .

Each of the  $N/Q$  MSUs is connected to the memory modules of  $Q$  PEs. An example for the prototype size of  $N = 16$  and  $Q = 4$  is shown in Fig. 11. The benefit of this MSU to PE connection scheme is that the memories of all  $N/Q$  PEs connected to any one PEC can be loaded or unloaded in one parallel block transfer. For

**PASM Parallel Processing System. Fig. 11** The organization of the PASM Memory Storage System for the prototype size of  $N = 16$  Processing Elements (PEs),  $Q = 4$  Processing Element Controllers (PECs), and  $N/Q$  Memory Storage Units (MSUs)

example, in [Fig. 11](#), PEC 2's group of PEs (PEs 2, 6, 10, and 14) are loaded by having MSU 0 load PE 2, MSU 1 load PE 6, MSU 2 load PE 10, and MSU 3 load PE 14, all simultaneously.

In the general case, MSU  $i$  is connected to and stores files for the  $Q$  PEs whose  $n - q$  high-order bits of their PE physical numbers are equal to  $i$  (see [Fig. 5](#)). This high-order mapping is used so that each of the  $N/Q$  PEs connected to a given PEC is connected to a different MSU. Recall that the low-order  $q$  bits of the physical number of a PE correspond to the number of the PEC to which it is attached (see [Fig. 5](#)). Thus, the full bandwidth of the Memory Storage System can be used when transferring files between the Memory Storage System and the Parallel Computation Unit. If there are only  $N/(Q^*D)$  distinct MSUs, where  $1 \leq D \leq N/Q$ , then this scheme can be scaled so that  $D$  parallel block transfers are required to load or unload the memories of the PEs connected to any one PEC. Each MSU contains a mass storage unit and a processor to manage the file system and to transfer files to and from its associated PE memory units.

Similarly, a submachine formed by combining the  $(R^*N)/Q$  PEs controlled by  $R$  PECs can be loaded or unloaded in  $R$  parallel block transfers if there are  $N/Q$  MSUs. For example, in [Fig. 11](#), a submachine comprised of the PEs of PEC 0 and PEC 2 can be loaded in  $R = 2$  parallel block loads as follows: First PEC 0's PEs are loaded in one parallel block transfer, and then PEC

2's PEs are loaded. If there are only  $N/(Q^*D)$  distinct MSUs, only  $R^*D$  parallel block transfers are required.

[Figure 5](#) demonstrates which MSU connects to which PE. MSU  $i$  is connected to the PE whose high-order  $n - q$  bits of its logical number are  $i$  (which equal the  $n - q$  high-order bits of its physical number). As a result, no matter which PECs are assigned to a task, the data will be in the appropriate MSUs. For example, in [Fig. 11](#), for any submachine of size  $N/Q = 4$ , MSU 0 is connected to logical PE 0 (which could be physical PE 0, 1, 2, or 3).

The Memory Management System ([Fig. 3](#)) is a set of processors that send file system requests from the System Control Unit, PECs, and PEs to the appropriate MSUs; control data transfers between the Memory Storage System and the PEs; supervise input/output operations involving peripheral devices; and enforce consistent file naming and placement across the multiple Memory Storage System disks.

## Using the PASM System

ELP (Explicit Language for Parallelism) was a C-based language and associated compiler designed as part of the PASM project for programming mixed-mode parallel machines [13]. ELP provided constructs for both SIMD and MIMD parallelism, and an ELP application program could perform computations that use these parallelism modes in an instruction-level interleaved fashion for mixed-mode operation. ELP provided a vehicle for the exploration of and experimentation with mixed-mode parallelism on the PASM prototype.

CAPS (Coding Aid for the PASM System) was designed to assist in the development and evaluation of application and system software for the PASM prototype [11]. CAPS integrated hardware support and software tools to provide a remote execution and program debugging/monitoring environment for the PASM prototype. The PASM prototype was accessible over the Internet using CAPS, and multiple windows could be displayed to monitor different processors simultaneously.

The programming challenges for partitionable mixed-mode systems are a superset of those for SIMD and MIMD single-mode systems. Application and algorithm research activities to explore PASM's three dimensions of flexibility included theoretical analyses,

simulations, and experiments on the PASM prototype [19]. These studies examined issues such as mapping tasks onto multistage cube network-based parallel processing systems; trade-offs among the SIMD, MIMD, and mixed-mode classes of parallelism; PEC/PE computational overlap in SIMD mode; impact of increasing the number of PEs used; and partitioning for improved performance. Applications considered include edge-guided thresholding, FFTs, global histogramming, image correlation, image smoothing, matrix multiplication, and range-image segmentation (references are given in Armstrong, Watson, and Siegel [2]). Here, we will summarize three application studies that utilized the PASM prototype.

Fineberg, Casavant, and Siegel [7] used the PASM prototype to study the benefits of mixed-mode parallel architectures for bitonic sequence sorting. Four variations of the bitonic sequence sorting algorithm were developed: a SIMD version, a MIMD version, a MIMD version with hardware barrier synchronizations, and a mixed-mode version that allowed switching between SIMD and MIMD modes during execution. The algorithm variations were then coded and profiled on the PASM prototype using varying problem and partition sizes.

The research demonstrated that, by supporting hardware barrier synchronization and mode switching, a machine can achieve better performance than with only SIMD or MIMD parallelism on problems that are computationally similar to bitonic sequence sorting. The authors also proposed a modification to the PASM prototype condition code logic that would increase the performance of the SIMD version.

Saghi, Siegel, and Gray [16] programmed cyclic reduction (a method for solving a general tridiagonal set of irreducible linear algebraic equations) on three parallel systems, including the PASM prototype, to study the trade-offs between SIMD and MIMD parallelism, the effects of increasing the number of processors used on execution time, the impact of the interconnection network on performance, and the advantages of a partitionable system. The cyclic reduction algorithm was implemented using SIMD parallelism on the MasPar MP-1 [5], using MIMD parallelism on the nCUBE 2 [9], and using the same four versions of parallelism on the PASM prototype as mentioned above. The authors also developed a mechanism

to predict the algorithm performance on each machine using algorithm analysis and performance measurements from each machine.

By using the PASM prototype as a common basis to compare the modes of parallelism, the authors concluded that a cyclic reduction algorithm using mixed-mode was better than a purely SIMD or purely MIMD algorithm. Execution-time measurements from the other two parallel machines emphasized the need to carefully choose the number of processing elements and distribution of data to obtain efficient computation.

Tan, Siegel, and Siegel [22] used several parallel machines to study block-based motion vector estimation. A SIMD MasPar MP-1 [5], a MIMD Intel Paragon XP/S, a MIMD IBM SP2, and the mixed-mode PASM prototype were used with different data partitioning schemes to perform the estimation, and the results were analyzed to contrast the benefits of each mode of parallelism. In this research, the PASM prototype used SIMD, SPMD, and mixed-mode parallelism.

The research demonstrated a method to analytically predict the performance of various parallel implementations of the algorithm. It also described the impact of the number of processors and mode of parallelism used on algorithm performance. The authors found that, using the PASM prototype, the mixed-mode implementation slightly outperformed the pure SPMD implementation and significantly outperformed the pure SIMD implementation.

## Conclusions

Designing, simulating, prototyping, using, and evaluating the PASM partitionable SIMD/MIMD mixed-mode system, based on a multistage cube network, was a great research and educational experience for a large group of faculty and students at Purdue University from the 1970s through the 1990s. As stated earlier, PASM was flexible along three dimensions: partitionability, mode of parallelism, and variable connectivity among PEs. We found that advantages of systems with such flexibility over a pure SIMD machine or a pure MIMD machine included the following [20]:

1. *Multiple simultaneous users:* Because there can be multiple simultaneous independent submachines, there can be multiple simultaneous users of the

system, each executing a different program (not allowed in a pure SIMD machine).

2. *Program development*: Rather than trying to debug a new parallel program on, for example, 1,024 PEs, it can be debugged on a smaller size submachine of 32 PEs, and then extended to 1,024 PEs.
3. *Variable submachine size for increased utilization*: If a task requires only  $N'$  of  $N$  available PEs, the other  $N - N'$  can be used for another task (not allowed in a pure SIMD machine).
4. *Variable submachine size for decreased execution time*: There are some algorithms for which the minimum execution time is obtained when fewer than  $N$  PEs are used due to inter-PE communication overhead (e.g., image smoothing [19]); thus, it is desirable to create a submachine consisting of the optimal number of PEs.
5. *Subtask parallelism*: Two independent subtasks that are part of the same job can be executed in parallel, sharing resources if necessary, which may result in improved overall task execution time [12] (not allowed in a pure SIMD machine).
6. *Multiple processing modes*: An algorithm can be executed by using a combination of SIMD and MIMD control with the same set of PEs (mixed-mode parallelism), using the mode that best matches the computations required at each step of the program (Fig. 1).
7. *Matching inter-PE connectivity to the task*: The multistage cube allows different connection patterns among PEs to be established depending on the task (as opposed to, for example, having a fixed mesh network).
8. *System fault tolerance*: If a single PE fails, only those submachines that include the failed PE are affected. This provides some robustness, as mentioned in section “►Introduction,” and is not allowed in a pure SIMD machine.
9. *Submachine fault tolerance*: If a PE in a submachine fails, it may be possible to redistribute data and make use of mixed-mode parallelism (i.e., changing from SIMD to MIMD mode) and the variable connectivity (i.e., to establish connection patterns that do not include the faulty PE) so that the job executing on the submachine may continue on that submachine with minimal degradation (this is another form of robustness).

The references cited in this list of advantages, and the complete reading list of PASM-related publications (<http://hdl.handle.net/10217/34662>), give much more detail about our experiences.

## Path Expressions

ROY H. CAMPBELL

University of Illinois at Urbana-Champaign, Urbana, IL, USA

## Synonyms

**Coordination;** **Concurrency control;** **Mutual exclusion;** **Process synchronization**

## Definition

A path expression is a declaration of the permitted sequences of operations on an object that is shared by parallel processes.

For example, consider a path expression based on a regular expression notation for a shared buffer. The shared buffer may have operations read and write that may only occur in a sequence specified by the regular expression (write; read)\* where a write to the buffer may be followed by a read before it can be repeated. The reads and writes are mutually exclusive. The expression indicates the sequence of actions that may occur independent of the number of processes or the order in which the processes invoke the operations.

## Discussion

Path expressions provide a declarative specification of synchronization and coordination of parallel processes performing operations on an object in parallel computing systems [4]. They provide a language mechanism to separate the specification of synchronization from the algorithmic means of providing that synchronization [5]. Although the regular expression is used in our example, other languages that are well defined can be used instead.

In general, the synchronization for an object being manipulated by parallel processes involves mutual exclusion, sequence, and repetition and these may be combined to form path expressions. In more detail, a path expression language based on regular expressions can be described as:

1. A sequence of operations on a resource.
2. A selection from one or more operations on a resource.
3. A repetition of a sequence or selection.
4. A path expression composed of (1), (2), or (3) above.

Other primitives besides these three have been considered including:

1. A burst of parallel sequences of executions: If there is one execution of the operations in a path expression, then there can be parallel executions of the sequences of operations in a path expression up until the event when there are no more parallel executions of those operations occurring. For example, the expression  $(\text{write}, \{\text{read}\})^*$  for a buffer would specify that a write or a burst of parallel reads can occur, but not a read and a write in parallel [4].
2. A concurrency restriction: This allows parallel executions of the path expression up to the limit of the restriction. For example, the expression  $5:(\text{write}; \text{read})$  would allow up to 5 parallel instances of a write followed by a read [13].
3. Guarded selection: A path expression selection that describes the synchronization of the parallel execution of its operations when a guard is true. For example, the expression  $\#\text{buffers} < 5 | (\text{put}), \#\text{buffers} > 0 | (\text{get})$  would describe synchronization where if the variable  $\#\text{buffers}$  is less than 5, a put may occur or if the variable  $\#\text{buffers}$  is greater than 0, a get may occur (see also [2]).

More general forms of path expression may also be described [4]. For example, a general path expression can be composed of independent path expressions such that if all the path expressions allow the execution of an operation, it may occur. The general path expression:

```
path (A; B)* end
path (A; C)* end
```

requires an operation A to be followed by operation B and C. Operations B and C may possibly occur in parallel since there are no constraints between B and C but there are constraints between A and B and between A and C.

## Implementation

An operation on an object can be considered as a transition that changes the state of the object. When a process invokes an operation on an object, it can be viewed as a request for a transition from one state of the object to another. The implementation of a path expression decides whether to accept the request and proceed or whether to delay the request until an appropriate state and block the process invocation of that operation. When a path expression is built upon a regular expression that has the property that an operation can only occur when the object is in one particular state, then a simple implementation can be built using semaphores to represent the states.

In this exposition, the implementation for open path expressions is described. An open path expression allows much of the power of a semaphore to be used in a declarative expression and forms the basis for the implementation of “Path Pascal,” a version of Pascal that includes concurrency and synchronization [13]. Open path expressions are composed of four constraints: sequence, selection, restriction, and derestriction.

The open path expression notation allows a simple rewriting scheme to translate a path expression synchronization declaration into the prologues and the epilogues of semaphore operations of each of the operations mentioned in the path expression:

```
[path<op_expr>end] ←
|α <op_expr>β
```

Where  $\leftarrow$  designates a rewrite rule and  $\alpha^i, \beta^i$  are empty strings of semaphore operations forming the prologue and epilogue to be inserted in each of the operations named in op\_expr.

The following set of path expression rewrite rules evaluated in the order specified either by parentheses or by following precedence from left to right generate prologues and epilogues that implement the four synchronization constraints: sequence, selection, restriction, and burst:

*Rule Selection (comma):*  $\alpha <\text{op\_expr}_1>, <\text{op\_expr}_2> \beta \vdash$

|  $\alpha <\text{op\_expr}_1> \beta$   
|  $\alpha <\text{op\_expr}_2> \beta$

*Rule Sequence (semicolon):*  $\alpha <\text{op\_expr}>; <\text{op\_expr}_2>$

$\beta \vdash$

|  $\alpha <\text{op\_expr}_1> "S_j.V();"$   
| "S\_j.P();"  $<\text{op\_expr}_2> \beta$

where Semaphore  $S_j$  is initialized to 0

*Rule Restriction (colon):*  $\alpha n: (<\text{op\_expr}_1>) \beta \vdash$

|  $\alpha || "S_k.P();" <\text{op\_expr}_1> "S_k.V();" || \beta$

where Semaphore  $S_k$  is initialized to n and  $||$  expresses the concatenation of two strings making up a prologue or epilogue.

*Rule Derestriction (brace):*  $\alpha \{<\text{op\_expr}_1>\} \beta \vdash$

| "  $S_k.P();$  if count $++ == 1$  then [ "  $\alpha || "S_k.V();]$ ; " $<\text{op\_expr}_1> " S_k.P();$  if count $-- == 1$  then [ "  $\beta || "S_k.V();]$  ];

where Semaphore  $S_k$  is initialized to 1, integer count is initialized to 0, the  $++$  and  $--$  operators denote incrementing or decrementing a counter count by 1, and square parentheses within the strings denote a block of instructions.

The derestriction rule applies the synchronization prologue  $\alpha$  if count is incremented through 1 in the prologue and applies the synchronization epilogue  $\beta$  if count is decremented through 1 in the epilogue.

Finally, the prologues and epilogues are complete when  $<\text{op\_expr}>$  contains only a method\_name of an operation declared in an object.

*Operation:*  $\alpha <\text{method\_name}> \beta$

| insert prologue  $\alpha$ ; < method\_body>; insert epilogue  $\beta$

The following are some examples of the implementations of open path expressions:

## 1. **path x, y end**

creates empty prologues and epilogues in the methods x and y allowing them to be executed without synchronization constraints.

## 2. **path 1: (x) end**

rewrites to:

|  $S_1.P(); <x\_body>; S_1.V();$

Semaphore  $S_1 = 1$ ;

The body of x is executed in mutual exclusion.

## 3. **path 1: (x, y) end**

rewrites to:

|  $S_1.P(); <x\_body>; S_1.V();$

|  $S_1.P(); <y\_body>; S_1.V();$

Semaphore  $S_1 = 1$ ;

and creates prologues and epilogues in the methods x and y constraining their execution to mutual exclusion.

## 4. **path 1: (x; y) end**

rewrites to:

|  $S_1.P(); <x\_body>; S_2.V();$

|  $S_2.P(); <y\_body>; S_1.V();$

Semaphore  $S_1, S_2 = (1, 0)$ ;

and creates prologues and epilogues in the methods x and y constraining their execution to mutual exclusion and a sequence that alternates the execution of x with one of y.

## 5. **path 1: (write; {read}) end**

rewrites to:

|  $S_1.P(); <write\_body>; S_2.V();$

|  $S_3.P();$  if count $++ == 1$  then [  $S_2.P(); S_3.V();$  ]

| <read\_body>  $S_3.P();$  if count $-- == 1$  then [  $S_2.V(); S_3.V();$  ];

Semaphore  $S_1, S_2, S_3 = (1, 0, 1)$ ; Integer count = 0; and allows one write operation to be followed by a burst of read operations.

## 6. **path 5: (1: (write); 1: (read)) end**

rewrites to:

|  $[S_1.P(); S_2.P(); <write\_body>; S_2.V(); S_4.V();]$

|  $[S_4.P(); S_3.P(); <read\_body>; S_3.V(); S_1.V();]$

Semaphore  $S_1, S_2, S_3, S_4 = (5, 1, 1, 0)$ ;

The body of write is executed in mutual exclusion as is the body of read. However, there must always be more writes than reads and there may be up to 5 more writes than reads.

## Uses of Path Expressions

Path expressions as a declarative form of specifying synchronization have found use in several parallel programming languages [2, 14, 18]. They have also been employed in single-assignment languages [7], real-time control languages [17], distributed objects [16], event systems [12], multimedia systems [11], debugging [3], VLSI design [1], synchronization contracts for web services [15], and workflow languages [10]. Typically,

processes and path expressions are dual approaches to specifying the traces created in a computation; the processes generate sequences of actions which are constrained by path expressions to achieve particular synchronization constraints associated with the operations on abstract data types.

## Summary

In practice, synchronization of parallel processes remains a difficult problem that becomes ever more complex with increased concurrency in architecture. Path expressions provide a separate specification of synchronization from the code of processes that, under some circumstances, can simplify parallel programming. Although not widely adopted, their declarative approach to specifying synchronization has been found useful in various parallel applications. Path expressions have been used to synchronize parallel operations on objects in parallel languages, real-time languages, event systems, VSLI, workflow, and debugging.

## Bibliographic Notes and Further Reading

The semantics of parallel programs may be described using trace-based semantics. Path expression implementations restrict or recognize the permitted traces of parallel programs as described by Lauer and Campbell [6]. A semantics for path expressions is given by Dinning and Mishra using partially ordered multisets [8] and the authors provide a fully parallel implementation for a path expression language on MIMD shared memory architectures. Path Pascal and open path expressions were used as pedagogical tools for teaching parallel programs [9, 13].

## Synonyms

Partitioning tool for hypergraphs (PaToH)

## Definition

PaToH is a sequential, multilevel, hypergraph partitioning tool that can be used to solve various combinatorial scientific computing problems that could be modeled as hypergraph partitioning problem, including sparse matrix partitioning, ordering, and load balancing for parallel processing.

## Discussion

### Introduction

Hypergraph partitioning has been an important problem widely encountered in VLSI layout design [22]. Recent works since the late 1990s have introduced new application areas, including one-dimensional and two-dimensional partitioning of sparse matrices for parallel sparse-matrix vector multiplication [6–8, 12], sparse matrix reordering [6, 11], permuting sparse rectangular matrices into singly bordered block-diagonal form for parallel solution of LP problems [3], and static and dynamic load balancing for parallel processing [5]. PaToH [9] has been developed to provide fast and high-quality solutions for these motivating applications.

In simple terms, the hypergraph partitioning problem can be defined as the task of dividing a hypergraph into two or more roughly equal sized parts such that a cost function on the hyperedges connecting vertices in different parts is minimized. The hypergraph partitioning problem is known to be NP-hard [22], therefore a wide variety of heuristic algorithms have been developed in the literature to solve this complex problem [1, 15, 21, 23, 25]. Following the success of multilevel partitioning schemes in ordering and graph partitioning [4, 16, 18], PaToH [9] has been developed as one of the first multilevel hypergraph partitioning tools.

### Preliminaries

A hypergraph  $\mathcal{H} = (\mathcal{V}, \mathcal{N})$  is defined as a set of vertices (also called cells)  $\mathcal{V}$  and a set of nets (hyperedges)  $\mathcal{N}$  among those vertices. Every net  $n \in \mathcal{N}$  is a subset of vertices, that is,  $n \subseteq \mathcal{V}$ . The vertices in a net  $n$  are called its *pins* in PaToH. The *size* of a net,  $s[n]$ , is equal to the number of its pins. The *degree* of a vertex is equal to the number of nets it is connected to. Graph is a special instance of hypergraph such that each net has exactly two pins. Vertices and nets of a hypergraph can be associated with weights. For simplicity in the presentation,

net weights are referred as *cost* here and denoted with  $c[\cdot]$ , whereas  $w[\cdot]$  will be used for vertex weights.

$\Pi = \{\mathcal{V}_1, \mathcal{V}_2, \dots, \mathcal{V}_K\}$  is a *K-way partition* of  $\mathcal{H}$  if the following conditions hold:

- Each part  $\mathcal{V}_k$  is a nonempty subset of  $\mathcal{V}$ , that is,  $\mathcal{V}_k \subseteq \mathcal{V}$  and  $\mathcal{V}_k \neq \emptyset$  for  $1 \leq k \leq K$ .
- Parts are pairwise disjoint, that is,  $\mathcal{V}_k \cap \mathcal{V}_\ell = \emptyset$  for all  $1 \leq k < \ell \leq K$ .
- Union of  $K$  parts is equal to  $\mathcal{V}$ , that is,  $\bigcup_{k=1}^K \mathcal{V}_k = \mathcal{V}$ .

In a partition  $\Pi$  of  $\mathcal{H}$ , a net that has at least one pin (vertex) in a part is said to *connect* that part. *Connectivity*  $\lambda_n$  of a net  $n$  denotes the number of parts connected by  $n$ . A net  $n$  is said to be *cut (external)* if it connects more than one part (i.e.,  $\lambda_n > 1$ ), and *uncut (internal)* otherwise (i.e.,  $\lambda_n = 1$ ). In a partition  $\Pi$  of  $\mathcal{H}$ , a vertex is said to be a *boundary* vertex if it is incident to a cut net. A *K-way partition* is also called a *multiway partition* if  $K > 2$  and a *bipartition* if  $K = 2$ . A partition is said to be balanced if each part  $\mathcal{V}_k$  satisfies the *balance criterion*:

$$W_k \leq W_{avg}(1 + \varepsilon), \quad \text{for } k = 1, 2, \dots, K. \quad (1)$$

In (1), weight  $W_k$  of a part  $\mathcal{V}_k$  is defined as the sum of the weights of the vertices in that part (i.e.,  $W_k = \sum_{v \in \mathcal{V}_k} w[v]$ ),  $W_{avg}$  denotes the weight of each part under the perfect load balance condition (i.e.,  $W_{avg} = (\sum_{v \in \mathcal{V}} w[v])/K$ ), and  $\varepsilon$  represents the predetermined maximum imbalance ratio allowed.

The set of external nets of a partition  $\Pi$  is denoted as  $\mathcal{N}_E$ . There are various [13, 27] *cutsizes* definitions for representing the cost  $\chi(\Pi)$  of a partition  $\Pi$ . Two relevant definitions are:

$$(a) \quad \chi(\Pi) = \sum_{n \in \mathcal{N}_E} c[n] \quad \text{and} \\ (b) \quad \chi(\Pi) = \sum_{n \in \mathcal{N}_E} c[n](\lambda_n - 1). \quad (2)$$

In (2a), the cutsize is equal to the sum of the costs of the cut nets. In (2b), each cut net  $n$  contributes  $c[n](\lambda_n - 1)$  to the cutsize. The cutsize metrics given in (2a) and (2b) will be referred to here as *cut-net* and *connectivity* metrics, respectively. The hypergraph partitioning problem can be defined as the task of dividing a hypergraph into two or more parts such that the cutsize is minimized, while a given balance criterion (1) among part weights is maintained.

A recent variant of the above problem is the *multi-constraint hypergraph* partitioning [2, 6, 10, 19, 24] in which each vertex has a vector of weights associated

with it. The partitioning objective is the same as above, and the partitioning constraint is to satisfy a balancing constraint associated with each weight. Let  $w[v, i]$  denote the  $C$  weights of a vertex  $v$  for  $i = 1, \dots, C$ . Then balance criterion (1) can be rewritten as:

$$W_{k,i} \leq W_{avg,i} (1 + \epsilon) \text{ for } k = 1, \dots, K \text{ and } i = 1, \dots, C, \quad (3)$$

where the  $i$ th weight  $W_{k,i}$  of a part  $\mathcal{V}_k$  is defined as the sum of the  $i$ th weights of the vertices in that part (i.e.,  $W_{k,i} = \sum_{v \in \mathcal{V}_k} w[v, i]$ ), and  $W_{avg,i}$  is the average part weight for the  $i$ th weight (i.e.,  $W_{avg,i} = (\sum_{v \in \mathcal{V}} w[v, i]) / K$ ), and  $\epsilon$  again represents allowed imbalance ratio.

Another variant is the *hypergraph partitioning with fixed vertices*, in which some of the vertices are fixed in some parts before partitioning. In other words, in this problem, a *fixed-part* function is provided as an input to the problem. A vertex is said to be *free* if it is allowed to be in any part in the final partition, and it is said to be fixed in part  $k$  if it is required to be in  $\mathcal{V}_k$  in the final partition  $\Pi$ .

## Using PaToH

PaToH provides a set of functions to read, write, and partition a given hypergraph, and evaluate the quality of a given partition. In terms of partitioning, PaToH provides a user customizable hypergraph partitioning via multilevel partitioning scheme. In addition, PaToH provides hypergraph partitioning with fixed cells and multi-constraint hypergraph partitioning.

Application developers who would like to use PaToH can either directly use PaToH through a simple, easy-to-use C library interface in their applications, or they can use stand-alone executable.

## PaToH Library Interface

PaToH library interface consists of two files: a header file `patoh.h` which contains constants, structure definitions, and functions proto-types, and a library file `libpatoh.a`.

Before starting to discuss the details, it is instructive to have a look at a simple C program that partitions an input hypergraph using PaToH functions. The program is displayed in Fig. 1. The first statement is a function call to read the input hypergraph file which is given by the first command line

argument. PaToH partition functions are customizable through a set of parameters. Although the application user can set each of these parameters one by one, it is a good habit to call PaToH function `PaToH_Initialize_Parameters` to set all parameters to one of the three preset default values by specifying `PATOH_SUGPARAM_<preset>`, where `<preset>` is `DEFAULT`, `SPEED`, or `QUALITY`. After this call, the user may prefer to modify the parameters according to his/her need before calling `PaToH_Alloc`. All memory that will be used by PaToH partitioning functions is allocated by `PaToH_Alloc` function, that is, there will be no more dynamic memory allocation inside the partitioning functions. Now, everything is set to partition the hypergraph using PaToH's multilevel hypergraph partitioning functions. A call to `PaToH_Partition` (or `PaToH_MultiConst_Partition`) will partition the hypergraph, and the resulting partition vector, part weights, and cutsizewill be returned in the parameters. Here, variable `cut` will hold the cutsizew of the computed partition according to cutsizew definition (2b) since, this metric is specified by initializing the parameters with constant `PATOH_CONPART`. The user may call partitioning functions as many times as he/she wants before calling function `PaToH_Free`. There is no need to reallocate the memory before each partitioning call, unless either the hypergraph or the desired customization (like changing coarsening algorithm, or number of parts) is changed.

A hypergraph and its representation can be seen in Fig. 2. In the figure, large circles are cells (vertices) of the hypergraph, and small circles are nets. `xpins` and `pins` arrays store the beginning index of pins (cells) connected to each net, and IDs of the pins, respectively. Hence, `xpins` is an array of size equal to the number of nets plus one (11 in this example), and `pins` is an array of size equal to the number of pins in the hypergraph (31 in this example). Cells connected to net  $n_j$  are stored in `pins[xpins[j]]` through `pins[xpins[j+1]-1]`.

## Stand-Alone Program

Distribution includes a stand-alone program, called `patoh`, for single constraint partitioning (this executable will not work with multiple vertex weights; for multi-constraint partitioning there is an interface and some sample source codes). The program `patoh` gets

its parameters from command line arguments. PaToH can be run from command line as follows:

```
> patch <hypergraph-file>
<number-of-parts> [[parameter1]
[parameter2]].
```

Partitioning can be customized by using the optional [parameter] arguments. The syntax of these optional parameters is as follows: two-letter abbreviation of a parameter is followed by an equal sign and a value. For example, if the user wishes to change refinement algorithm (abbreviated as “RA”) to “Kernighan–Lin with dynamic locking” (sixth algorithm out of 12 implemented in PaToH), the user should specify “RA=6.” For a complete example, consider the sample hypergraph displayed in Fig. 2. In order to partition this hypergraph into three parts by using the Kernighan–Lin refinement algorithm with cut-net metric (the default is connectivity metric (Equation (2b)), one has to issue the following command whose output is shown next:

```
> patch sample.u 3 RA=6 UM=U

+++++
+++ PaToH v3 (c) Nov 1999-, by Umit V. Catalyurek
+++ Build # 872 Date: Fri, 09 Oct 2009
++++

Hypergraph : sample.u #Cells : 12 #Nets : 11 #Pins : 31

3-way partitioning results of PaToH:

Cut Cost: 2
Part Weights : Min= 4 (0.000) Max= 4 (0.000)

I/O : 0.000 sec
I.Perm/Cons.H: 0.000 sec (2.9%)
Coarsening : 0.000 sec (1.1%)
Partitioning : 0.000 sec (75.8%)
Uncoarsening : 0.000 sec (3.7%)
Total : 0.001 sec
Total (w I/O): 0.001 sec

```

This output shows that the cutsize (cut cost) according to cut-net metric is 2. Final imbalance ratios (in parentheses) for the least loaded and the most loaded parts are 0% (perfect balance with four vertices in each part), and partitioning only took about 1 ms. The input hypergraph and resulting partition is displayed in Fig. 3. A quick summary of the input file format (the details are provided in the PaToH manual [9]) is as follows: the first non-comment line of the file is a header containing the index base (0 or 1) and the size of the hypergraph, and information for each net (only pins in this case) and cells (none in this example) follows.

All of the PaToH customization parameters that are available through library interface are also available as command line options. PaToH manual [9] contains details of each of those customization parameters.

## Customizing PaToH’s Hypergraph Partitioning

PaToH achieves  $K$ -way hypergraph partitioning through recursive bisection (two-way partition), and at each bisection step it uses a multilevel hypergraph bisection

---

```

#include <stdio.h>
#include "patch.h"

int main(int argc,char *argv[])
{
 PaToH_Parameters args;
 int _c, _n, _nconst, *cwghts, *nwghts,
 *xpins, *pins, *partvec, cut, *partweights;

 PaToH_Read_Hypergraph(argv[1], &_c, &n, &_nconst, &cwghts, &nwghts,
 &xpins, &pins);

 printf("Hypergraph %10s -- #Cells=%6d #Nets=%6d #Pins=%8d #Const=%2d\n",
 argv[1], _c, _n, xpins[_n], _nconst);

 PaToH_Initialize_Parameters(&args, PATOH_CONPART, PATOH_SUGPARAM_DEFAULT);

 args._k = atoi(argv[2]);
 partvec = (int *) malloc(_c*sizeof(int));
 partweights = (int *) malloc(args._k*sizeof(int));

 PaToH_Alloc(&args, _c, _n, _nconst, cwghts, nwghts, xpins, pins);

 if (_nconst==1)
 PaToH_Partition(&args, _c, _n, cwghts, nwghts,
 xpins, pins, partvec, partweights, &cut);
 else
 PaToH_MultiConst_Partition(&args, _c, _n, _nconst, cwghts,
 xpins, pins, partvec, partweights, &cut);

 printf("%d-way cutsize is: %d\n", args._k, cut);

 free(cwghts); free(nwghts);
 free(xpins); free(pins);
 free(partweights); free(partvec);

 PaToH_Free();
 return 0;
}

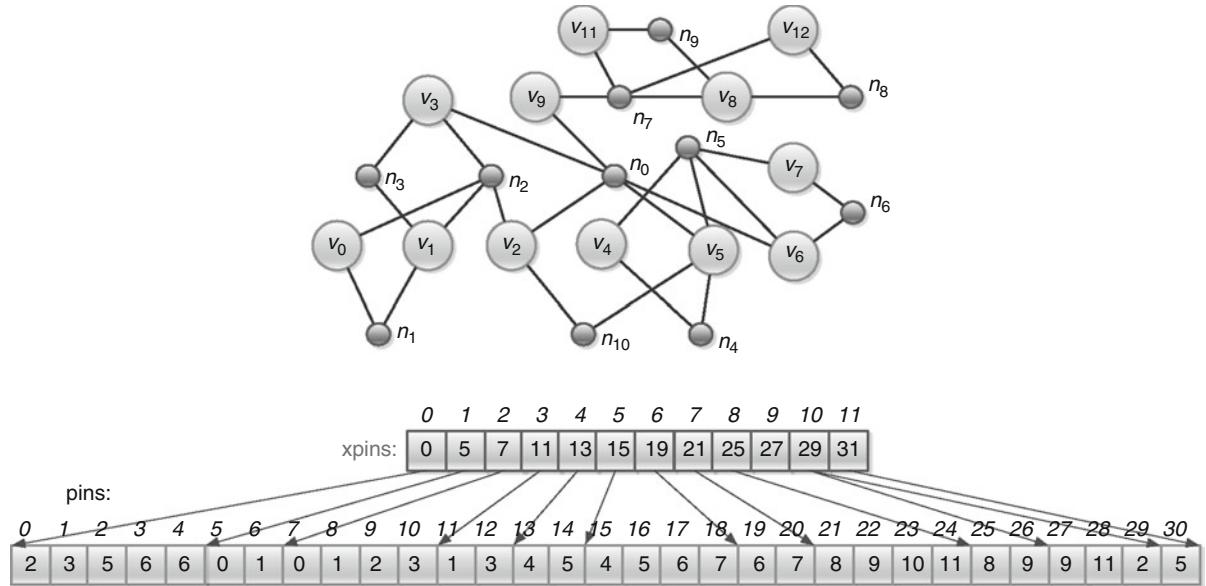

```

---

**PaToH (Partitioning Tool for Hypergraphs).** Fig. 1 A simple C program that partitions an input hypergraph using PaToH functions

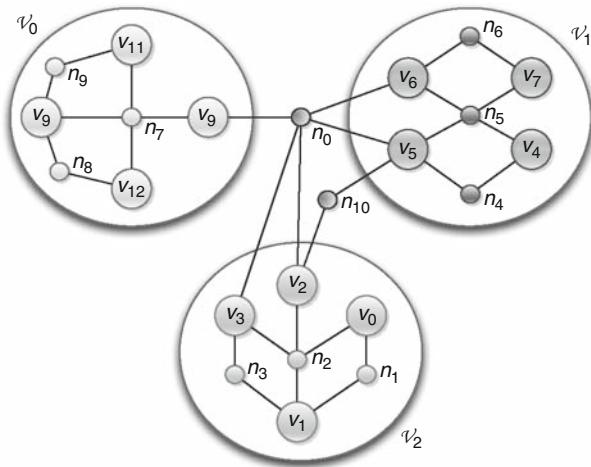

algorithm. In the recursive bisection, first a bisection of  $\mathcal{H}$  is obtained, and then each part of this bipartition is further partitioned recursively. After  $\lg_2 K$  steps, hypergraph  $\mathcal{H}$  is partitioned into  $K$  parts. Please note that,  $K$  is not restricted to be a power of 2. For any  $K > 1$ , one can achieve  $K$ -way hypergraph partitioning through recursive bisection by first partitioning  $\mathcal{H}$  into two parts with a load ratio of  $\lfloor K/2 \rfloor$  to  $(K - \lfloor K/2 \rfloor)$ , and then recursively partitioning those parts into  $\lfloor K/2 \rfloor$  and  $(K - \lfloor K/2 \rfloor)$  parts, respectively, using the same approach.

A pseudo-code of the multilevel hypergraph bisection algorithm used in PaToH is displayed in Algorithm 1. Mainly, the algorithm has three phases: *coarsening*, *initial partitioning*, and *uncoarsening*. In the first phase, a bottom-up multilevel clustering is successively applied starting from the original hypergraph until either the number of vertices in the coarsened hypergraph reduces below a predetermined threshold value or clustering fails to reduce the size of the hypergraph significantly. In the second phase, the coarsest

hypergraph is bipartitioned using one of the 12 initial partitioning techniques. In the third phase, the partition found in the second phase is successively projected back towards the original hypergraph while it is being improved by one of the iterative refinement heuristics. These three phases are summarized below.

**1. Coarsening Phase:** In this phase, the given hypergraph  $\mathcal{H} = \mathcal{H}_0 = (\mathcal{V}_0, \mathcal{N}_0)$  is coarsened into a sequence of smaller hypergraphs  $\mathcal{H}_1 = (\mathcal{V}_1, \mathcal{N}_1)$ ,  $\mathcal{H}_2 = (\mathcal{V}_2, \mathcal{N}_2)$ , ...,  $\mathcal{H}_\ell = (\mathcal{V}_\ell, \mathcal{N}_\ell)$  satisfying  $|\mathcal{V}_0| > |\mathcal{V}_1| > |\mathcal{V}_2| > \dots > |\mathcal{V}_\ell|$ . This

coarsening is achieved by coalescing disjoint subsets of vertices of hypergraph  $\mathcal{H}_i$  into *clusters* such that each cluster in  $\mathcal{H}_i$  forms a single vertex of  $\mathcal{H}_{i+1}$ . The weight of each vertex of  $\mathcal{H}_{i+1}$  becomes equal to the sum of its constituent vertices of the respective cluster in  $\mathcal{H}_i$ . The net set of each vertex of  $\mathcal{H}_{i+1}$  becomes equal to the union of the net sets of the constituent vertices of the respective cluster in  $\mathcal{H}_i$ . Here, multiple pins of a net  $n \in \mathcal{N}_i$  in a cluster of  $\mathcal{H}_i$  are contracted to a single pin of the respective net  $n' \in \mathcal{N}_{i+1}$  of  $\mathcal{H}_{i+1}$ . Furthermore, the single-pin

```

---

nets obtained during this contraction are discarded. The coarsening phase terminates when the number of vertices in the coarsened hypergraph reduces below the predetermined number or clustering fails to reduce the size of the hypergraph significantly.

In PaToH, two types of clusterings are implemented, *matching-based*, where each cluster contains at most of two vertices; and *agglomerative-based*, where clusters can have more than two vertices. The former is simply called *matching* in PaToH, and the latter is called *clustering*.

The matching-based clustering works as follows. Vertices of  $\mathcal{H}_i$  are visited in a user-specified order (could be random, degree sorted, etc.). If a vertex  $u \in \mathcal{V}_i$  has not been matched yet, one of its unmatched *adjacent* vertices is selected according to a criterion. If such a vertex  $v$  exists, the matched pair  $u$  and  $v$  are merged into a cluster. If there is no unmatched adjacent vertex of

$u$ , then vertex  $u$  remains unmatched, that is,  $u$  remains as a singleton cluster. Here, two vertices  $u$  and  $v$  are said to be adjacent if they share at least one net, that is,  $nets[u] \cap nets[v] \neq \emptyset$ .

In the agglomerative clustering schemes, each vertex  $u$  is assumed to constitute a singleton cluster  $C_u = \{u\}$  at the beginning of each coarsening level. Then, vertices are again visited in a user specified order. If a vertex  $u$  has already been clustered (i.e.,  $|C_u| > 1$ ) it is not considered for being the source of a new clustering. However, an unclustered vertex  $u$  can choose to join a multi-vertex cluster as well as a singleton cluster. That is, all adjacent vertices of an unclustered vertex  $u$  are considered for selection according to a criterion. The selection of a vertex  $v$  adjacent to  $u$  corresponds to including vertex  $u$  to cluster  $C_v$  to grow a new multi-vertex cluster  $C_u = C_v = C_v \cup \{u\}$ .

PaToH includes a total of 17 coarsening algorithms: eight matchings and nine clustering algorithms, and the default method is a clustering algorithm that uses *absorption* metric. In this method, when selecting the adjacent vertex  $v$  to cluster with vertex  $u$ , vertex  $v$  is selected to maximize  $\sum_{n \in nets[u] \cap nets[C_v]} \frac{|C_v \cap n|}{s[n]-1}$ , where  $nets[C_v] = \bigcup_{w \in C_v} nets[w]$ .

**2. Initial Partitioning Phase:** The goal in this phase is to find a bipartition on the coarsest hypergraph  $\mathcal{H}_\ell$ . PaToH includes various random partitioning methods as well as variations of *Greedy Hypergraph Growing* (GHG) algorithm for bisecting  $\mathcal{H}_\ell$ . In GHG, a cluster is grown around a randomly selected vertex. During the coarse of the algorithm, the selected and unselected vertices induce a bipartition on  $\mathcal{H}_\ell$ . The unselected vertices connected to the growing cluster are inserted into a priority queue according to their *move-gain* [15], where the gain of an unselected vertex corresponds to the decrease in the cutsize of the current bipartition if the vertex moves to the growing cluster. Then, a vertex with the highest gain is selected from the priority queue. After a vertex moves to the growing cluster, the gains of its unselected adjacent vertices that are currently in the priority queue are updated and those not in the priority queue are inserted. This cluster growing operation continues until a predetermined bipartition balance criterion is reached. The quality of this algorithm is sensitive to the choice of the initial random vertex. Since the coarsest hypergraph  $\mathcal{H}_\ell$  is small, initial partitioning heuristics can be run multiple times and select the best bipartition for refinement during the uncoarsening

phase. By default, PaToH runs 11 different initial partitioning algorithms and selects the bipartition with lowest cost.

**3. Uncoarsening Phase:** At each level  $i$  (for  $i = \ell, \ell-1, \dots, 1$ ), bipartition  $\Pi_i$  found on  $\mathcal{H}_i$  is projected back to a bipartition  $\Pi_{i-1}$  on  $\mathcal{H}_{i-1}$ . The constituent vertices of each cluster in  $\mathcal{H}_{i-1}$  is assigned to the part of the respective vertex in  $\mathcal{H}_i$ . Obviously,  $\Pi_{i-1}$  of  $\mathcal{H}_{i-1}$  has the same cutsize with  $\Pi_i$  of  $\mathcal{H}_i$ . Then, this bipartition is refined by running a KL/FM-based iterative improvement heuristics on  $\mathcal{H}_{i-1}$  starting from initial bipartition  $\Pi_{i-1}$ . PaToH provides 12 refinement algorithms that are based on the well-known Kernighan–Lin (KL) [20] and Fiduccia–Mattheyses (FM) [15] algorithms. These iterative algorithms try to improve the given partition by either swapping vertices between parts or moving vertices from one part to other, while not violating the balance criteria. They also provide heuristic mechanisms to avoid local minima. These algorithms operate on passes. In each pass, a sequence of unmoved/unswapped vertices with the highest *gains* are selected for move/swaps, one by one. At the end of a pass, the maximum prefix subsequence of moves/swaps with the maximum prefix sum that incurs the maximum decrease in the cutsize is constructed, allowing the method to jump over local minima. The permanent realization of the moves/swaps in this maximum prefix subsequence is efficiently achieved by rolling back the remaining moves at the end of the overall sequence. The overall refinement process in a level terminates if the maximum prefix sum of a pass is not positive.

PaToH includes original KL and FM implementations, hybrid versions, like one pass FM followed by one pass KL, as well as improvements like *multilevel-gain* concept of Krishnamurthy [21] that adds a lookahead ability, or *dynamic locking* of Hoffman [17], and Dasdan and Aykanat [14] that relaxes vertex moves allowing a vertex to be moved multiple times in the same pass. PaToH also provides heuristic trade-offs, like *early-termination* in a pass of KL/FM algorithms, or *boundary KL/FM*, which only considers vertices that are in the boundary, to speed up the refinement. The default refinement scheme is boundary FM+KL.

## PC Clusters

### ►Clusters

## PCI Express

JASMIN AJANOVIC  
Intel Corporation, Portland, OR, USA

### Synonyms

3GIO; PCI-Express; PCIe; PCI-E

### Definition

PCI (Peripheral Component Interconnect) Express is a highly scalable interconnect technology that is the most widely adopted IO interface standard used in the computer and communication industry [2]. By providing scalable speed/width, extendable protocol capabilities, a common configuration/software model, and various mechanical form-factors, PCI Express supports a broad range of applications. It allows implementation of flexible connectivity between a processor/memory complex and an IO subsystems, including peripheral controllers, such as graphics, networking, storage, etc. PCI Express technology development is managed by PCI-SIG (PCI Special Interest Group), an industry association comprising of over 800 member companies.

### Discussion

#### Introduction – A Brief History of PCIe

PCI Express has its roots in Peripheral Component Interconnect (PCI), an open standard specification that was developed by the computing industry in 1992. PCI was a replacement for the ISA bus which was a mainstream PC architecture IO expansion standard at the time. Although there were several alternative solutions, such as MicroChannel, EISA, and VL-bus, that were aiming to replace/supplement ISA, none of them fully addressed the needs of an evolving PC industry. The PCI specification covered both the hardware and software interfaces between PC's CPU/memory complex and add-in cards, such as graphics, network, and disk controllers. One of the most important aspects of PCI was support for the so called “plug-and-play” mechanisms

## Partitioning Tool for Hypergraphs (PaToH)

### ►PaToH (Partitioning Tool for Hypergraphs)

which allowed operating system software to detect installed hardware components, including both add-in cards and motherboard-down devices, configure system resources required for their operations, including memory address ranges and interrupts, and install appropriate software device drivers. From a hardware perspective, PCI was initially defined as a 32-bit multiplexed address/data bus that was shared among multiple devices attached to it, operating at 5 Volt and at speed of 33 MHz. Over time, faster variants of PCI evolved to support ever increasing performance requirements of CPUs which rose operational frequencies from 66 MHz in 1993 to over 3 GHz by 2003. These variants include:

- 66 MHz 32- and 64-bit PCI operating at 5 V or 3 V.
- AGP (Accelerated Graphic Port), a graphics-optimized interface operating at a common clock speed of 66 MHz and carrying data transfers at 2x, 4x, and 8x of that nominal speed resulting in maximum bandwidth of 0.5, 1, and 2 GB/s over the 32-bit interface.
- PCI-X, a server-optimized solution operating at clock speeds of 66, 100, and 133 MHz and resulting in maximum bandwidth of 0.5, 0.8, and 1 GB/s over the 64-bit interface.

Towards the end of the twentieth century, neither of these solutions proved to be an adequate answer to emerging applications that required higher scalability (performance and protocol capabilities) and a more efficient interface (pins, bandwidth, and power). In 2001, Intel Corporation, together with several other industry leaders, spearheaded the development of the next generation IO architecture. Initially called 3GIO [1], this architecture was later endorsed by the PCI-SIG as PCI Express (PCIe).

Appearing in systems starting in 2003, PCI Express was rapidly adopted by the PC/PCI ecosystem replacing entirely AGP and PCI-X, and in some instances PCI, within 1 or 2 product generations. The key to the PCI Express success was in leveraging of PCI base architecture by supporting full backwards compatibility at the software level while providing a more optimized interconnect solution. The PCI Express physical interface is based on width- and speed-scalable, point-to-point,

differential serial signaling technology operating initially at 2.5 GT/s (Giga Transfers/second). As fast as the new PCI Express standard was, processor architectures have continued to accelerate to meet the demands of emerging applications, and PCI Express needed to keep up. For an example, increasing bandwidth was needed to improve the performance of data-intensive graphics workloads as well as server-class storage and network solutions. PCI Express continued to improve by scaling-up speed as well adding architectural/protocol extensions. [Figure 1](#) shows the evolution of PCI Express technology.

## Technology Overview

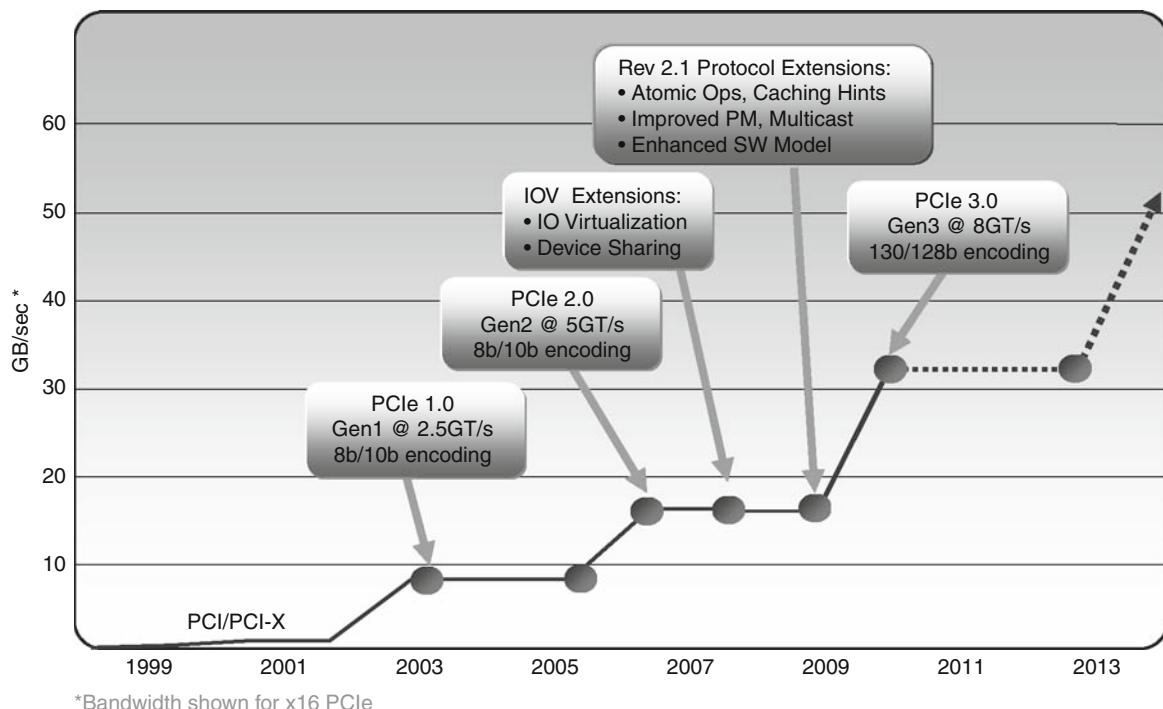

### Basic Elements and Concepts

#### Link and Lane

PCI Express is a point-to-point interconnect technology where Link represents a fundamental element of PCIe-based interconnect fabric. A basic Link is a dual-simplex communications channel between two components that represents a single Lane. Lane consists of two low-voltage, differentially driven signal pairs: a Transmit pair and a Receive pair as shown in [Fig. 2](#). To aggregate the bandwidth of a PCIe Link, multiple Lanes can be grouped together to provide a “wider” Link. In PCIe terminology, Link width is expressed using xN (“by N”) denotation, where N is the number of Lanes that form the Link. PCIe architecture specification defines operations for x1, x2, x4, x8, x12, x16, and x32 Link widths. Companion form-factor specifications (add-in card and connector) define operations for a subset of operational widths (x1, x4, x8, and x16).

#### Signaling, Speed, and Bandwidth

To carry communication over the Link, PCIe uses Low-Voltage Differential Signaling (LVDS) with embedded clocking. Embedded clocking is a mechanism where clock information is embedded within the transmitted data by providing a guaranteed number of transitions between “1’s” and “0’s” that are required to correctly extract the clock on the receiver side. Revision 1.0 (Gen1) and Revision 2.0 (Gen2) of PCIe Specification use standard 8b/10b encoding scheme [3] which is a common mechanism for a number of industry standard interfaces based on serial signaling technology (e.g., Infiniband, Fibre Channel, SATA, etc.). This scheme

**PCI Express. Fig. 1** PCI express technology roadmap

comes with an overhead of 20% because it uses 10bits to carry 8bits of actual information. Since it is relatively simple and very robust, 8b/10b was used by PCIe as a reasonable tradeoff between efficiency and complexity allowing PCIe Gen1 and Gen2 to hit target effective bandwidths while operating at moderately high speeds of 2.5 GT/s and 5 GT/s respectively. However, continuing with 2x increase of operational speed proved to be difficult from a technology enabling/adoptability and ecosystem perspective. For PCIe 3.0 (Gen 3), the PCI-SIG defined a new more efficient 128b/130b encoding scheme, which with ~1% overhead effectively doubles the bandwidth of 5 GT/s Gen2 while operating only at 8 GT/s instead of 10 GT/s (Note that 20% overhead of 8b/10b brings effective data transfers of Gen2 from 5 GT/s down to 4 GT/s.) The following Table 1 shows raw and effective speeds of all three generations of PCIe, including a total bandwidth based on an example of x16 PCIe link.

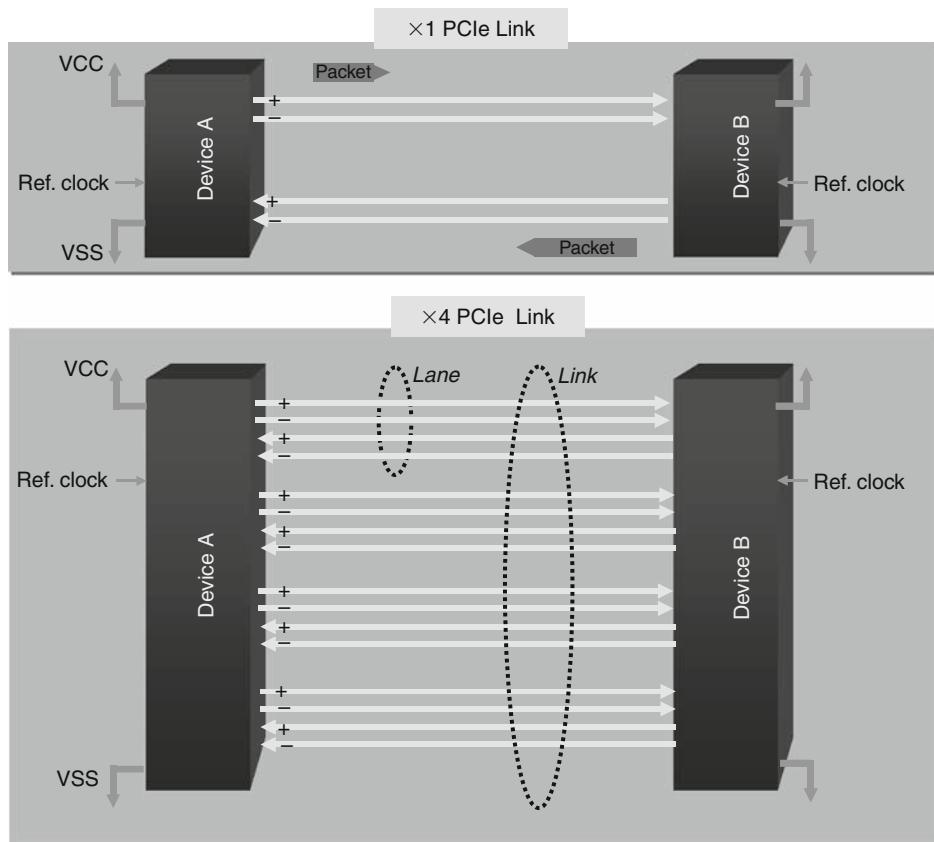

To support backwards compatibility at the system and component/add-in card level, PCI Express Specification requires newer generation devices that operate at higher speeds to support operations at

lower speed. Examples: Gen2 PCIe device operating at nominal 5 GT/s must support operations at 2.5 GT/s, Gen3 device must support operations at both 5 GT/s and 2.5 GT/s.

P

### Link Configuration

PCI Express architecture allows devices that support different Link widths and speeds to be configured for proper operation. The negotiation of width and speed is done as a part of Link initialization process where two devices exchange information about their capabilities using a lowest common denominator method to determine the operational width and speed. For an example, if Device A that supports x8 width at 5.0 GT/s is connected to Device B that supports x4 width at 2.5 GT/s, the Link that connects them will be initialized for x4 width operating at 2.5 GT/s. Note that PCIe allows only configurations of the devices with symmetric Link width. Link width/speed configuration occurs at the Link hardware level without any involvement of software.

**PCI Express. Fig. 2** PCI express link examples - x1 and x4

**PCI Express. Table 1** PCI express speeds and bandwidths

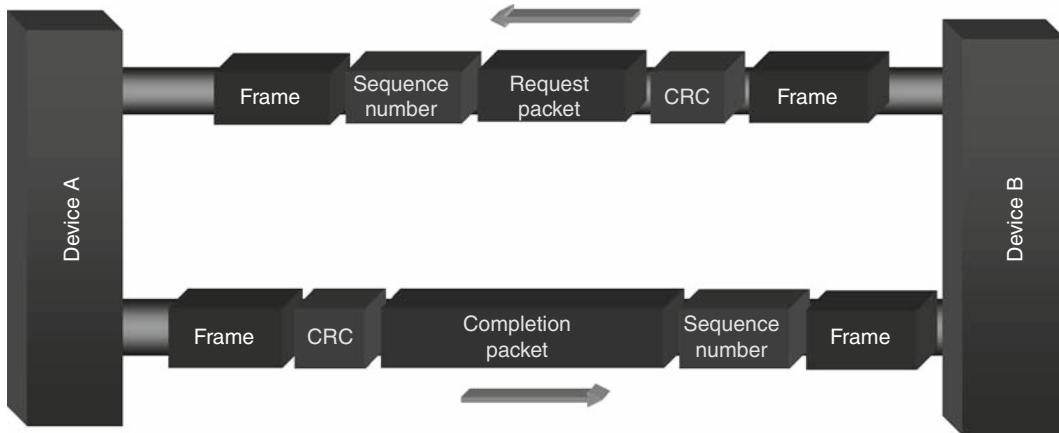

| PCIe Generation | Raw bit rate | Effective bit rate | Bandwidth per lane<br>Per direction | Total bandwidth*<br>For x16 link |
|-----------------|--------------|--------------------|-------------------------------------|----------------------------------|
| PCIe 1.x        | 2.5 GT/s     | 2 Gb/s             | ~250 MB/s                           | ~8 GB/s                          |
| PCIe 2.0        | 5.0 GT/s     | 4 Gb/s             | ~500 MB/s                           | ~16 GB/s                         |
| PCIe 3.0        | 8.0 GT/s     | 8 Gb/s             | ~1 GB/s                             | ~32 GB/s                         |

\*Total bandwidth represents the aggregate interconnect bandwidth in both directions

Once Link is initialized and configured for proper width/speed operations, it may be re-configured during the run-time as a result of a RAS (Reliability, Serviceability, Availability) event due to, for example, data integrity problems. Speed and/or width can be reduced in an attempt to correct the problem and keep the system running with reduced performance/functionalities. Note that the PCIe Specification defines a mechanism where software, through access to configuration/-control registers, can override the established hardware configuration of the Link and force Link to operate at lower speed than nominally capable.

#### Packet-Based Protocol

Instead of using dedicated signals for address, control, and data (such as its predecessor PCI), PCIe uses packets to communicate information between components connected to the PCIe fabric. Packets contain all of the information related to transactions such as: source and target identification/address, type (e.g., Memory Read, Memory Write, Message), attributes (e.g., Isochronous, No Snoop), and data. In addition to this information, Link hardware logic inserts additional information required for correct packet transfer across the Link such as framing, sequencing and packet

**PCI Express. Fig. 3** Packet-based protocol

integrity protection (CRC). Packets can be differentiated as Request and Response packets. To complete the entire transaction (e.g., Memory Read), a single Request packet may cause one or multiple Response packets. Note that some request transaction types (e.g., Message) do not require responses (Fig. 3).

### PCI Express Layering Overview

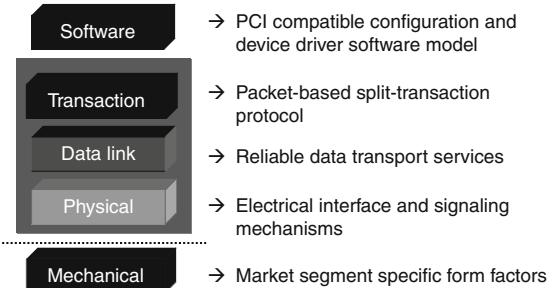

The PCIe interface stack is defined using a layered approach with PCIe Transaction, Data Link, and Physical Layers being formally defined in PCIe Base Specification and the rest of the stack related to Software and Mechanical being covered in companion documents. The following simplified Fig. 4 shows PCIe interface stack and highlights major aspects of each layer.

#### Transaction Layer

The Transaction Layer is responsible for assembly (for transmit) and disassembly (upon receive) of Transaction Layer Packets (TLPs). PCIe supports load-store as well as message-based transactions, where TLPs are used to communicate transactions such as reads, writes, messages, and events using different type of semantics (Memory, I/O, Configuration, and Message), address types/formats (32-bit/64-bit, device ID), and attributes (No Snoop, Relaxed Ordering, and ID-Based Ordering).

The Transaction Layer manages flow of packets between transmitting and receiving devices using credit-based flow control scheme.

Instead of using physical pins/wires to support side-band signals, such as interrupts, power-management

**PCI Express. Fig. 4** PCI express interface stack

requests, etc., PCIe uses Messages as “virtual wires” that carry information in-band. This improves overall efficiency of the interface by eliminating large number of pins/wires.

#### Data Link Layer

This layer provides Link management and data integrity, including error detection and error correction. On the transmit side the Data Link Layer calculates and applies a CRC (Cyclic Redundancy Check) data protection code on the TLP submitted by Transaction Layer. It also adds a TLP sequence number, and passes entire packet to Physical Layer for transmission across the Link. On the receive side the Data Link Layer checks the integrity of received TLPs before passing them to the Transaction Layer for further processing. In the case if an error is detected, this Layer requests retransmission of TLPs until information is correctly received, or the Link is determined to have failed.

### Physical Layer

The Physical Layer converts information received from the Data Link Layer into an appropriate serialized format and transmits it across the Link. This Layer consists of Electrical and Logical functional blocks. Electrical block includes all circuitry required for interface operation: output and input buffers, parallel-to-serial and serial-to-parallel conversion, PLL(s), and transmitter/receiver signal conditioning circuitry. Logical block supports functions required for interface initialization and maintenance, including configuration of Link speed and width.

### Packet Flow Through the Layers

The TLPs are formed in the Transaction Layer to carry the information from the transmitting component to the receiving component. As the transmitted packets flow through the other layers, they are extended with additional information necessary to carry out transfers. At the receiving side the reverse process occurs and packets get transformed from their Physical Layer representation to the Data Link Layer representation and finally to the form that can be processed by the Transaction Layer of the receiving device. [Figure 5](#) shows the conceptual flow of transaction -level packet information through the layers.

Note that for the purpose of Link management, a simpler form of packet communication is supported between two Data Link Layers that are connected to the same Link. These packets are referred to as Data Link Layer Packets (DLLP).

### PCI Express Platform Examples

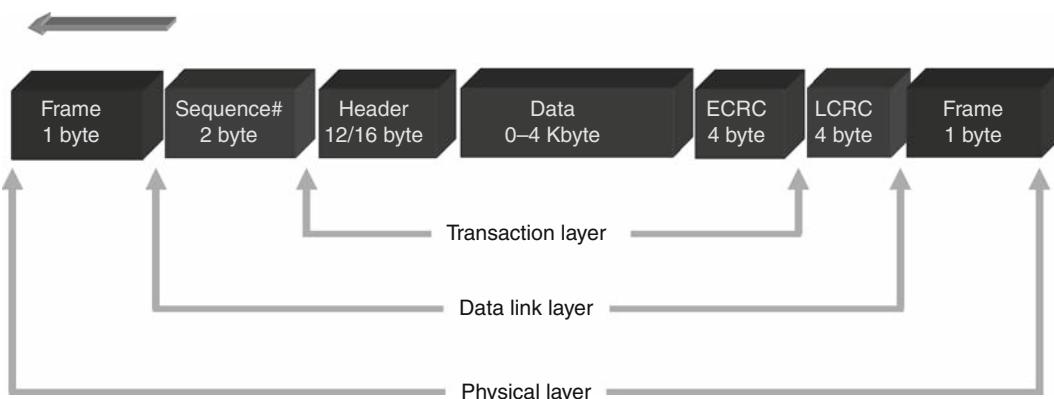

The PCIe architecture supports a variety of platform configurations by allowing the mixing and matching of PCIe link speeds and widths to support different applications. [Figure 6](#) shows examples of PCIe -based client and server computer platforms.

To support high-performance graphics applications, client/workstation computer platforms typically utilize x16 PCIe. Lower bandwidth functions such as network adapters typically use x1 PCIe. Various additional functions (e.g., enhanced audio) can be provided using add-in card slots. Note that an IO Bridge shown on a client platform in [Fig. 6](#) also provides support for some legacy functions, such as old 5 V/33 MHz PCI bus that is required until the technology transition completes.

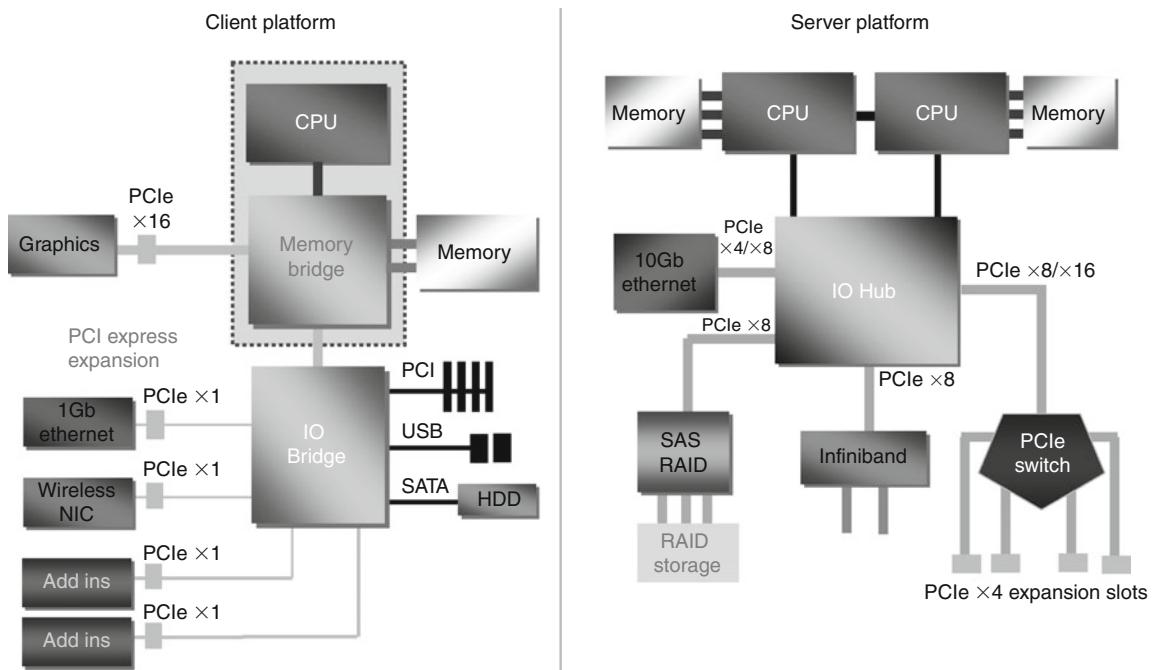

Server platforms typically use x4 and x8 PCIe ports that are required by the high-bandwidth application such as high-performance network (10GigE) and storage (SAS) adapters, Infiniband, Fibre Channel, etc. An important building block for servers is PCIe Switch which is architecturally supported by the PCIe Specification. PCIe Switch is typically used for expansion of IO subsystem by providing additional PCIe interface ports.

### Architecture Features

PCI Express is a scalable architecture that provides a highly flexible and expandable set of capabilities. This section highlights essential features of PCIe.

PCI Express. [Fig. 5](#) Packet formation

PCI Express. Fig. 6 Examples of PCIe based platforms

### Scalable Protocol

PCIe uses a fully packetized split-transaction protocol as described under the Technology Overview section. In addition to load-store semantics, it provides messaging support that is used by the Virtual Wire mechanism to eliminate side-band signals by converting them into in-band messages. PCIe uses a credit-based scheme to control the flow of packets within the PCIe fabric. This scheme applies per Link, and it is used to prevent buffer overflow. To minimize the dependency between different traffic flows in a system, PCIe provides Virtual Channel (VC) mechanism and transaction ordering relaxations. These mechanisms mitigate the overhead of a strict producer-consumer ordering model (that may create head-of-line blocking conditions) and allow support for differentiated Quality of Service at the platform level.

For future scalability of supported packet formats, PCIe defines Transaction Layer Packet Prefix, a mechanism for extending TLP headers.

### PCI Compatible Software Model

PCIe leverages standard mechanisms defined in the PCI Plug-and-Play specification for device initialization, enumeration, and configuration. This allows legacy

software operating systems to boot without modifications on a PCIe-based system. It also preserves compatibility with device driver software model, enabling existing API, and application software to execute unchanged. To remove platform overhead and limitations associated with legacy PCI software configuration, PCIe provides Enhanced Configuration mechanism. This mechanism needs to be supported by newer operating systems to fully take the advantage of PCIe advanced capabilities (e.g., Advanced Error Logging/Reporting, Virtual Channel Mechanism). Enhanced Configuration also allows new capabilities to be added in the future.

### Scalable Performance

Primary factor in PCIe performance scaling as measured by the interface bandwidth is function of interface width and operational frequency and can be expressed using the following formula:

$$\begin{aligned}
 & \text{Total Link Bandwidth [GB/s]} \\
 & = \text{Link_Width[Number of lanes]} \\
 & \quad \times \text{Effective_Signaling_Rate[Gb/s]} \\
 & \quad \times 2[\text{directions}]/8[\text{bits}]
 \end{aligned}$$

GB/s = Giga Byte per second, Gb/s = Giga bit per second, GT/s = Giga Transfer per second

for Gen1 and Gen2: Effective\_Signaling\_Rate[Gb/s] = Raw\_Signaling\_Rate[GT/s] × 0.8

for Gen3: Effective\_Signaling\_Rate [Gb/s] ≈ Raw\_Signaling\_Rate [GT/s]

Secondary factor of PCIe performance is related to the fact that PCIe is point-to-point interconnect with two unidirectional signaling paths which are contention-free i.e., do not require arbitration. This means that in systems that contain multiple PCIe Links, traffic on each Link can occur independently and simultaneously which improves total system throughput. An additional contributor to performance is related to PCIe -pin/bandwidth efficiency. By improving this aspect, PCIe allows a tighter IO integration within the platform, e.g., direct PCIe attach to high-integration CPUs. This can result in lower IO system latencies in an optimized system.

Note that the above formula shows only theoretical bandwidths, but that actual performance as seen at the application level depends on number of factors. These factors include PCIe -interface and system implementation aspects such as: supported data payload size, interface-level data buffering/queuing and effectiveness of flow-control, arbitration mechanisms throughout the platform (e.g., competing for host memory access), power -management mechanisms and policies, software device driver and API overheads, etc.

## Advanced Power Management

PCIe defines Link level power -management scheme including the active-state power -management (ASPM) protocol. The ASPM manages power -state transitions on the Link transparently to run-time software by detecting idle conditions on the Link, i.e., when no actual data is being communicated over the Link. Note that in signaling schemes that use embedded clocking, data needs to be transmitted continuously to maintain synchronization between transmitter and receiver. To reduce the power consumption during “idle,” PCIe defines low-power link states. These states save power but transitions into and out of them require recovery time to resynchronize the transmitter and receiver which potentially may impact the Link latency and affect the overall system performance. In addition to

Link level, power-management PCIe defines related system level power-management mechanisms such as:

- Latency Tolerance Reporting – reduces platform power based on PCIe device service requirements.
- Opportunistic Buffer Flush and Fill – aligns PCIe -device activity with platform power-management events to further reduce platform power.
- Dynamic Power Allocation–dynamic control of power/thermal budget per PCIe device.

## Reliability, Availability, Serviceability (RAS) Support

RAS capabilities are defined to: ensure data integrity, provide ability to identify/manage errors, and allow installation/removal of components in the running system without requiring operating system shutdown.

- Data Integrity – As a basic/required mechanism, PCIe defines a data integrity scheme where 32-bit CRC (Cyclic Redundancy Check) is used to protect packets transmitted over the single Link. For platforms that use more complex topologies (i.e., with PCIe Switches) and require end-to-end data integrity, PCIe defines an optional end-to-end 32-bit CRC. This CRC code is used in addition to Link local 32-bit CRC to protect the data in high -reliability server applications.
- Hot Plug and Hot Swap – PCIe defines native support for hot plugging or hot swapping of IO cards/modules. Solutions based on PCIe hot plug/ swap address requirements of both server and portable computer platforms and support industry standard software stacks for platform management and configuration.
- Advanced Error Reporting/Handling – PCIe defines support for error logging/reporting to improve system -fault isolation and enable recovery solutions.

## Differentiated Quality of Service (QoS) Support

Using Virtual Channel (VC) mechanism as a foundation, PCIe supports eight levels of QoS differentiated traffic including isochronous traffic type. PCIe specification defines VC-system configuration and programmable-VC arbitration mechanism necessary to support an end-to-end solution designed for applications, such as isochronous that require real-time delivery of voice and video related data.

## IO Virtualization and Device Sharing Support

PCIe defines an IO interface-level mechanism for support of platform virtualization. In virtualized platforms, a single instance of platform hardware is mapped in to a multiple independent Virtual Machines, each running their own operating system and application software stacks. In addition to PCI Express Base Specification, the PCI-SIG maintains a set of specifications that cover PCIe support for:

- Address Translation Services: allow PCIe devices to obtain copies of translated system addresses to mitigate address translation latencies in IO Virtualized platform.
- Single-Root IO Virtualization and Device Sharing: improves system performance scaling by allowing a single PCIe device to be presented to the software as multiple independent/pseudo-independent hardware devices.
- Multi-Root IO Virtualization: allows multiple independent PCIe-based platforms (such as in blade-server systems) to overlap/share system resources.

Note that IO Virtualization capabilities require new software, both at the PCIe fabric configuration/management level as well as at the system level.

## Support for Heterogeneous Processing and Application Acceleration

There is a set of capabilities that are provided to support high-performance applications which require efficient co-processing and data sharing, such as GP-GPU, computational accelerators, and network/storage accelerators. These include:

- Transaction Layer Packet Processing Hints – Request hints from PCIe device to enable optimized processing within host memory/cache hierarchy.
- Atomic Read-Modify-Write Transactions – Reduce synchronization overhead for shared data structures.
- Address Based Multicast – Allows significant gains in efficiency compared to multiple unicast transactions by carrying transaction between the single source and multiple destinations.

## Form-Factors

In addition to chip-chip connectivity usage, PCI Express supports a variety of system board and add-in

card form-factors. To address diversity of applications across many segments (desktop and mobile PCs, servers, embedded/communications, etc.), the following add-in form-factors are defined:

- PCIe Card Electromechanical (CEM) used for desktops, workstations, and servers.
- PCIe Mini Card used for portable computers.
- PCIe Module also known as Server IO Module (SIOM) optimized for server/communication systems.
- ExpressCard used for portable computers and small form-factor desktops.
- PCIe External Cabling Spec used for embedded/communication.

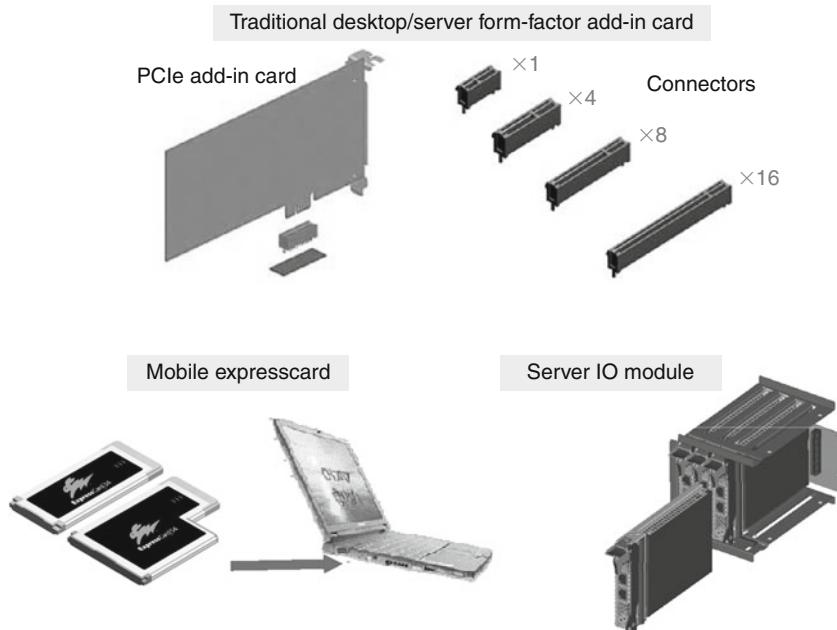

[Figure 7](#) shows a sample of form-factors including the most common PCIe CEM add-in card specified by the PCI-SIG. This card is defined to fit into the traditional desktop PC and server systems and comes with different connector widths (x1, x4, x8, and x16). It supports power usage from baseline 25 W up to 300 W in x16 variant used for high-end graphics and similar applications.

In addition to the PCI-SIG, there are several other industry associations, such as PCMCIA and PICMG that have been involved in development of PCI Express based form-factors.

## PCI Express Today

Products based on first generation (2.5 GT/s) and second generation (5 GT/s) of PCIe technologies are deployed broadly across computer and communication/embedded industries. When you consider this in light of the PCI-SIG's 800 members, many of them very active, the PCIe product development and users community represents a large ecosystem. According to a report from an industry analyst organization, In-Stat [2], the size of market of components that include PCIe interface will exceed 440 million units/year by 2010.

PCI-SIG is marching towards the milestone of releasing a third generation of PCI Express spec, i.e., PCIe Rev 3.0 in second half of 2010. In addition to 2.5 and 5 GT/s, PCIe 3.0 supports 8 GT/s operational speed by using a new, more efficient signaling encoding scheme which will allow doubling of bandwidth compared to the prior generation. In addition, the new generation of PCIe products based on Rev 3.0 will support enhanced power management as well as features for

PCI Express. Fig. 7 Example of PCIe form-factors

application performance acceleration through: atomic read-modify-write, data reuse/caching hints, multicast operations, etc.

### Future Directions

There are two very significant trends within the mainstream computer and communication industry that will influence the evolution of PCI Express technology:

- Increasing level of integrated functionality resulting in very high-integration single die devices, known as SoC (System on a Chip), or high-integration multi-die components/modules, known as SiP (System in a Package).
- Evolution of Internet with ever increasing need for improved computational, storage, and communication performance of the main building blocks that provide the service.

First trend is mainly driven by the applications that dictate small form-factors, low-power, and low-cost. They range from smart-phones and entertainment devices to the components used in embedded control applications such as home appliances, cars, printers, etc. For some of these products, levels of integration will result in removal of external interfaces such as PCIe and for

the others, external interfaces will be still needed, but with a requirement for significantly improved power efficiency. This may dictate evolution of PCIe technology in two directions:

- On-die interconnects that are architecturally equivalent to PCIe and allow integration of PCIe devices in the form of IP (Intellectual Property) building blocks.
- Lower power and lower speed variants of PCIe.

Note that significant value of PCIe ecosystem comes from the ability to support standard operating system software, device drivers, and applications. On-die interconnects that are an architectural equivalent (not necessarily physical/electrical equivalent) of PCIe, will enable integration of hardware functionality without the requirement to change the software stack. This may result in huge R&D savings and faster time-to-market for SoC/SiP designs that use PCIe IP building blocks.

Second trend, evolution and expansion of Internet, will translate into a requirement to the computer industry to provide new generations of communication

servers and data centers that are capable of handling increasing and diverse workloads. This will drive a need for hardware and software optimizations for virtualization and cloud computing. Evolution of traditional rack-servers and blade-servers may open room for a new interconnect backbone/fabric based on PCIe technology. This will drive the following enhancements to the PCIe technology:

- Enhanced routing and configuration to support more elaborate topologies (besides PCI/PCIe hierarchical tree) to allow system scalability through aggregation of large number of discrete devices as well as high-integration devices (that consist of multiple logical devices).
- Capability for tunneling and mapping other protocols (e.g., for storage, networking, system management, etc.) which will allow consolidation of interconnect technologies within the rack/blade and perhaps even a data center.
- Doubling/multiplying bandwidth needed to support next generation of Internet, HPC (High-Performance Computing), and cloud computing. This will eventually result in emergence of PCIe Optical connectivity starting with discrete solutions at speeds ranging from 16GT/s to 25 GT/s and evolving to 50 GT/s silicon-photonics-based integrated solution.

Evolution of PCI Express will likely track the future path of the computer industry. New IO technologies will continue to emerge in the future, using some elements of PCI Express as its foundation.

## Bibliographic Notes and Further Reading

As mentioned in the introduction, development of PCI Express technology as an industry standard is being coordinated through PCI Special Interest Group (PCI-SIG). This organization maintains the website with officially published specification documents and other collaterals that are part of PCI Express standard. For detailed information go to:

- PCI-SIG: [www.pcisig.com](http://www.pcisig.com).

Note that, although some documents are available to a general audience, membership with the PCI-SIG is required for non-restricted access to all documents and specifications managed by the SIG.

In addition to PCI-SIG, there are several other industry organizations, such as:

- PCMCIA: [www.pcmcia.org](http://www.pcmcia.org)
- PICMG: [www.picmg.org](http://www.picmg.org)

that manage development of complementary industry standards based on PCIe Base Specification. These organizations enhance PCI Express technology by defining additional form-factors and design collaterals that allow even broader adoption of PCI Express component-level hardware products as well as companion software.

Among the component and platform vendors that provide significant additional support for PCI Express technology is Intel Corporation with: Intel® Developer Network for PCI Express\* Architecture. This forum provides members with technical data, marketing support and industry connections needed to accelerate the innovation and marketing of PCI Express based solutions. For more details see:

- PCIe DevNet: [http://www.intel.com/technology/pci\\_express/devnet/](http://www.intel.com/technology/pci_express/devnet/)

There are several technical books that provide overviews of PCI Express technology as well as detailed implementation guidelines. See references [4–6].

## Synonyms

Distributed hash table (DHT); Overlay network; Decentralization; Open distributed systems; Consistent hashing

## Definition

The term *peer-to-peer* (p2p) is ambiguous, and is used in a variety of different contexts, such as:

- In popular media coverage, p2p is often synonymous to software or protocols that allow users to “share” files (music, software, books, movies, etc.). p2p file sharing is very popular and a large fraction of the total Internet traffic is due to p2p.
- In academia, the term p2p is used mostly in two ways. A narrow view essentially defines p2p as the “theory behind file-sharing protocols.” In other words, how do Internet hosts need to be organized in order to deliver a search engine to find (share) content (files) efficiently? A popular term is “distributed hash table” (DHT), a distributed data structure that implements such a content search engine. A DHT should support at least a search (for a key) and an insert(key, object) operation. A DHT has many applications beyond file sharing, e.g., the Internet domain name system (DNS).
- A broader view generalizes p2p beyond file sharing: Indeed, there is a growing number of applications operating outside the juridical gray area, e.g., p2p Internet telephony à la Skype, p2p mass player games, p2p live audio and video streaming as in PPLive, StreamForge or Zattoo, or p2p social storage and cloud computing systems such as Wuula. Trying to account for the new applications beyond file sharing, one might define p2p as a large-scale distributed system that operates without a central server bottleneck. However, with this definition almost “everything decentralized” is p2p!
- From a different viewpoint, the term p2p may also be synonymous for privacy protection, as various

p2p systems such as Freenet allow publishers of information to remain anonymous and uncensored.

In other words, there is no single well-fitting definition of p2p, as some definitions in use today are even contradictory. In the following, an academic viewpoint is assumed (second and third definition above).

## Discussion

### The Paradigm

At the heart of p2p computing lies the idea that each network participant serves both as a producer (“server”) and consumer (“client”) of services. Depending on the application, the shared resources can be data (files), CPU power, disk storage, or network bandwidth. Often p2p systems have an open clientele, and do not rely on the availability of specific individual machines; rather they can deal with dynamic resources and do not exhibit single points of failure or bottlenecks.

Compared to centralized solutions, the p2p paradigm features a better scalability because the amount of resources grows with the network size, availability (avoiding a single point of failure), reliability, fairness, cooperation incentives, privacy, and security – just about everything researchers expect from a future Internet architecture. As such, it is not surprising that new “clean slate” Internet architecture proposals often revolve around p2p concepts.

One might naively assume that for instance scalability is not an issue in today’s Internet, as even most popular web pages are generally highly available. However, this is not necessarily due to our well-designed Internet architecture, but rather due to the help of so-called overlay networks: The Google Web site for instance manages to respond so reliably and quickly because Google maintains a large distributed infrastructure, essentially a p2p system. Similarly, companies like Akamai sell “p2p functionality” to their customers to make today’s user experience possible in the first place. Quite possibly today’s p2p applications are just testbeds for tomorrow’s Internet architecture.

### Implications

p2p networks are often highly dynamic in nature. While traditional computer systems are typically based on fixed infrastructures and are under a single administrative domain (e.g., owned and maintained by a single

company or corporation), the participating machines in p2p networks are under the control of individual (and to some extent: anonymous) users who can join and leave at any time and concurrently. In p2p parlance, such membership changes are called *churn*.

A second implication of the autonomy of the machines in p2p networks is that the network consists of different stakeholders. Users can have various reasons for joining the network. For instance, an (anonymous) user may not voluntarily contribute his or her bandwidth, disk space, or CPU cycles to the system, but prefer to *free ride*. This adds a socioeconomic aspect to p2p computing. As the p2p paradigm relies on the contributions of the participating machines, effective incentive mechanisms have to be designed, which foster cooperation and punish free riders.

Another source of inequality in p2p systems apart from selfishness is *heterogeneity*: Due to the open membership, different machines run different operating systems, have different Internet connections, and so on.

### Applications

The best-known representatives of p2p technology are probably the numerous file-sharing applications such as Napster, Gnutella, KaZaA, eMule, or BitTorrent. Also, the Internet telephony tool Skype is very popular and used by millions everyday. Zattoo, PPLive, and StreamForge, among many others, use p2p principles to stream video or audio content. The cloud computing service Wuala offers free online storage by exploiting the participants’ disks and Internet connections to improve performance. Recently, the power and anonymity of decentralized Internet working has gained the attention of operators of botnets in order to attack certain infrastructure components by a denial-of-service attack. Finally, p2p technology is used for large-scale computer games.

### Architecture Variants

Several p2p architectures are known:

- Client/Server goes p2p: Even though Napster is known to be the first p2p system (1999), by today’s standards its architecture would not deserve the label p2p anymore. Napster clients accessed a central server that managed all the information of the shared files, i.e., which file was to be found on

- which client. Only the downloading process itself was between clients (“peers”) directly, hence p2p. In the early days of Napster the load of the server was relatively small, so the simple Napster architecture was sufficient. Over time, it turned out that the server may become a bottleneck – and an attractive target for an attack. Indeed, eventually a judge ruled the server to be shut down (a “juridical denial of service attack”). However, it remains to note that many popular P2P networks today still include centralized components, e.g., KaZaA or the eDonkey network accessed by the eMule client. Also, the peer swarms downloading the same file in the BitTorrent network are organized by a so-called tracker whose functionality today is still centralized (although initiatives exist to build distributed trackers).
- **Unstructured p2p:** The Gnutella protocol is the antithesis of Napster, as it is a fully decentralized system, with no single entity having a global picture. Instead each peer connects to a random sample of other peers, constantly changing the neighbors of this virtual overlay network by exchanging neighbors with neighbors of neighbors. (Any unstructured system also needs to solve the so-called *bootstrap problem*, namely how to discover a first neighbor in a decentralized manner. A popular solution is the use of well-known peer lists.) The fact that users often turn off their clients once they downloaded their content implies high levels of churn (peers joining and leaving at high rates), and hence selecting the right “random” neighbors is an interesting research problem. The Achilles’ heel of unstructured p2p architectures such as Gnutella is the cost of searching. A search request is typically flooded in the network and each search operation will cost  $m$  messages,  $m$  being the number of virtual edges in the architecture. In other words, such an unstructured p2p architecture will not scale. Indeed, when Napster was unplugged, Gnutella broke down as well soon afterward due to the inrush of former Napster users.
  - **Hybrid p2p:** The synthesis of client/server architectures such as Napster and unstructured architectures such as Gnutella are hybrid architectures. Some powerful peers are promoted to so-called superpeers (or, similarly, trackers). The set of superpeers may change over time, and taking down

a fraction of superpeers will not harm the system. Search requests are handled on the superpeer level, resulting in much less messages than in flat/homogeneous unstructured systems. Essentially, the superpeers together provide a more fault-tolerant version of the Napster server, as all regular peers connect to a superpeer. As of today, almost all popular p2p systems have such a hybrid architecture, carefully trading off reliability and efficiency.

- **Structured p2p:** Inspired by the early success of Napster, the academic world started to look into the question of efficient file sharing. Indeed, even earlier, in 1997, Plaxton et al. [34] proposed a hypercubic architecture for p2p systems. This was a blueprint for many so-called structured p2p architecture proposals, such as Chord [46], CAN [36], Pastry [37], Tapestry [50], Viceroy [26], Kademia [27], Koord [15], SkipGraph [3], and SkipNet [11]. Maybe surprisingly, in practice, structured p2p architectures did not take off yet, apart from certain exceptions such as the Kad architecture (from Kademia [27]), which is accessible with the eMule client.

## Scientific Origins

The scientific foundations of p2p computing were laid many years before the most simple “real” p2p systems like Napster emerged. As already mentioned, in 1997, a blueprint for structured systems has been proposed in [34]. Indeed, also the [34] paper was standing on the shoulders of giants. Some of its eminent precursors are the following:

- Research on linear and consistent hashing, e.g., [16].
- Research on locating shared objects, e.g., [4] or [5].
- Research on so-called compact routing: The idea is to construct routing tables such that there is a trade-off between memory (size of routing tables) and stretch (quality of routes), e.g., [31] or [49].
- Even earlier, hypercubic networks, see below.

## Hypercubic Overlays and Consistent Hashing

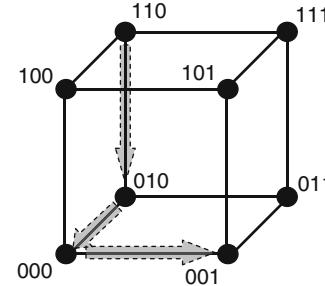

Every application run on multiple machines needs a mechanism that allows the machines to exchange information. A naive solution is to store at each machine the domain name or IP address of every other machine.

While this may work well for a small number of machines, large-scale distributed applications such as file sharing, grid computing, cloud computing, or data center networking systems need a different, more scalable approach: instead of forming a clique (where everybody knows everybody else), each machine should only be required to know some small subset of other machines. This graph of knowledge can be seen as a logical network interconnecting the machines; it is also known as an *overlay network*. A prerequisite for an overlay network to be useful is that it has good topological properties. Among the most important are small peer degree, small network diameter, robustness to churn, or absence of congestion bottlenecks.

The most basic network topologies used in practice are trees, rings, grids, or tori. Many other suggested networks are simply combinations or derivatives of these. The advantage of trees is that the routing is very easy: for every source-destination pair there is only one possible path. However, the root of a tree can be a severe bottleneck. An exception is a p2p streaming system where the single content provider forms the network root. However, trees are also highly vulnerable, e.g., with respect to membership changes.

Essentially all state-of-the-art p2p networks today have some kind of hypercubic topology (e.g., Chord, Pastry, Kademlia). Hypercube graphs have many interesting properties, e.g., they allow for efficient routing: although each peer only needs to store a logarithmic number of other peers in the system (the peers' neighbors), by a simple routing scheme, a peer can reach each other peer in a logarithmic number of steps (or "hops"). In a nutshell, this is achieved by assigning each peer a unique  $d$ -bit identifier. A peer is connected to all  $d$  peers that differ from its identifier at exactly one bit position. In the resulting hypercube network, routing is done by adjusting the bits in which the source and the destination peers differ – one at a time (at most  $d$  many). Thus, if the source and the destination differ by  $k$  bits, there are  $k!$  routes with  $k$  hops. [Figure 1](#) gives an example.

Given a hypercubic topology, it is then simple to construct a distributed hash table (DHT): Assume there are  $n = 2^d$  peers that are connected in a hypercube topology as described above. Now a globally known hash function  $f$  is used, mapping file names to long bit strings. Let  $f_d$  denote the first  $d$  bits (prefix) of

**Peer-to-Peer. Fig. 1** A simplified p2p topology: a three-dimensional hypercube. Each peer has a three-bit identifier. For example, peer 110 is connected to the three peers 010, 100, 111 whose identifiers differ at exactly one position. In order to route a message from peer 110 to say peer 001, one bit is fixed after the other. One possible routing path is depicted in the figure: 110 → 010 → 000 → 001. An alternative path could be 110 → 111 → 101 → 001

the bitstring produced by  $f$ . If a peer is searching for file name  $X$ , it routes a request message  $f(X)$  to peer  $f_d(X)$ . Clearly, peer  $f_d(X)$  can only answer this request if all files with hash prefix  $f_d(X)$  have been previously registered at peer  $f_d(X)$ .

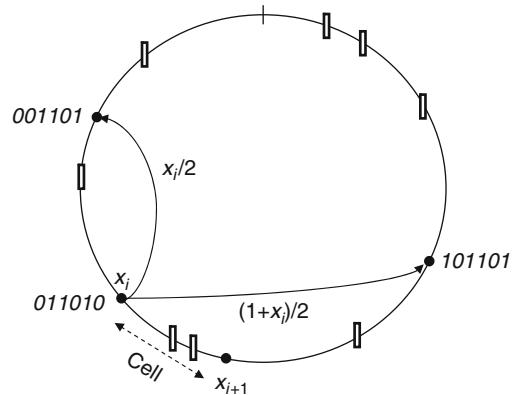

There are some additional issues to be addressed in order to design a DHT from a hypercubic topology, in particular how to allow peers to join and leave without notice. To deal with churn the system needs some level of replication, i.e., a number of peers, which are responsible for each prefix such that failure of some peers will not compromise the system. In addition, there are security and efficiency issues that can be addressed to improve the system.

There are many hypercubic networks that are derived from the hypercube: among these are the butterfly, the cube-connected-cycles, the shuffle-exchange, and the de Bruijn graph. For example, the butterfly graph is basically a "rolled out" hypercube (hence directly providing replication!) of constant degree. Another important class of hypercubic topologies are skip graphs [3, 11].

A simple, interesting way to design dynamic p2p systems is the *continuous-discrete approach* described by Naor and Wieder [29]. This approach is based on a "think continuously, act discretely" strategy, and can be used to design a variety of hypercubic topologies. The continuous-discrete approach gives a unified method

for performing join/leave operations and for dealing with the scalability issue, thus separating it from the actual network. The idea is as follows: Let  $I$  be a Euclidean space, e.g., a (cyclic) one-dimensional space. Let  $G_c$  be a graph where the vertex set is the continuous set  $I$ . Each point in  $I$  is connected to some other points. The actual network then is a discretization of this continuous graph based on a dynamic decomposition of the underlying space  $I$  into cells where each “server” is responsible for a cell. Two cells are connected if they contain adjacent points in the continuous graph. Clearly, the partition of the space into cells should be maintained in a distributed manner. When a join operation is performed, an existing cell splits, when a leave operation is performed two cells are merged into one. The task of designing a dynamic and scalable network follows these design rules: (1) Choose a proper continuous graph  $G_c$  over the continuous space  $I$ . Design the algorithms in the continuous setting, which is often simpler (also in terms of analysis) than in the discrete case. (2) Find an efficient way to discretize the continuous graph in a distributed manner, such that the algorithms designed for the continuous graph would perform well in the discrete graph. The discretization is done via a decomposition of  $I$  into the cells. If the cells that compose  $I$  are allowed to overlap, then the resulting graph would be fault tolerant.

To give an example, in order to build a dynamic *de Bruijn* network (a so-called Distance Halving DHT), a peer at position  $x \in [0,1)$  (in binary form  $b_1 b_2 \dots$  such that  $x = \sum_{i=1}^{\infty} 2^{-b_i}$ ) connects to positions  $l(x) := x/2 \in [0,1)$  and  $r(x) := (1+x)/2 \in [0,1)$  in  $G_c$  (out-degree two per peer). Observe that if position  $x$  is written in binary form, then  $l(x)$  effectively shifts in a “0” from the left and  $r(x)$  shifts in a “1” from the left. Thus, routing is straightforward: based solely on the current position and the destination (without the overhead of maintaining routing tables), a message can be forwarded by a peer by fixing one bit per hop. The set of peers in the cyclic  $[0,1)$  space then define the p2p network: Let  $x_i$  denote the position of the  $i^{th}$  peer (ordered in increasing order with respect to position). Peer  $i$  is responsible for the cell  $[x_i, x_{i+1})$ , computed in a modulo manner, i.e., this peer is responsible to store the data mapped to this cell plus for the establishment of the corresponding connections defined in  $G_c$ . Figure 2 gives an example.

**Peer-to-Peer. Fig. 2** The continuous–discrete approach for the dynamic de Bruijn graph. Peers are indicated using circles, files using rectangles. In the continuous setting, the peer at position  $x_i = 0.011010$  (in binary notation) is connected to positions  $x_i/2$  and  $(1+x_i)/2$ . In the discrete setting, it is responsible for the cell (i.e., the connections and files that are mapped there) between positions  $x_i$  and  $x_{i+1}$

## Dealing with Churn

A distinguishing property of p2p systems are the frequent membership changes. Measuring the churn levels of existing p2p systems is challenging and one has to be careful when generalizing a given measurement to entire application classes (e.g., [10]). Nevertheless, several insightful measurement studies have been conducted. For instance, [9, 38] reported on the dynamic nature of early p2p networks such as Napster and Gnutella, and [41] analyzed low-level data of a large Internet Service Provider (ISP) to estimate churn. Also the Kad DHT has been subject to measurement studies, and the reader is referred to the results in [47] and [43].

It is widely believed that hypercubic structures are a good basis for churn-resilient p2p systems. As written earlier, a DHT is essentially a hypercubic structure with peers having identifiers such that they span the ID space of the objects to be stored. A simple approach to map the ID space onto the peers has already been described for the hypercube. To give another example, in the butterfly network, we may use its layers for replication, i.e., all peers with the same ID redundantly store the data of the same hash prefix. Other hypercubic DHTs can be more difficult to design, e.g., networks based on the pancake graph [19].

For many well-known systems, theoretic analyses exist showing that the networks remain well-structured after some joins, leaves, or failures occur. In order to evaluate the robustness formally, metrics such as the network *expansion* (for deterministic failures) or the *span* [6] (for randomized failures) are used. Unfortunately, the span is difficult to compute, and the span value is known only for the most simple topologies.

The continuous-discrete approach [29] already mentioned constitutes the basis of several dynamic systems. For example, the SHELL system [40] is robust to certain attacks by connecting older or more reliable peers in a core network where access can be controlled; SHELL also allows to organize heterogeneous peers in an efficient topology.

Many systems proposed in the literature offer a high robustness in the average case, i.e., they provide probabilistic guarantees that hold with high probability. Robustness under attacks or worst-case dynamics is less well understood. In [19], a system is developed that achieves an optimal worst-case robustness in the sense that there is no alternative system that can tolerate higher churn rates without disconnecting. The basic idea is to simulate a hypercube: each peer is part of a distinct hypercube *node*; each hypercube node consists of a logarithmic number of peers. Peers have connections to other peers of their hypercube node and to peers of the neighboring hypercube nodes. After a number of joins and leaves, some peers may have to change to another hypercube node such that up to constant factors, all hypercube nodes have the same cardinality at all times. If the total number of peers grows or shrinks above or below a certain threshold, the dimension of the hypercube is increased or decreased by one, respectively. The balancing of peers among the nodes can be seen as a *dynamic token distribution problem* on the hypercube: Each node of a graph (hypercube) has a certain number of tokens, and the goal is to distribute the tokens along the edges of the graph such that all nodes end up with the same or almost the same number of tokens. Thus, the system builds on two basic components: (1) an algorithm, which performs the described dynamic token distribution and (2) an information aggregation algorithm, which is used to estimate the number of peers in the system and to adapt the hypercube's dimension accordingly. These techniques also work for alternative graphs, like pancake graphs [19].

An appealing notion of robustness is *topological self-stabilization*: A p2p topology is called self-stabilizing if it is guaranteed that from any weakly connected initial state (e.g., after an attack), it will quickly converge to a desirable network in the absence of further membership changes. In contrast to the worst-case churn considered in [19], self-stabilization focuses on the convergence time in periods without membership changes, but allows for general initial system states. While until recently, self-stabilizing algorithms with guaranteed runtime have only been known for simple one-dimensional or two-dimensional linearization problems [14], recently a construction for a variation of skip graphs, namely SKIP+ graphs [13], has been proposed. Single joins and leaves in SKIP+ can be handled locally, and require logarithmic time and polylogarithmic work only. However, there remains the important open question of how to provide degree guarantees during convergence from arbitrary states.

## Fostering Cooperation

The appeal of p2p computing arises from the collaboration of the system's constituent parts, the peers. If all the participating peers contribute some of their resources, highly scalable decentralized systems can be built. However, in reality, peers may act selfishly and strive for maximizing their own utility by benefitting from the system without contributing much themselves [42]. Hence, the performance of a p2p system crucially depends on its capability of dealing with selfishness.

Already in 2000, Adar and Huberman [1] noticed that there exists a large fraction of free riders in the file-sharing network Gnutella. The problem of selfish behavior in p2p systems has been a hot topic in p2p research ever since, and many mechanisms to encourage cooperation have been proposed [30]. Perhaps the simplest fairness mechanism is to directly incorporate contribution monitoring into the client software. For instance, in the file-sharing system KaZaA, the client records the contribution of its user. However, such a solution can simply be bypassed by implementing a different client that hard-wires the contribution level to the maximum, as it was the case with *KaZaA Lite*. Inspired by real economies, some researchers have also proposed the introduction of some form of virtual money, which is used for the transactions.

BitTorrent has incorporated a fairness mechanism from the beginning and has hence been subject to intensive research (e.g., [21, 22, 35]). Although this mechanism has similarities to the well-known tit-for-tat scheme, the strategy employed in BitTorrent distinguishes itself from the classic mechanism in many respects. For instance, it is possible for peers to obtain parts of a file “for free,” i.e., without reciprocating. While this may be a useful property for bootstrapping newly joined peers, it has been shown that the BitTorrent mechanism can be exploited: the *BitThief* BitTorrent client [24] allows to download entire files fast without uploading any data. It has also been demonstrated in [24] that sharing communities are particularly vulnerable to such exploits. BitThief is not the only client cheating BitTorrent. Piatek et al. [32] presented *BitTyrant*. BitTyrant’s strategy is to exploit the BitTorrent protocol in order to maximize download rates. For instance, BitTyrant uses a smart neighbor selection strategy and connects to those peers with the best reciprocation ratios. In contrast to BitThief, BitTyrant does not free ride. BitTyrant seeks to provide the minimal necessary contribution, and also increases the active neighbor set if this is beneficial to the download rate. The authors claim that their client provides a median 70% performance gain in certain environments.

There can be many other forms of strategic behavior in open distributed systems. One subject that has recently gained attention, especially by the game-theoretic research community, is *neighbor selection* in unstructured p2p networks (e.g., [28]). There may be several reasons for a peer to prefer connecting to some peers rather than others. For instance, a peer may want to connect to peers with high bandwidths, peers storing many interesting files, or peers having large degrees and hence provide quick access to many other peers. At the same time, a selfish peer itself may not be eager to store and maintain too many neighbors itself.

### Current Trends and Outlook

One can argue that today, p2p computing is already a relatively mature (research) field; nevertheless, there are still many active discussions and developments, also in the context of the future Internet design. Moreover, there exists a discrepancy between the technology of the systems in use and what is actually known in theory.

For example, the Kad network is still vulnerable to quite simple attacks [44].

If employed by the wrong people, the flexibility and robustness of p2p technology also constitutes a threat. Denial-of-service attacks are arguably one of the most cumbersome problems in today’s Internet, and it is appealing to coordinate botnets in a p2p fashion. A DHT can be used by the bots, e.g., to download new instructions. For instance, it was estimated that in 2007, the DHT-based *Storm botnet* [20] ran on several million computers. Apart from mechanisms to detect or prevent attacks even before they take place, a smart redundancy management may improve availability during the attack itself (see, e.g., the Chameleon system [7]).

In terms of cooperation, there is a tension between the goal of providing incentive compatible mechanisms that exclude free riders and the goal of designing heterogeneous p2p systems that also tolerate (and make use of!) weak participants. Moreover, in addition to design mechanisms dealing with pure selfishness, there is a trend toward p2p systems that are also resilient to malicious behavior (see, e.g., [23] or [39]).

Another active discussion regards the interface between p2p systems and ISPs. The large amount of p2p traffic raises the question of how ISPs should deal with p2p, e.g., by caching contents. p2p networks often employ inefficient overlay-to-ISP mappings as the logical overlay network is typically not aware of the underlying “real” networks and constraints, and much overhead can be avoided by improving the interface between p2p networks and ISPs, e.g., by an oracle [2]. For a critical point of view on the subject, the reader is referred to [33].

It seems that while a few years ago the lion’s share of Internet traffic was due to p2p, the proportion seems to be declining [12] now. Especially web services and server-based solutions such as the popular YouTube and RapidShare are catching up. The measured data traces should be interpreted with care however, as they do not take into account what happens behind the scenes of big corporations. Indeed, it is believed that there is a paradigm shift in p2p computing: While p2p retreats (relatively to other applications) from public Internet traffic, today p2p technology plays a crucial role in the coordination and management of large data centers and server farms of corporations such as Akamai or Google.

## Bibliographic Notes and Further Reading

Beyond the specific literature pointed to directly in the text, there are several recommendable introductory books on p2p computing. In particular, the reader is referred to the classic books [8, 45, 48] and two more recent issues [8, 17]. The theoretically more inclined reader may also be interested in [25], which provides an overview of compact routing solutions, and [18] which discusses trade-offs in local algorithms that achieve global goals based on local information only and without centralized entities whatsoever. Regarding the challenges of distributed cooperation, the recent book [30] gives a thorough and up-to-date survey of current (game-theoretic) trends, and also includes a chapter on p2p specific questions.

## Definition

In 2002, IBM started to develop a pioneering supercomputer, codenamed PERCS (Productive, Easy-to-use, Reliable Computing System), with support from the

Defense Advanced Research Project Agency (DARPA). The project was part of DARPA's High Productivity Computing Systems (HPCS)[3] initiative, a 10-year research program that sought to change the landscape of high-end computing by shifting the focus away from just floating point performance toward overall system productivity. Enhancing system productivity required unprecedented innovation in the system design to simplify system usage and programming tasks, all while maintaining the system cost within the requirements of a realistic commercial offering. The system's productivity is orders of magnitude better than previous supercomputers as expressed by the High Productivity Challenge benchmark suite [7].

## Discussion

### Introduction

High-end computing went through a generational transformation during the 1990s, which saw emerging clusters of commodity processors and networks gradually replace traditional supercomputer systems based on vector and large shared-memory systems. Commodity clusters offered advantages in cost and scalability compared with the technologies they replaced. The simultaneous emergence of the Message Passing Interface (MPI) provided programmers with a portable, standard programming environment that exploited these clusters well. Interest in high-performance computing gained momentum, and a semiannual "top 500 supercomputers" contest was created based on the Linpack benchmark [4] to assess the available supercomputers in the market and to provide an arena for vendors to compete.

With the Linpack benchmark's emphasis on floating-point performance, designers focused on improving processor performance, and the resulting systems were showing great leaps in Linpack performance. These improvements however did not benefit mainstream applications that required a system design that balances floating-point operations with commensurate memory and communication bandwidths. For example, streaming data applications, message-intensive applications exemplified by the GUPS benchmark [7], and digital-signal processing applications based on Fast Fourier Transform [5] are sensitive to network performance and memory bandwidth. Programmers were forced to adapt

their algorithms to reduce data transfers and harness the increased computational capability of commodity clusters. The approach proved futile as programmers generally failed to achieve performance gains to show for the added code complexity and programming efforts. A programmer and system productivity crises were clearly at hand.

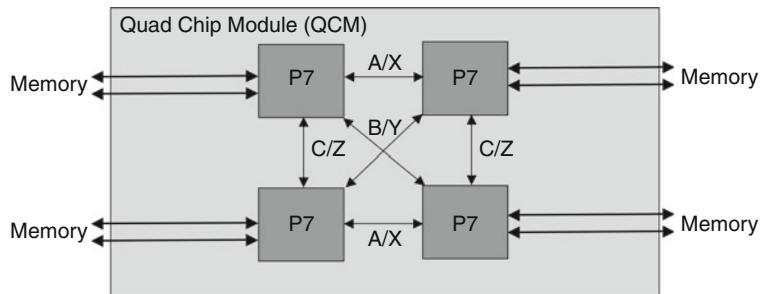

In 2001, visionaries at DARPA and various U.S. defense agencies took the initiative to confront the situation and started the High Productivity Computing System (HPCS) program. HPCS took the form of three competitive stages, the first two being devoted to pure research with each round culminating in the elimination of proposals that were deemed noncompetitive or noninnovative. The third stage was devoted to the commercialization of the research results of the first two stages into a mainstream product. Five companies competed in the initial stage, namely Cray, HP, IBM, SGI, and Sun, and by 2007, only Cray and IBM were supported to proceed with the third stage of commercialization. The HPCS vision called for balanced system attributes and high-level computing abstractions that alleviate programmers from the chores of adapting code to improve performance. The program aimed to foster research that would result in systems that are amenable to productive use without too much effort on the part of the programmer. This article provides a short summary of IBM's PERCS project. Compared to state-of-the-art high-performance computing (HPC) systems, PERCS achieves high performance and productivity goals through tight integration of computing, networking, storage, and software. PERCS focuses on scaling all parts of the system while easing the programming complexity.

## Key Elements of the PERCS Design

### Compute Node Design

The building block for the PERCS design is the compute node as shown in Fig. 1.

There are four POWER7 chips [6] in a node with a single operating system image that controls resource allocation. Each chip features eight cores, four threads per core, and two memory controllers that can connect to 128GB of DRAM memory. Applications executing on a single compute node can thus utilize 32 cores, 128 SMT threads, eight memory controllers, up

**PERCS System Architecture. Fig. 1** PERCS compute node architecture

to 512 GB of memory capacity, one teraflop of compute power, and over 512 GB/s of memory bandwidth. The four POWER7 chips are cache coherent and are tightly coupled using three pairs of buses. Each processor has six fabric bus interfaces to connect to three other processors in a multi-chip module (MCM). These 1-teraflop tightly coupled shared-memory nodes deliver 192 GB/sec of bandwidth (0.2 Byte/flop) to a specialized hub chip used for I/O, messaging, and switching. The POWER7 chip represents a large leap forward in single-chip performance, available both in terms of computational ability and achievable memory bandwidth over other processor chip offerings.

### PERCS Interconnect

The challenge of building a highly productive system required the entire system infrastructure to scale along with the microprocessor's capabilities. Previous solutions such as fat-tree Interconnect suffered from substantial communication latency due to message copying, protocol processing, multiple data conversions between optical and electrical signaling, and switching overheads. Other approaches such as toroidal networks mitigated some of these issues at the expense of handing the programmer very complex communication topologies.

Such limitations have forced programmers traditionally to consolidate data communications into large messages that amortize the communications overhead. Applications that required frequent exchange of short messages [7] either had to settle for poor performance or had to be modified in nontrivial ways to exploit large messages. To solve this problem, we had to design an

Interconnect that obeyed the following design principles in a cost-effective product:

- (a) Minimum data copying
- (b) Only one conversion from electrical to optical domain was allowed for any message
- (c) Simple communications protocol with limited processing overhead
- (d) Maintain a simple topology that simplifies programming

We approached the problem in an unorthodox way by building on the shared-memory protocol that IBM uses to build highly-scalable shared-memory machines. The communication is treated at three levels:

- (a) Within a node, communications take place over the shared-memory bus.
- (b) A second level consists of a *supernode*, which is a group of 32 nodes connected via noncoherent shared-memory buses. Physically, two supernodes fit within a single rack.
- (c) A third level consists of communications between supernodes. Supernodes are connected using a fully connected graph of optical cables. Thus, each supernode has an equal distance to other supernodes, simplifying the topology and the programming task.

A communication coprocessor [1] resides on the memory bus within each node, and thus data can be streamed from source to destination using the shared-memory protocol, using a 128-byte payload. This eliminates the data copying common in previous solutions where data had to be copied from the memory to the I/O bus.

The communication coprocessor, also called the hub-chip [1], is directly connected to the POWER7 MCM at 192 GB/s and provides 336 GB/s to seven other nodes in the same drawer on copper connections; 240 GB/s to 24 nodes in the same supernode (composed of four drawers, or 32 compute nodes) on optical connections; 320 GB/s to other supernodes on optical connections; and 40 GB/s for general I/O, for a total of 1,128 GB/s peak bandwidth per hub chip (see Fig. 2).

Two key design goals for PERCS were to dramatically improve bisection bandwidth (over other topologies such as fat-tree interconnects) and to eliminate the need for external switches. With these goals in mind, the hub chip was designed to support a large number of links that connect it to other hub chips. These links are classified into two categories “L,” and “D,” which permit the system to be organized into a two-level direct-connect topology. Every hub chip has thirty-one L links that connect to 31 other hub chips. Within this group of thirty-two hub chips, every chip has a direct communication link to every other chip. The hub chip implementation further divides the L links into two categories: seven electrical LL links with a combined bandwidth of 336 GB/s and 24 optical LR links with a combined bandwidth of 240 GB/s. The L links bind thirty-two compute nodes into a supernode.

Every hub chip also has 16 D links that are used to connect to other supernodes with a combined bandwidth of 320 GB/s. The topology maintains at least one D link between every pair of supernodes in the system, although smaller systems can employ multiple D links between supernode pairs.

The hub chip is connected to the POWER7 chips in the compute node at a bandwidth of 192 GB/s and has 40 GB/s of bandwidth for general I/O. The peak

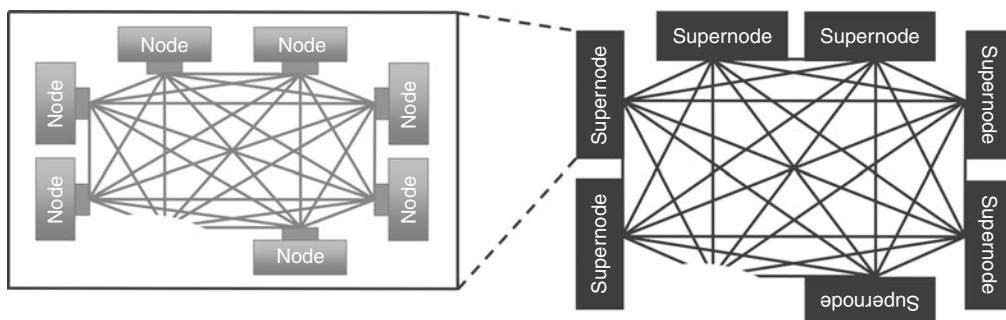

switching bandwidth of the hub chip exceeds 1.1 GB/s. When all links are populated and operate at peak, the injection bandwidth to network bandwidth ratio is 1:4.6. Note though that by performing the dual roles of data routing and interconnect gateway, the majority of traffic through the hub chip will typically be destined for other compute nodes. The low injection to network bandwidth ratio means that plenty of bandwidth is available for that other traffic.

The topology used by PERCS permits routes to be made up of very small numbers of hops. Within a supernode, any compute node can communicate with any other compute node using a distinct L link. Across supernodes, a compute node has to employ at most one L hop to get to the “right” compute node within its supernode that is connected to the destination supernode (recall that every supernode pair is connected by at least one D link). At the destination supernode, at most one L hop is again sufficient to reach the destination compute node.

## Routing Between Nodes

The above-described principles form the basis for direct routing in the PERCS system. A direct route employs a shortest path between any two compute nodes in the system. Since a pair of supernodes can be connected together by more than one D link, there can be multiple shortest paths between a given set of compute nodes. With only two levels in the topology, the longest direct route L-D-L can have at most three hops made up of no more than two L hops and at most one D hop.

PERCS also supports indirect routes to guard against potential interconnect hot spots. An indirect route is one that has an intermediate compute node in

PERCS System Architecture. Fig. 2 Diagram of PERCS interconnect

the route that resides on a different supernode from that of the source and destination compute nodes. An indirect route must employ a shortest path from the source compute node to the intermediate one, and a shortest path from the intermediate compute node to the destination compute node. The longest indirect route L-D-L-D-L can have at most five hops made up of no more than three L hops and at most two D hops. [Figure 3](#) illustrates direct and indirect routing within the PERCS system.

A specific route can be selected in three ways when multiple routes exist between a source-destination pair. First, software can specify the intermediate supernode but let the hardware determine how to route to and then from the intermediate supernode. Second, hardware can select amongst the multiple routes in a round robin manner for both direct and indirect routes. Finally, the hub chip also provides support for route randomization, whereby the hardware can pseudo-randomly pick one of the many possible routes between a source-destination pair.

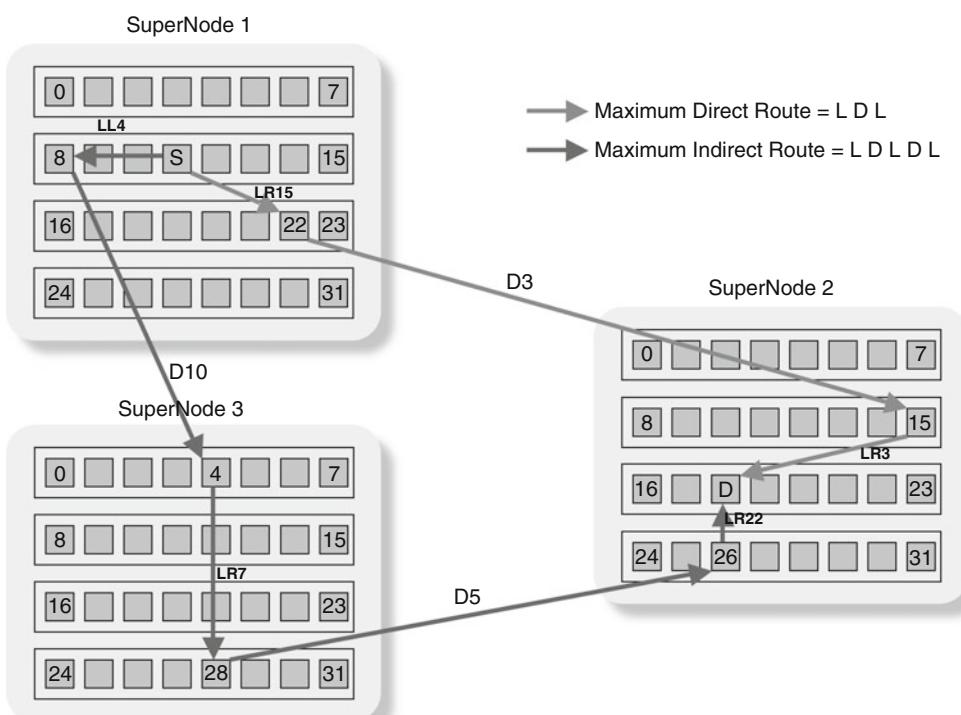

The minimum direct-routed message latency in the system is approximately  $1 \mu$  second. The peak unidirectional link bandwidths are as follows: 24 GB/s from each POWER7 chip in an SMP to its hub/switch, 24 GB/s from a given hub/switch to each of the other seven hub/switches in the same drawer (336 GB/s total), 5 GB/s from a given hub/switch to each of the other 24 hub/switches in different drawers in the same supernode (240 GB/s total), and 10 GB/s from a given hub/switch in one supernode to a hub/switch in another supernode to which that particular hub/switch is directly connected (320 GB/s total).

### Novel Features of the PERCS Hub Chip

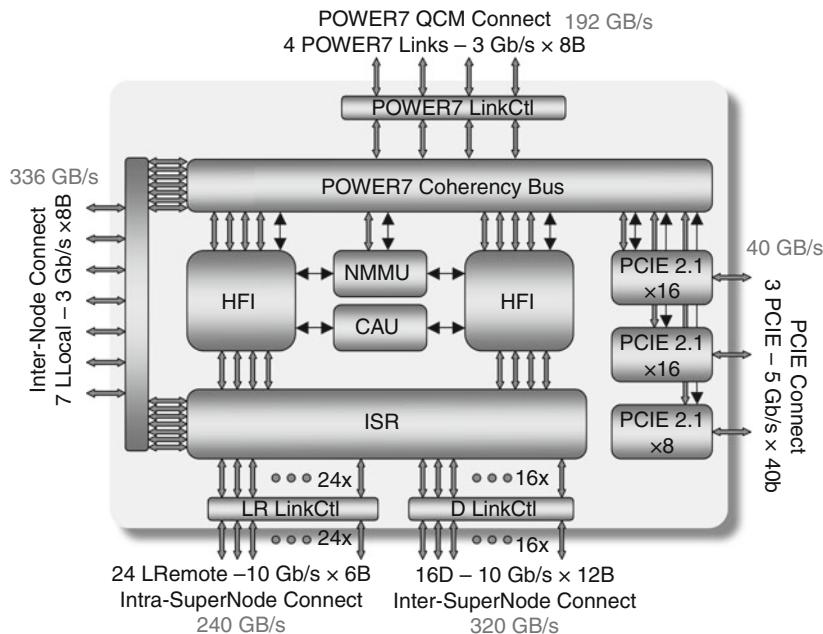

The PERCS Hub Chip, detailed in [Fig. 4](#), incorporates many features to enable the high-performance targets set for the system on HPC applications.

### Collective Accelerator Unit (CAU)

Many HPC applications perform collective operations that involve all or a large subset of the nodes

**PERCS System Architecture. Fig. 3** Direct and indirect routing in PERCS

**PERCS System Architecture. Fig. 4** Details of PERCS Hub chip

participating in the computation. Forward progress can only be realized when each node has completed the collective operation and results have been returned to all participating nodes. The PERCS hub chip provides specialized hardware to accelerate frequently used collective operations such as multicast, barriers, and reduction operations. For reductions, a dedicated arithmetic logic unit (ALU) within the CAU supports the following operations and data types:

- Fixed point: NOP, SUM, MIN, MAX, OR, AND, XOR (signed and unsigned)
- Floating point: MIN, MAX, SUM, PROD (single and double precision)

Software organizes the CAUs in the system into collective trees, firing when data on all of its inputs are available with the result being fed to the next “upstream” CAU in a data-flow manner. Each hub chip contains a single CAU. A multiple-entry content addressable memory (CAM) structure per CAU supports multiple independent trees that can be concurrently used by different applications, for different collective patterns within the same application, or some combination thereof.

### Power Bus Interface

The on-chip interconnect for the POWER7 processor is the newly-designed PowerBus architecture. Each hub chip contains a PowerBus interface that enables it to participate in the coherency operations taking place between the four POWER7 chips in the compute node, providing the hub chip visibility to coherence transactions taking place in the node.

### Host Fabric Interface

The two Host Fabric Interface (HFI) units in the hub chip manage communication to and from the PERCS interconnect. The HFI was designed to provide user-level access to applications. The basic construct provided by the HFI to applications for delineating different communication contexts is the “window.” The HFI supports many hundreds of such windows each with its associated hardware state.

An application invokes the operating system to reserve a window for its use. The reservation procedure maps certain structures of the HFI into the application’s address space with window control being possible from that point onward through user-level reads and write to the HFI-mapped structures.

The HFI supports three APIs for communication: a general packet transfer mechanism that can be used for composing either reliable or unreliable protocols upon which to build MPI or other messaging layers; a protocol for global address space operations that allow user-level codes to directly manipulate memory of a task residing on a different compute node; and direct internet protocol transfer ability.

The HFI can extract data that needs to be communicated over the interconnect from either the POWER7 memory or directly from the POWER7 caches. The choice of source is transparent, and data is automatically sourced from the faster location (caches can typically source data faster than memory). In addition to writing network data to memory, the HFI can also inject network data directly into a processor's L3 cache, lowering the data access latency for code executing on that processor [8].

### Integrated Switch Router (ISR)

The ISR implements the two-tiered full-graph network utilized in the PERCS system. It is organized as a  $56 \times 56$  full crossbar that operates at up to 3 GHz. In addition to the 47 L and D ports described previously, the ISR also has eight ports to the two local Host Fabric Interfaces, and one service port.

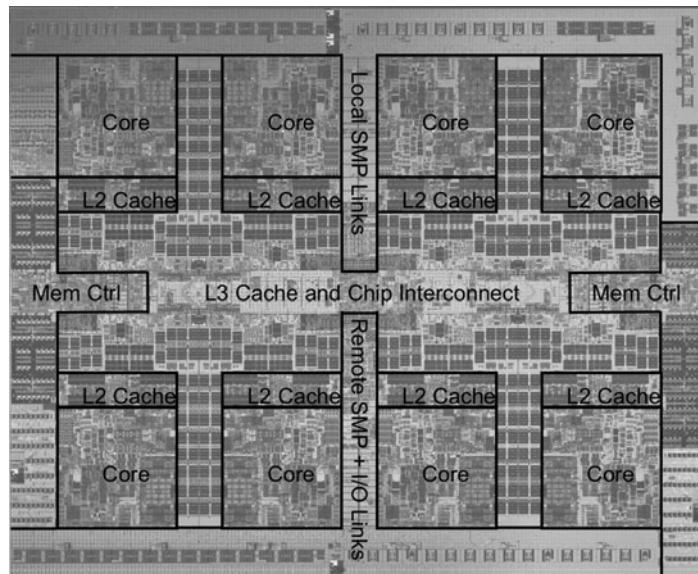

The ISR uses both input and output buffering with a packet replay mechanism to tolerate transient link

errors. This feature is especially important since the D links can be several tens of meters in length. The ISR operates in units of 128-byte FLITs with a maximum packet size of 2,048 bytes. Messages are composed of multiple packets with the packets making up a message being potentially delivered out of order.

High-performance computing applications benefit from having access to a single global clock across the entire system. The ISR implements a global clock feature, whereby a clock onboard is globally distributed across the interconnect and kept consistent with the clocks on other Hub chips. Deadlock prevention is achieved through virtual channels, each corresponding to a hop in the L-D-L-D-L worst case route.

### POWER7 Processor Overview

PERCS systems use a version of the new POWER7 processor chip fabricated in IBM's 45nm SOI CMOS technology, a die photo of which is shown in Fig. 5. POWER7 incorporates eight high-performance processor cores, L1, L2, and L3 caches per core, on-chip interconnect, multiple I/O controllers, memory controllers, and the SMP fabric controller. The processor design is closely linked with the technology node development, which is co-developed with the high-performance server processors to produce a high-performance server

PERCS System Architecture. Fig. 5 Die photo of the POWER7 processor chip

processor as well as a world class CMOS technology node.

The version of the POWER7 processor chip used in PERCS is fabricated utilizing IBM's 45nm technology at frequencies ranging up to 4 GHz. The chip size is 567 mm<sup>2</sup> and contains eight multithreaded cores. The processor design offers an excellent balance between floating and fixed-point operations, and between computation and memory access. Each core has four double precision floating-point units (*FPU*) implemented as two 2-way SIMD engines (scalar floating point instructions can only use two FPUs), two fixed-point units (*FXU*), two load-store units (*LSU*), a vector (*VMX*) unit, a decimal floating point unit, a branch unit, and a condition register. Each FPU is capable of performing one multiply-add instruction (*FMA*) in one cycle, and each LSU can execute simple integer operations. Thus the chip is capable of 256GF/s and 128GOp/s at 4GHz. The chip also features two memory controllers serving up to eight memory channels, with an aggregate bandwidth of 128GB/s. This offers about 0.5 B/F or 1B/Op greater memory bandwidth balance.

## Processor Core

POWER7 implements the 64-bit Power PC-AS architecture and is backward compatible with previous POWER chips, ensuring that existing binaries will run on the new architecture without the need to recompile. IBM's continued focus on single-thread performance in POWER7 remains an important component in its viability in the HPC marketplace. The core uses an extremely power-efficient, high-frequency design with a superscalar, out-of-order execution engine with highly-accurate branch prediction mechanism. Up to eight instructions may be executed in a given cycle.

POWER7 also provides excellent performance for throughput-oriented workloads. Simultaneous multithreading consisting of four hardware contexts per core provides up to 32 different instruction streams per chip for use by software. The multithreaded design ensures that a thread does not block the flow of instructions for other threads through the instruction pipeline, the cache or memory hierarchy, while keeping the area and power overhead low.

## Processor Cache Hierarchy

The POWER7 processor chip has three levels of cache, all sharing a common line size of 128 bytes. ECC is used extensively to ensure reliability and data integrity across all cache levels. While the Level 2 (L2) and Level 3 (L3) caches contain both instruction and data, the Level 1 (L1) cache is split into separate instruction and data caches. The L1 instruction cache is 32KB, 4-way set-associative and provides a maximum bandwidth of 64B per processor cycle. The L1 data cache is 32KB, 8-way set-associative and can be accessed in every processor cycle to deliver two 16B load operations, and one 16B store operation.

Each core has a private, 8-way set-associative, 256KB L2 cache. The L2 cache access latency is about seven processor cycles, and in every processor cycle, the processor core can load 32B of data or instructions from L2 and store 16B of data.

Each core has a private 16-way set-associative L3 cache of size 4MB constructed from on-chip embedded DRAM (eDRAM), which offers low power, high density, and excellent access times. The L3 cache access latency is about 22 processor cycles, and in every processor cycle, it can supply 16B of data to the L2 cache and receive 8B of data from the L2 cache. The L3 cache serves as a victim cache of the L2 cache. All L3 caches on a chip may be virtually aggregated into a quasi-shared cache by causing L3s to write back dirty lines to each other before writing them off-chip to memory. A sophisticated multi-tier LRU algorithm maintains balance among this confederation of L3 caches. The L3 cache arrays can also be reconfigured so that two adjacent banks are combined into a larger L3 cache of size 8MB shared between the two corresponding cores, which is useful for commercial workloads. This is another instance of the configurability of the architecture, and how this configurability is used to meet different workload characteristics and enhance the commercial viability of the system as outlined in the vision set forth by DARPA for the HPCS program.

## On-chip Integrated Fabric and Chip Interconnect

Another innovative aspect of the POWER7 design is the use of existing system buses to both implement shared-memory traffic and integrate the network switching functionality. Effectively, the POWER7 implements a

distributed switch function within the computer rack. The POWER7 Fabric Bus Controller (FBC) is the building block that implements this distributed switch functionality.

The FBC is integrated on the POWER7 chip and acts as the central point of cache-coherent data traffic. It is responsible for implementing cache-to-cache data transfers, bus arbitration, address routing, etc. It maintains simple and configurable routing tables and implements all necessary flow control to ensure freedom from deadlocks and livelocks. The FBC acts as the hub of all coherent and noncoherent communications among all internal chip units (eight processor cores, two memory controllers, L2 and L3 caches, Non-Cacheable Unit, Gigabit Ethernet, and PCI-Express controller) to other internal units on or outside of the chip. The FBC provides all of the interfaces, buffering, and sequencing of address and data operations within the coherent memory subsystem.

Physically, the Fabric bus is an 8-Byte wide, split-transaction, multiplexed address and data bus. Data packets are four beats each carrying 32 bytes of data. It takes four data packets to transfer the entire 128 Byte cache line. Configuration switches assign node identification for each chip and also for data routing tables. Data transactions within the node are always sent along a unique point-to-point path. A tag travels with the data to help make routing decisions along the way. The Fabric busses provide fully connected topology to reduce latency.

## Memory Subsystem

Special care has been taken in the design of the POWER7 chipmemory subsystem to ensure the maximum bandwidth within reasonable constraints of cost and power. The design is flexible and configurable, offering different memory access modes, each optimized to a certain application profile, ranging from sequential access of memory to random access of memory. The memory subsystem also can perform partial cache line loads, improving the efficiency and bandwidth for applications with poor spatial locality such as sparse matrix computations.

The PERCS memory subsystem has two memory controllers with support for up to eight DIMM sockets and uses custom DDR3 DRAM chips running at 1.333 GHz. These DIMMs include specialized buffer chips

to increase the amount of memory and bandwidth to memory per chip.

Peak memory bandwidth (read + write) of a single channel is rated at 16GB/s, two thirds of which is for read bandwidth and the remaining one third for write bandwidth. The address space is split across the multiple fully buffered DIMM arrays in a manner that allows for an evenly distributed access pattern across them. This access pattern results in the highest bandwidth available at the processor interface and an evenly distributed thermal pattern.

## Blue Waters: The First PERCS Installation

The PERCS system design will first be implemented in the Blue Waters supercomputer to be placed at the National Center for Supercomputing Applications (NCSA) at the University of Illinois [2]. Blue Waters will be comprised of 304 supernodes with nearly 312,000 POWER7 cores, more than 1 PB memory, more than 10 PB disk storage, more than 0.5 EB archival storage, and will achieve close to 10 PF/s peak performance. Acquisition of the Blue Waters system is supported by the National Science Foundation and leverages the investment made by the Defense Advanced Research Projects Agency's High Productivity Computing Systems (HPCS) program.

IBM, the University of Illinois, and the NCSA will work together throughout Blue Waters' lifespan to enhance IBM's high-performance computing environment, ensuring that applications can take full advantage of Blue Waters and achieve performance on a variety of real-world applications. The enhanced high-performance computing environment will also increase the productivity of applications developers, system administrators, and researchers by providing an integrated toolkit for using, analyzing, monitoring, and controlling Blue Waters.

Blue Waters is expected to be one of the most powerful supercomputers in the world when it comes online. It will have a peak performance close to 10 petaflops (10 quadrillion calculations every second) and will achieve sustained performance of 1 petaflop per second running a range of science and engineering codes. Scientists will create breakthroughs in nearly all fields of science using Blue Waters, including predicting the behavior of complex biological systems; understanding how the cosmos

evolved after the Big Bang; designing new materials at the atomic level; predicting the behavior of hurricanes and tornadoes; and simulating complex engineered systems like the power distribution system, airplanes, and automobiles.

## Perfect Benchmarks

The Perfect Benchmarks [1] were created in the late 1980s under the leadership of the University of Illinois' Center for Supercomputing Research and Development (CSR) with the participation of several other institutions (the Perfect Club). The name Perfect is an acronym for PERformance Evaluation by Cost-effective Transformations. The Benchmarks came from real applications in contrast to the Livermore Loops and other simple codes used in the 1980s to evaluate machines. Thirteen Benchmarks were included: ADM, solves the hydrodynamics equations to simulate air pollution, contributed by IBM Kingston;

## Performance Analysis Tools

MICHAEL GERNDT

Technische Universität München, München, Germany

## Synonyms

[Performance measurement](#); [Profiling](#); [Tracing](#)

## Definition

Performance analysis tools support the application developer in tuning the application's performance for a given architecture. They measure performance data during the execution of the application and provide means to analyze and interpret the provided data and to detect performance bottlenecks.

## Discussion

### Introduction

The development of high-performance applications requires a careful adaptation of the program to the underlying parallel architecture. Due to the manifold interrelations of the parallel program and the architecture, designing an application with optimal performance on parallel systems is almost impossible. Therefore, the application goes through a tuning cycle which consists of measuring performance, detecting performance bottlenecks, and applying program transformations. The assumption for this tuning approach is that the performance will be the same for different runs with the same resources and the same input data.

Performance analysis tools support the programmer in the first two tasks of the tuning cycle. Performance data are gathered during program execution by monitoring the application's execution. Performance data are either summarized and stored as profile data or all the details are stored in so-called trace files.

In addition to application monitoring, performance analysis tools also provide the means to analyze and interpret the provided performance data and thus to detect performance problems. The following sections present the basis of performance analysis, i.e., the execution event model, the different monitoring techniques, and the most important analysis techniques.

### Event Model

The abstraction of the execution used in performance analysis is an event model. Events happen at a specific point in time in a process or thread. Events belong to event classes, such as enter and exit events of a user-level function, start and finish events of a send operation in MPI programs, iteration assignment in work-sharing constructs in OpenMP, and cache misses in sequential execution.

In profiling, information about events of the same class is aggregated during runtime. For example, cache misses are counted, the time spent between the start event and finish event of a send operation is accumulated as the communication time of the call site, and the time for taking a scheduling decision in work-sharing loops is accumulated as parallelization overhead.

In tracing, specific information is recorded for each event in a trace file. The event record written to the file

at least contains a time stamp and an identification of the executing process or thread. Frequently, additional information is recorded, such as the message receiver and the message length or the scheduling time for an iteration assignment.

### Monitoring

The general technique for collecting information about events is called *Monitoring*. Three different monitoring techniques can be distinguished: hardware monitoring, sampling, and instrumentation. These techniques are explained in the next three paragraphs.

### Hardware Monitoring

The monitoring of applications should not influence the program's execution. Therefore, hardware monitoring is required for frequent events, such as events in the processor or the caches. If cache misses, e.g., were to be counted via hardware interrupts, the intrusion would be immense. Therefore, current microprocessors provide event counters. A small number of hardware counters can be used to count a large number of different event types. Careful selection of the right event type is thus required.

The low-level APIs for accessing the system's hardware counters are quite different on different architectures. Therefore, standard APIs have been developed. The most notable one is the *Performance Application Programming Interface* (PAPI) [4, 8].

### Sampling

Many profiling tools such as the Unix *prof* utility collect statistical performance information via sampling. The processor is interrupted with a certain frequency, known as the sampling rate. The interrupt routine determines the address of the current instruction from the program counter and adds, e.g., the length of the sampling interval to the accumulated execution time of the currently executed source location. Instead of the execution time, other metrics such as the number of cache misses or of floating point operations can be used.

The most important advantage of this technique is that its intrusion is usually low and can be controlled by setting the sampling rate appropriately. The major drawback is that only statistical information is gathered. More precise information can be obtained via instrumentation.

A similar technique is called *Event-Based Sampling*. Each time a hardware counter passes a threshold, an interrupt is generated and information is accumulated for the current source line. The user can control the intrusion of this method by specifying the overflow threshold. A larger threshold will give less accurate information, but is less intrusive. This technique is used, e.g., in the Digital Continuous Profiling Infrastructure (DCPI) [1].

## Instrumentation

In contrast to sampling, precise information about the dynamic application behavior can be obtained via program instrumentation. Here the application is modified to gather information at specific events. For example, a call to a monitoring routine is inserted at the beginning and end of a user function to measure the execution time of the function.

Three important instrumentation techniques can be distinguished: source code instrumentation, object code instrumentation, and library interposition. In *source code instrumentation*, the compiler or a source-to-source transformation tool inserts the monitor calls into the program before compilation. In object code instrumentation, the instrumenter patches the machine code.

While the first approach is very portable, *object code instrumentation* is extremely machine specific. It depends not only on the machine's instruction set but also on the compiler, the OS, and the object format. On the other hand, with object code instrumentation, the source language is unimportant and programs can even be instrumented for which no source code is available.

Object code instrumentation can also be applied at runtime. While the program is already executing, instrumentation is inserted only at the required places. This technique was developed within the Paradyn environment and is supported in DYNINST [3, 5] and DPCL [2, 7].

While object code instrumentation is limited to code regions that can be deduced from the binary, it is typically limited to functions or basic blocks. Source code instrumentation can be used to gather information for arbitrary program regions.

Instrumentation of functions can also be done based on a technique called *library interposition*. This

technique is used to instrument MPI functions via the MPI profiling interface (PMPI). It determines for all MPI functions a second name via the PMPI prefix. The implementor of an MPI monitoring library can write wrappers for MPI functions and call the PMPI version inside. Within the wrapper, code can be inserted to collect performance information. The wrapper library is then linked to the application before the original MPI library so that the wrappers are called instead of the original functions.

## Analysis

The techniques and tools for performance analysis presented in this entry all assume that the performance behavior of the application is the same over multiple experiments. Based on this assumption, multiple experiments can be performed with different tools or different tool configurations to identify and rank performance problems.

The following aspects are relevant for performance analysis tools:

1. Level of detail
2. Performance aspects
3. Application perturbation
4. Level of automation
5. Scalability

## Level of Detail

Three classes of performance analysis tools can be distinguished depending on how detailed the raw performance data are gathered and analyzed, i.e., profiles, profile time series, and traces.

*Profiling tools* aggregate the raw performance data over possibly multiple dimensions. Most common is the aggregation over time, e.g., the number of cache misses for individual functions in each process. Some tools also aggregate the data over processes and threads or even into a single value for the entire execution, e.g., the number of floating point instructions executed by an application. Furthermore, tools apply aggregation with respect to the program regions, i.e., functions and loops. They either compute a flat profile, in which the data are aggregated for each region, or a call path profile, where the data are aggregated for each call path. Call path profiles are very useful if the behavior of functions is different for individual invocations. This is frequently

the case for library routines such as basic mathematical or MPI routines.

Some profiling tools provide not only aggregated data over the entire execution but also time series of snapshots of profile information. Such time series of profile data allow the analysis of time-dependent variations of the performance behavior.

The most detailed analysis is performed by *tracing tools* that store information about individual events in so-called traces. For each event a trace record with a time stamp is generated. A trace record includes additional data, such as the sender and receiver, the amount of data, and an identification of the message sent by an MPI send operation. The trace records are typically stored in trace files that are subsequently analyzed for performance problems.

While profiling tools have the advantage that the amount of performance data is not proportional to the execution time of the application, tracing tools generate performance data proportional to the execution time and the number of processes and threads. On the other hand, profiling tools are limited in the analyses they can perform.

## Performance Aspects

Most performance analysis tools are specialized for specific performance aspects. Tuning an application with respect to all possible performance problems probably requires the use of multiple performance analysis tools. The performance tools are typically specialized in one or multiple of the following aspects:

1. Execution time
2. Instruction execution
3. Memory access behavior
4. Memory usage
5. IO
6. Parallel execution

The most basic and thus the most frequently used performance tools provide the user with a time profile. This allows the user to detect the hot code regions, i.e., those regions where most of the execution time is spent and thus have the highest potential for performance improvement.

The next class of tools supports the programmer in the inspection of performance problems related to the utilization of the resources in an individual core. These

tools typically provide information about the instruction mix, highlight expensive operations such as divides or type conversions, point out exception handling, or identify pipeline stalls, e.g., due to branch mispredictions. They are based on measurements performed with the processor's hardware performance counters.

Very critical for the performance of applications is the memory access behavior. The long latency of memory accesses and the limited bandwidth require that most of the data accesses are served from the on-chip caches. Programs must be carefully tuned for data locality so that the caches are most effectively used. Performance tools support the analysis of the access behavior with information about the number of cache hits and misses as well as the number of stall cycles for memory references. More precise information can be obtained from cache simulators which are fed with memory reference traces of the application. Cache simulation tools, e.g., can determine the distribution of misses across miss classes, i.e., compulsory, conflict, capacity, and invalidation misses. They can identify false sharing as well as compute higher-level metrics, such as the reuse distance.

Another memory-related analysis supported by performance analysis tools is the inspection of memory usage. Performance problems might arise from allocating too much memory may be due to the size of data structures or to memory leakages.

High-performance applications tend to work on huge data sets. Thus performance tools need to help in the identification of performance problems with respect to file IO. Information can be obtained from runtime libraries implementing IO operations as well as from the OS.

Many performance analysis tools support the detection of performance problems with respect to the parallel execution. Certainly, the two standard programming interfaces MPI and OpenMP have the best support.

Profiling and tracing tools are available for message passing programs that support the analysis of communication among the processes. More elementary tools provide measurements on the time spent in certain MPI functions and the amount of data transferred between communication partners, while advanced tools provide information on different waiting times that indicate certain performance problems, e.g., the late sender problem where the sender of a message arrives later at the

send than the receiver at the receive statement. Tools for message passing also indicate load balancing problems based on the execution time of collective operations.

Analysis tools for shared memory programming, i.e., OpenMP, focus on load imbalances, synchronization, and management overhead. Currently available tools do not yet fully support the extensions of OpenMP 3.0, most notably the tasking concept.

## Perturbation

Performance analysis tools are based on measurements. If those measurements are not fully done by additional hardware, the tool will influence or change the codes performance behavior. The intrusion of tools has multiple sources. First of all the time spent in the monitoring library delays the execution. Another important overhead is flushing performance data to external files which needs to be done by tracing tools since the trace records cannot be stored in main memory. These flushes can either be done at global synchronization points and thus delay the execution of all processes, or they can be done asynchronously in the processes which might lead to artificial load imbalance. The intrusion can also be more subtle because memory accesses of the performance analysis tool might change the cache status, or execution delays might even influence the algorithmic behavior in the case of nondeterministic algorithms.

Performance analysis tools try to work around that problem by either correcting the obtained measurements or by reducing the amount of perturbation. Since the first approach is extremely difficult many current tools focus on the second approach.

While the overhead induced by the measurements can be controlled in the sampling approach by selecting an appropriate sampling rate, instrumentation-based measurements can be optimized by reducing the amount of instrumentation and by tuning the instrumentation functions. Instrumentation of program regions that are frequently called but have only little execution time suffer most from the instrumentation overhead. Performance analysis tools provide the means to guide the instrumentation, such as to instrument only certain region types or to exclude individual program regions.

Of course, perturbation not only results from the instrumentation but also from other time-consuming

activities of the analysis tools during the program's execution. Examples are the management of trace records and the computation of call path profiles. Various techniques have been developed to tune those operations.

## Automation

The ultimate goal of performance analysis tools is to indicate performance problems and thus potential for performance improvement. Ideally, the tools should perform that task in a fully automatic way. Full automation requires the formalization of the performance analysis specialist's and the application specialist's knowledge. Until now, this has only partially been achieved.

One area of automation is program instrumentation. The techniques here range from manual instrumentation to fully automatic instrumentation. Some tools require the user to insert instrumentation into the program. Other tools provide semiautomatic instrumentation via the compiler or a source-to-source instrumenter. The instrumentation can be configured to control the amount of program perturbation. Some tools assist the user in the configuration by pointing out regions that need not be or should not be instrumented based on a previous analysis run. In the fully automatic approach, the instrumentation is selected by the performance analysis tool. Based on the tool's knowledge of which instrumentation is required to obtain the required performance data, the instrumentation is automatically configured.

Automation is also required in the actual measurement of performance data via the monitoring. The analysis tool decides automatically which data will be measured. However for some tools, especially if they access the hardware performance counters, the measurement configuration is done manually. Depending on the type of performance problem the user is interested in, he or she can configure the analysis to measure certain events with the hardware counters. It might even be necessary to perform multiple runs of the application to gather all the required information.

In addition, the last step of the analysis process can be automated. A performance analysis tool should automatically extract and rank the performance problems such that the user can start by tuning the application to solve the most severe performance problem.

In most tools, this step is not automated. The tools allow the user to manually inspect the performance data either via textual or graphical displays. Textual information, i.e., a sorted list of hot regions, is provided with references to the source code or the source code is actually annotated with information such as the number of cache misses. Graphical diagrams are typically used in tracing tools. The dynamic behavior is visualized via timeline diagrams, statistics are shown as bar charts, and many other chart types are utilized to visually represent the huge data sets. It is the task of the user of those tools to select the right displays to identify performance problems.

Only a few tools automate the last step and automatically identify performance problems and their severity. The tools use a formal description of potential performance problems and verify whether those known potential problems can be found based on the measured data.

Fully automatic tools automate the whole process, covering instrumentation, measurement, and analysis. The search for performance problems is driven based on formalized potential performance problems. Following a certain search strategy, they deduce from the performance problem specifications which information is required, measure the data, verify whether a problem exists, and report the found problems to the tool user.

Fully automatic tools can perform the analysis online. Online tools have also been developed for semiautomatic tools that visualize performance data, but those require that the user performs the analysis while the application is executing. This is not appropriate especially since large-scale application runs are only possible in batch jobs. Therefore, most of those tools are offline tools. They produce the data by monitoring an actual run of the application but the inspection and analysis of the data is done independently of the execution.

## Scalability

Especially in the field of high-performance computing, performance analysis tools have to be scalable. Applications are run on thousands of processors and the performance behavior cannot be studied for scaled down runs. Tools have to be scalable with respect to the number of processors as well as to the duration of the application's execution. Typical limitations of the tools are the

time spent in the analysis as well as the space requirements to store and process performance data. Scalability is obviously a big issue for tracing tools, but profiling-based tools can also easily run into scalability problems if hundreds of thousands of processors are used as in the current BlueGene systems. This problem can be alleviated by processing the data in a tree analysis network (MRNet [15]). The leaves measure the performance data and while the data travel up the tree, they are aggregated to coarsen the information.

Several techniques for tracing tools have been developed to increase scalability. Most important is to reduce the size of the traces. Therefore, compression techniques as well as "on the fly" detection of recurring patterns in traces are applied. A few tools also parallelize the analysis step. SCALASCA post-processes the trace in parallel on the processors of the application after this has terminated. Vampir uses a parallel analysis server that processes the trace files while the user is working with the analysis tool to inspect the measured performance data. Periscope processes the performance data within a hierarchy of analysis agents while the application is executing.

## Representative Tools

This section identifies a few performance analysis tools and gives a short characterization. The mentioned tools are only a very small set of examples from the numerous tools developed.

*Gprof* is the GNU Profiler tool. It provides a flat profile and a callpath profile for the program's functions.

The measurements are done by instrumentation.

*Vtune* is a performance analysis tool from Intel that provides flat and callpath profiles based on sampling and instrumentation, as well as measurements based on the hardware performance counters. The measurements can be inspected on source and assembler level.

*pfmon* is a tool for accessing the hardware performance counters developed by HP. It can be used to collect certain events specified via command line arguments. Application-specific as well as system-wide measurements can be performed.

*ompP* is a profiling tool for OpenMP developed at Technische Universität München and University of Tennessee [9]. It is based on instrumentation with Opari

[13] and determines certain overhead categories of parallel regions.

*HPC Toolkit* from Rice University uses statistical sampling to collect a performance profile [17]. It relates the measurements back to the original source code based on a static analysis of the binary and presents the data by annotating the sources.

*Tau* is a flexible performance environment from the University of Oregon [16]. It can generate application profiles as well as traces. While it provides tools to analyze the profiles, traces can be analyzed with Vampir.

*Vampir* is a commercial trace-based performance analysis tool from the Technische Universität Dresden [14]. It provides a powerful visualization of traces and scales to thousands of processors based on a parallel visualization server.

*Paraver* is a trace visualization and analysis environment from the Barcelona Supercomputing Center. It provides powerful analysis services such as automatic phase detection [6] and clustering.

*Paradyn* from the University of Wisconsin was the first automatic online analysis tool [12]. Its performance consultant guided the search for performance bottlenecks while the application was executing.

*SCALASCA* is an automatic performance analysis tool developed at the Forschungszentrum Jülich [10]. It is based on performance profiles as well as on traces. The automatic trace analysis determines MPI wait time via a parallel trace replay after the application execution on the application's processors.

*Periscope* currently under development at the Technische Universität München follows the approach of Paradyn and performs an online search for performance problems [11]. It is based on a hierarchy of analysis agents to fulfill scalability requirements of current and future HPC systems.

### Definition

Periscope is an automatic performance analysis tool for highly parallel applications written in MPI or OpenMP. It performs an online search for performance properties in a distributed fashion. The properties found by Periscope point to areas of parallel programs that might benefit from further tuning.

### Discussion

#### Introduction

Performance analysis is an important step in the development of parallel applications for high-performance architectures. Due to the complexity of the architecture of these machines, applications can typically not be designed to be most efficient. Experiments are required to understand the performance obtained and to identify possible areas in the code that might profit from further tuning.

Performance analysis tools help the developer in analyzing the application's performance. During an execution of the application with a typical input data set

and a typical number of processors, performance data are measured. Afterwards those data are analyzed to detect performance problems of the application. Certain tuning actions can then be selected, e.g., selection of different compiler optimization switches or modifications of the source code, based on the detected performance problems.

Periscope is a performance analysis tool developed at Technische Universität München. It is a representative for a class of automatic performance analysis tools automating the whole analysis procedure. Specific for Periscope is that it is an online tool and it works in a distributed fashion. This means that the analysis is done while the application is executing (online) and by a set of analysis agents that are searching for performance problems in a subset of the application's processes (distributed).

Periscope was inspired by the work of the European American APART working group and especially by Paradyn developed at University of Wisconsin, Madison. Paradyn uses a performance consultant that does dynamic instrumentation and searches for bottlenecks based on summary information during the program's execution.

Automation in Periscope is based on formalized performance properties, e.g., inefficient cache usage or load imbalance. Those properties are formalized in the APART Specification Language (ASL). Based on a repository of performance properties the analysis agents can search for those properties in the program execution under investigation. They automatically determine which properties to search for, which measurements are required, which properties were found, and which are more specific properties to look for in the next step. The low-level performance data are analyzed in a distributed fashion and only high-level performance properties are finally reported to the user, significantly reducing the amount of data to be inspected by the user.

#### Performance Properties

The basis for the analysis is the formalization of performance properties. Each *performance property* consists of a condition, a severity, and a confidence. The *condition* uses measured performance data and static information to decide whether the property holds and thus is a *performance problem*. The *confidence* defines whether

the property is only a hint for a performance problem or a proof. For example, properties based on static information, e.g., the number of prefetch operations, are typically only hints since the actual execution of those operations depends on runtime values. The *severity* states the importance of the performance problem in comparison to the other found performance problems. Typically, the severity is calculated as the amount of time lost due to the problem.

## Search Strategies

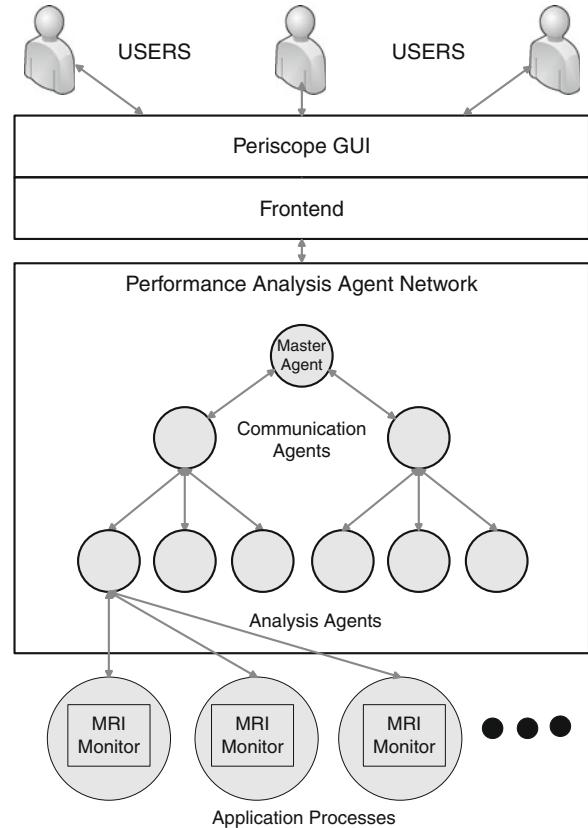

The overall search for performance problems is determined by search strategies. A *search strategy* defines in which order an analysis agent investigates the multidimensional search space of properties, program regions, and processes. Many of Periscope's search strategies are multistep strategies, i.e., they consist of multiple search steps. A very important concept for multistep strategies is a *program phase* which is determined by a certain repetitive program region. A good example for such a phase region is the body of the time loop in scientific simulations where each iteration simulates one time step.

In a first search step, the strategy determines a set of candidate properties, e.g., load imbalance at a barrier in a certain process. The agent then requests certain measurements from the monitor linked into the application. Afterwards the application is released for one execution of the phase. At the end of the phase the execution is stopped again and the measured performance data are returned to the agent. Based on the measurements the agent evaluates the candidate properties and determines the set of found properties. If a refinement is possible, i.e., for the found properties more precise properties are available, a next analysis step is started with a new candidate property set.

Periscope provides search strategies for single-node performance, e.g., searching for inefficient use of the memory hierarchy, MPI, and OpenMP.

## Architecture

Periscope consists of an agent hierarchy shown in Fig. 1. The leaves in the hierarchy are the *analysis agents* that perform the actual performance analysis. Each analysis agent is responsible for a subset of the application's processes. It communicates with the monitor linked with the application processes. The MRI monitor serves

**Periscope. Fig. 1** Architecture of periscope

two purposes: It performs the measurements of performance data requested by the analysis agent and it controls the execution of the process which means, it takes commands from the agent to release or stop the execution.

The root of the hierarchy is the master agent which takes commands from the frontend, propagates the commands to the analysis agents, and provides the list of found performance properties to the frontend. The agents in the middle of the hierarchy are responsible for forwarding information among the analysis agents and the master agent.

The search is controlled by the frontend. It invokes the application and creates the agent hierarchy. How many agents are created depends on the number of application processes and of additional processors provided in the batch job. The processes and agents are mapped to the available processors in a way that communication is local with respect to the physical interconnection network topology.

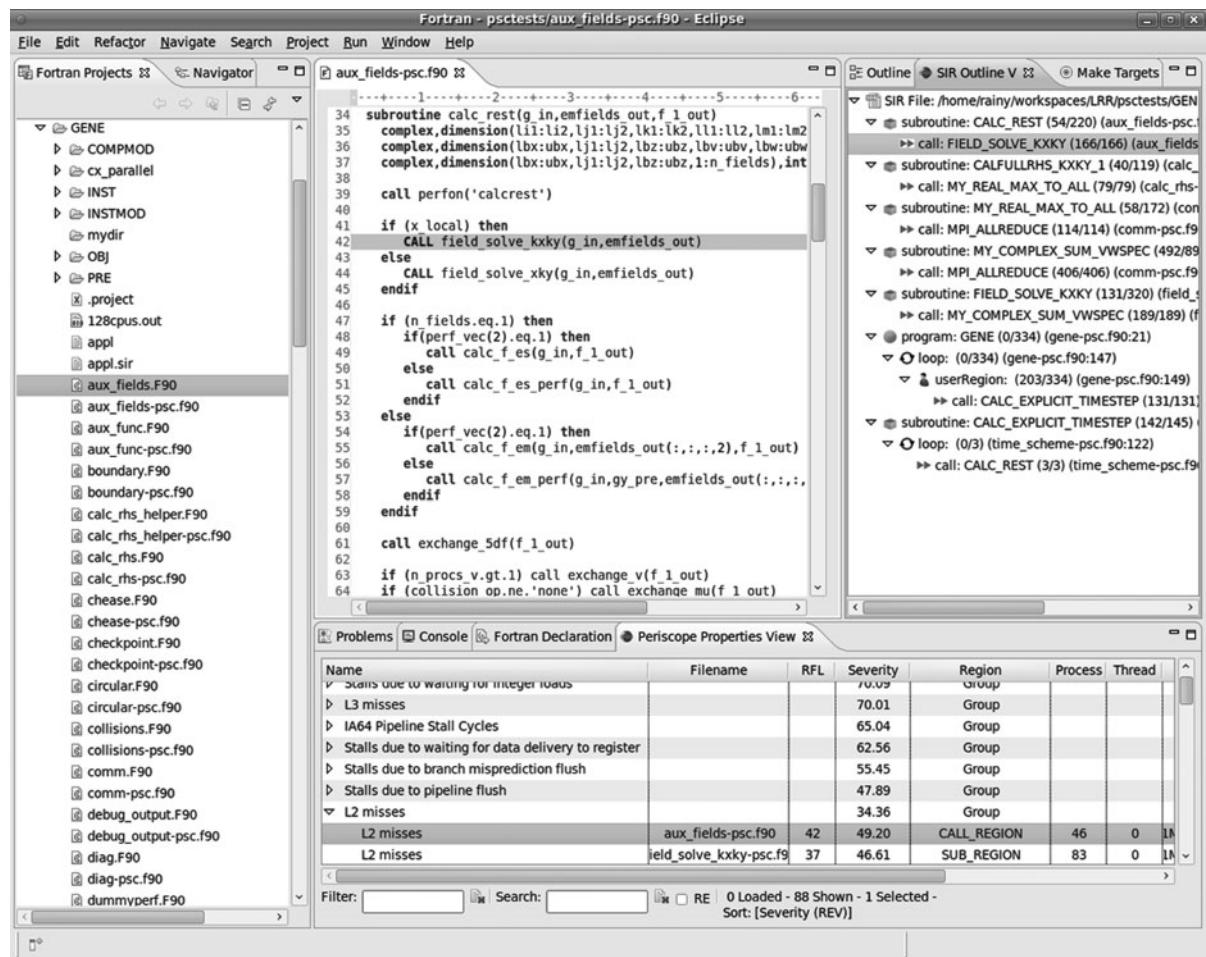

After the application and the agent hierarchy have been started, the frontend starts the search by propagating a command to all the analysis agents. If an agent requests a new experiment, i.e., an execution of the program phase with measurements to evaluate performance properties, the master agent starts the next experiment via another command. The reason for the global synchronization is that Periscope also supports *automatic restart*. If another experiment is requested but the application terminated, the application can automatically be restarted by the frontend.

On top of the frontend, Periscope provides a graphical user interface based on Eclipse and the Parallel Tools Platform (PTP). The GUI allows the programmer to define a project with all the source files, start a

performance analysis via the frontend and, most important, to investigate the performance properties found by Periscope.

Figure 2 illustrates Periscope's GUI. In the lower right a table view visualizes all the properties found in the application. It provides multi-criteria sorting to identify the most severe performance problems, filtering, regular expressions searching, multi-level grouping, as well as clustering. The clustering can be used to identify groups of processes with the same performance problems.

Double clicking on one of the properties will focus on the source code of the respective region in the central source editor. On the right, an outline view of the entire program is provided. It presents an overview of

**Periscope. Fig. 2** Inspection of performance properties with the graphical user interface of Periscope

the regions, the nesting of regions, and the number of properties found for a region. Selecting a region in the outline view can be used to enforce that only those properties found for that region are shown in the region view below.

## Summary

Periscope is an automatic performance analysis tool for large-scale parallel systems. It performs a distributed online search for performance properties. The properties are formalized and the set of properties can be easily extended. Specialized search strategies determine how the analysis agents walk the multidimensional search space. The result of a search is a set of high-level performance properties that can be inspected via a graphical user interface implemented as an Eclipse plugin. Therefore, the user can follow an integrated approach of program development in Eclipse and performance analysis with Periscope.

## Definition

A *Petri Net* is a graph model for the control behavior of systems exhibiting concurrency in their operation. The graph is bipartite, the two node types being *places* drawn as circles, and *transitions* drawn as bars. The arcs of the graph are directed and run from places to transitions or vice versa. Each place may be empty, or hold a finite number of *tokens*. The state of a Petri net is the distribution of tokens on its places, called a *marking* of the net.

A transition is *enabled* if each of its input places holds at least one token. *Firing* a transition means removing one token from each input place and adding one token to each output place. A *run* of a Petri net is any sequence of firings of enabled transitions; a run defines a sequence of markings. Because many transitions may be enabled in a state, there are often many possible distinct runs of a Petri net. Hence, a Petri net represents a kind of nondeterministic state machine, but in a convenient form for modeling and analyzing concurrent systems. Various extensions and generalizations of Petri nets have been found useful in applications.
