Preface

Parallelism, the capability of a computer to execute operations concurrently, has been a constant throughout the history of computing. It impacts hardware, software, theory, and applications. The fastest machines of the past few decades, the supercomputers, owe their performance advantage to parallelism. Today, physical limitations have forced the adoption of parallelism as the preeminent strategy of computer manufacturers for continued performance gains of all classes of machines, from embedded and mobile systems to the most powerful servers. Parallelism has been used to simplify the programming of certain applications which react to or simulate the parallelism of the natural world. At the same time, parallelism complicates programming when the objective is to take advantage of the existence of multiple hardware components to improve performance. Formal methods are necessary to study the correctness of parallel algorithms and implementations and to analyze their performance on different classes of real and theoretical systems. Finally, parallelism is crucial for many applications in the sciences, engineering, and interactive services such as search engines.

Because of its importance and the challenging problems it has engendered, there have been numerous research and development projects during the past half century. This Encyclopedia is our attempt to collect accurate and clear descriptions of the most important of those projects. Although not exhaustive, with over 300 entries the Encyclopedia covers most of the topics that we identified at the outset as important for a work of this nature. Entries include many of the best known projects and span all the important dimensions of parallel computing including machine design, software, programming languages, algorithms, theoretical issues, and applications.

This Encyclopedia is the result of the work of many, whose dedication made it possible. The 25 Editorial Board Members created the list of entries, did most of the reviewing, and suggested authors for the entries. Colin Robertson, the Managing Editor, Jennifer Carlson, Springer's Reference Development editor, and Editorial Assistants Julia Koerting and Simone Tavenrath, worked for 3 long years coordinating the recruiting of authors and the review and submission process. Melissa Fearon, Springer's Senior Editor, helped immensely with the coordination of authors and Editorial Board Members, especially during the difficult last few months. The nearly 400 authors wrote crisp, informative entries. They include experts in all major areas, come from many different nations, and span several generations. In many cases, the author is the lead designer or researcher responsible for the contribution reported in the entry. It was a great pleasure for me to be part of this project. The enthusiasm of everybody involved made this a joyful enterprise. I believe we have put together a meaningful snapshot of parallel computing in the last 50 years and presented a believable glimpse of the future. I hope the reader agrees with me on this and finds the entries, as I did, valuable contributions to the literature.

Actors

RAJESH K. KARMANI, GUL AGHA

University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

Actors is a model of concurrent computation for developing parallel, distributed, and mobile systems. Each actor is an autonomous object that operates concurrently and asynchronously, receiving and sending messages to other actors, creating new actors, and updating its own local state. An actor system consists of a collection of actors, some of whom may send messages to, or receive messages from, actors outside the system.

Preliminaries

An *actor* has a name that is globally unique and a behavior which determines its actions. In order to send an actor a message, the actor's name must be used; a name cannot be guessed but it may be communicated in a message. When an actor is idle, and it has a pending message, the actor accepts the message and does the computation defined by its behavior. As a result, the actor may take three types of actions: *send messages*, *create new actors*, and *update* its local state. An actor's behavior may change as it modifies its local state.

Actors do not share state: an actor must explicitly send a message to another actor in order to affect the latter's behavior. Each actor carries out its actions concurrently (and asynchronously) with other actors. Moreover, the path a message takes as well as network delays it may encounter are not specified. Thus, the arrival order of messages is indeterminate. The key semantic properties of the standard Actor model are *encapsulation* of state and *atomic* execution of a method in response to a message, *fairness* in scheduling actors and in the delivery of messages, and *location transparency* enabling distributed execution and mobility.

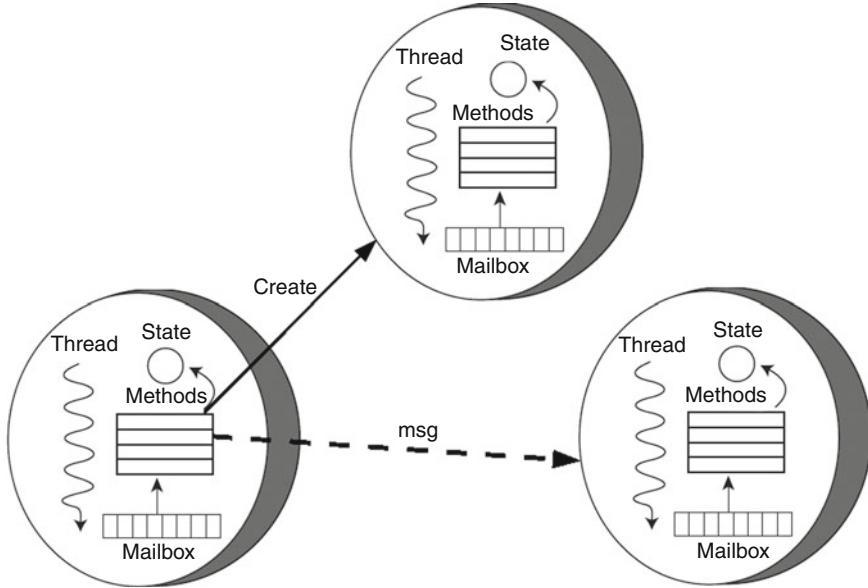

Advantages of the Actor Model

In the object-oriented programming paradigm, an object encapsulates data and behavior. This separates the interface of an object (what an object does) from its representation (how it does it). Such separation enables modular reasoning about object-based programs and facilitates their evolution. Actors extend the advantages of objects to concurrent computations by separating control (where and when) from the logic of a computation.

The Actor model of programming [3] allows programs to be decomposed into self-contained, autonomous, interactive, asynchronously operating components. Due to their asynchronous operation, actors provide a model for the nondeterminism inherent in distributed systems, reactive systems, mobile systems, and any form of interactive computing.

History

The concept of actors has developed over 3 decades. The earliest use of the term "actors" was in Carl Hewitt's *Planner* [23] where the term referred to rule-based active entities which search a knowledge base for patterns to match, and in response, trigger actions. For the next 2 decades, Hewitt's group worked on actors as

Actors. Fig. 1 Actors are concurrent objects that communicate through messages and may create new actors. An actor may be viewed as an object augmented with its own control, a *mailbox*, and a globally unique, immutable *name*

agents of computation, and it evolved as a model of concurrent computing. A brief history of actor research can be found in [7]. The commonly used definition of actors today follows the work of Agha (1985) which defines actors using a simple operational semantics [3].

In recent years, the Actor model has gained in popularity with the growth of parallel and distributed computing platforms such as multicore architectures, cloud computers, and sensor networks. A number of actor languages and frameworks have been developed. Some early actor languages include *ABCL*, *POOL*, *ConcurrentSmalltalk*, *ACT++*, *CEiffel* (see [11] for a review of these), and *HAL* [22]. Actor languages and frameworks in current use include *Erlang* (from Ericsson) [8], *E* (Erights.org), *Scala Actors* library (EPFL) [24], *Ptolemy* (UC Berkeley) [31], *ASP* (INRIA) [15], *JCoBox* (University of Kaiserslautern) [40], *SALSA* (UIUC and RPI) [42], *Charm++* [28] and *ActorFoundry* [10] (both from UIUC), the *Asynchronous Agents Library* [17] and *Axum* [18] (both from Microsoft), and *Orleans* framework for cloud computing from Microsoft Research [37]. Some well-known open source applications built using actors include Twitter's message queuing system and Lift Web Framework, and among commercial applications are Facebook Chat system and Vendetta's game engine.

Illustrative Actor Language

In order to show how actor programs work, consider a simple imperative actor language *ActorFoundry* that extends Java. A class defining an actor behavior extends `os1.manager.Actor`. Messages are handled by methods; such methods are annotated with `@message`. The `create(class,args)` method creates an actor instance of the specified actor class, where `args` correspond to the arguments of a constructor in the class. Each newly created actor has a unique name that is initially known only to the creator at the point where the creation occurs.

Execution Semantics

The semantics of *ActorFoundry* can be informally described as follows. Consider an *ActorFoundry* program *P* that consists of a set of actor definitions. An actor communicates with another actor in *P* by sending asynchronous (non-blocking) messages using the `send` statement: `send(a,msg)` has the effect of *eventually* appending the contents of `msg` to the mailbox of the actor *a*. However, the call to `send` returns immediately, that is, the sending actor does not wait for the message to arrive at its destination. Because actors operate asynchronously, and the network has indeterminate delays, the arrival order of messages is

nondeterministic. However, we assume that messages are *eventually* delivered (a form of *fairness*).

At the beginning of execution of P , the mailbox of each actor is empty and some actor in the program must receive a message from the environment. The Actor-Foundry runtime first creates an instance of a specified actor and then sends a specified message to it, which serves as P 's entry point.

Each actor can be viewed as executing a loop with the following steps: remove a message from its mailbox (often implemented as a queue), decode the message, and execute the corresponding method. If an actor's mailbox is empty, the actor blocks – waiting for the next message to arrive in the mailbox (such blocked actors are referred to as *idle actors*). The processing of a message may cause the actor's local state to be updated, new actors to be created, and messages to be sent. Because of the encapsulation property of actors, there is no interference between messages that are concurrently processed by different actors.

An actor program “terminates” when every actor created by the program is idle and the actors are not open to the environment (otherwise the environment could send new messages to their mailboxes in the future). Note that an actor program need not terminate – in particular, certain interactive programs and operating systems may continue to execute indefinitely.

Listing 1 shows the HelloWorld program in Actor-Foundry. The program comprises of two actor definitions: the HelloActor and the WorldActor. An instance of the HelloActor can receive one type of message, the greet message, which triggers the execution of greet method. The greet method serves as P 's entry point, in lieu of the traditional main method.

On receiving a greet message, the HelloActor sends a print message to the stdout actor (a built-in actor representing the standard output stream) along with the string “Hello.” As a result, “Hello” will eventually be printed on the standard output stream. Next, it creates an instance of the WorldActor. The HelloActor sends an audience message to the WorldActor, thus delegating the printing of “World” to it. Note that due to asynchrony in communication, it is possible for “World” to be printed before “Hello.”

Listing 1 Hello World! program in ActorFoundry

```
public class HelloActor extends Actor {
    @message
    public void greet() throws RemoteCodeException
    {
        ActorName other = null;
        send(stdout, "print", "Hello");
        other = create(WorldActor.class);
        send(other, "audience");
    }
}

public class WorldActor extends Actor {
    @message
    public void audience() throws RemoteCodeException
    {
        send(stdout, "print", "World");
    }
}
```

Synchronization

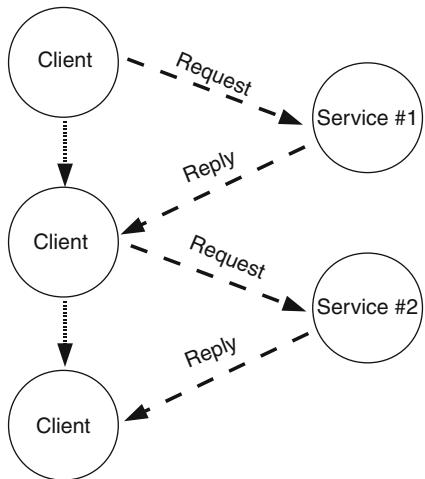

Synchronization in actors is achieved through communication. Two types of commonly used communication patterns are Remote Procedure Call (RPC)-like messaging and local synchronization constraints. Language constructs can enable actor programmers to specify such patterns. Such language constructs are definable in terms of primitive actor constructs, but providing them as first-class linguistic objects simplifies the task of writing parallel code.

RPC-Like Messaging

RPC-like communication is a common pattern of message-passing in actor programs. In RPC-like communication, the sender of a message waits for the reply to arrive before the sender proceeds with processing other messages. For example, consider the pattern shown in Fig. 2 for a client actor which requests a quote from a travel service. The client wishes to wait for the quote to arrive before it decides whether to buy the trip, or to request a quote from another service.

Without a high-level language abstraction to express RPC-like message pattern, a programmer has to explicitly implement the following steps in their program:

1. The client actor sends a request.
2. The client then checks incoming messages.

Actors. Fig. 2 A client actor requesting quotes from multiple competing services using RPC-like communication. The *dashed slanted arrows* denote messages and the *dashed vertical arrows* denote that the actor is waiting or is blocked during that period in its life

3. If the incoming message corresponds to the reply to its request, the client takes the appropriate action (accept the offer or keep searching).
4. If an incoming message does not correspond to the reply to its request, the message must be handled (e.g., by being buffered for later processing), and the client continues to check messages for the reply.

RPC-like messaging is almost universally supported in actor languages and libraries. RPC-like messages are particularly useful in two kinds of common scenarios. One scenario occurs when an actor wants to send an ordered sequence of messages to a particular recipient – in this case, it wants to ensure that a message has been received before it sends another. A variant of this scenario is where the sender wants to ensure that the target actor has received a message before it communicates this information to another actor. A second scenario is when the state of the requesting actor is dependent on the reply it receives. In this case, the requesting actor cannot meaningfully process unrelated messages until it receives a response.

Because RPC-like messages are similar to procedure calls in sequential languages, programmers have a tendency to overuse them. Unfortunately, inappropriate usage of RPC-like messages introduces unnecessary

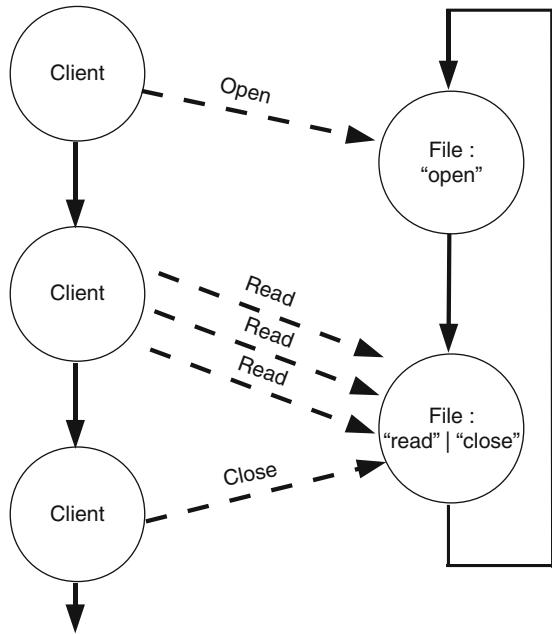

dependencies in the code. This may not only make the program’s execution more inefficient than it needs to be, it can lead to *deadlocks* and *livelocks* (where an actor ignores or postpones processing messages, waiting for an acknowledgment that never arrives).

Local Synchronization Constraints

Asynchrony is inherent in distributed systems and mobile systems. One implication of asynchrony is that the number of possible orderings in which messages may *arrive* is exponential in the number of messages that are “pending” at any time (i.e., messages that have been sent but have not been received). Because a sender may be unaware of what the state of the actor it is sending a message to will be when the latter receives the message, it is possible that the recipient may not be in a state where it can process the message it is receiving. For example, a spooler may not have a job when some printer requests one. As another example, messages to actors representing individual matrix elements (or groups of elements) asking them to process different iterations in a parallel Cholesky decomposition algorithm need to be monotonically ordered. The need for such orderings leads to considerable complexity in concurrent programs, often introducing bugs or inefficiencies due to suboptimal implementation strategies. For example, in the case of Cholesky decomposition, imposing a global ordering on the iterations leads to highly inefficient execution on multicomputers [6].

Consider the example of a print spooler. Suppose a ‘get’ message from an idle printer to its spooler may arrive when the spooler has no jobs to return the printer. One way to address this problem is for the spooler to refuse the request. Now the printer needs to repeatedly poll the spooler until the latter has a job. This technique is called *busy waiting*; busy waiting can be expensive – preventing the waiting actor from possibly doing other work while it “waits,” and it results in unnecessary message traffic. An alternate is to the spooler buffer the “get” message for deferred processing. The effect of such buffering is to change the order in which the messages are processed in a way that guarantees that the number of messages put messages to the spooler is always greater than the number of get messages processed by the spooler.

If pending messages are buffered explicitly inside the body of an actor, the code specifying the functionality

Actors. Fig. 3 A file actor communication with a client is constrained using local synchronization constraints. The *vertical arrows* depict the timeline of the life of an actor and the *slanted arrows* denote messages. The labels inside a circle denote the messages that the file actor can accept in that particular state

(the *how* or representation) of the actor is mixed with the logic determining the order in which the actor processes the messages (the *when*). Such mixing violates the software principle of *separation of concerns*. Researchers have proposed various constructs to enable programmers to specify the correct orderings in a modular and abstract way, specifically, as logical formulae (predicates) over the state of an actor and the type of messages. Many actor languages and frameworks provide such constructs; examples include local synchronization constraints in ActorFoundry, and pattern matching on sets of messages in Erlang and Scala Actors library.

Patterns of Actor Programming

Two common patterns of parallel programming are *pipeline* and *divide-and-conquer* [4]. These patterns are illustrated in Fig. 4a and 4b, respectively.

An example of the pipeline pattern is an image processing network (see Fig. 4a) in which a stream of

images is passed through a series of filtering and transforming stages. The output of the last stage is a stream of processed images. This pattern has been demonstrated by an image processing example, written using the *Asynchronous Agents Library* [17], which is part of the Microsoft Visual Studio 2010.

A *map-reduce* graph is an example of the divide-and-conquer pattern (see Fig. 4b). A master actor maps the computation onto a set of workers and the output from each of these workers is reduced in the “join continuation” behavior of the master actor (possibly modeled as a separate actor) (e.g., see [21]). Other examples of divide-and-conquer pattern are naïve parallel quicksort [38] and parallel mergesort. The synchronization idioms discussed above may be used in succinct encoding of these patterns in actor programs since these patterns essentially require ordering the processing of some messages.

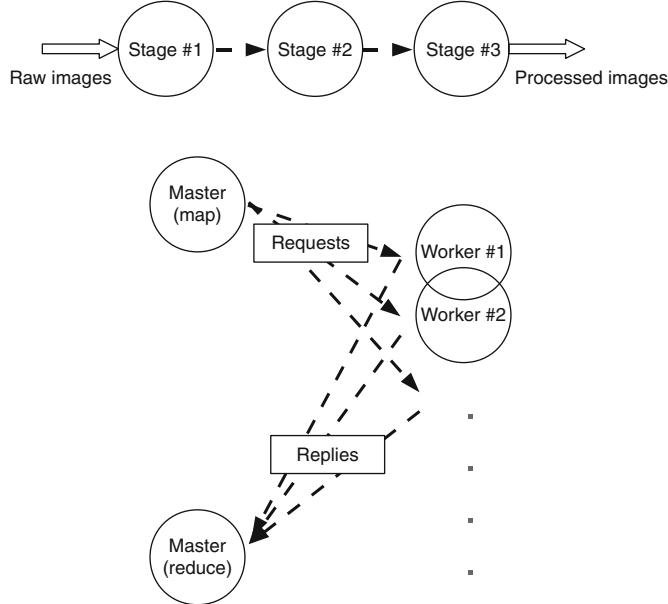

Semantic Properties

As mentioned earlier, some important semantic properties of the pure Actor model are encapsulation and atomic execution of methods (where a method represents computation in response to a message), fairness, and location transparency [29]. We discuss the implications of these properties.

Note that not all actor languages enforce all these properties. Often, the implementations compromise some actor properties, typically because it is simpler to achieve efficient implementations by doing so. However, it is possible by sophisticated program transformations, compilation, and runtime optimizations to regain almost all the efficiency that is lost in a naïve language implementation, although doing so is more challenging for library-like actor frameworks [29]. By failing to enforce some actor properties in an actor language or framework implementation, actor languages add to the burden of the programmers, who have to then ensure that they write programs in a way that does not violate the property.

Encapsulation and Atomicity

Encapsulation implies that no two actors share state. This is useful for enforcing an object-style decomposition in the code. In sequential object-based languages, this has led to the natural model of atomic change in objects: an object invokes (sends a message to) another

Actors. Fig. 4 Patterns of actor programming (from top): (a) pipeline pattern (b) divide-and-conquer pattern

object, which finishes processing the message before accepting another message from a different object. This allows us to reason about the behavior of the object in response to a message, given the state of the target object when it received the message. In a concurrent computation, it is possible for a message to arrive while an actor is busy processing another message. Now if the second message is allowed to interrupt the target actor and modify the target's state while the target is still processing the first message, it is no longer feasible to reason about the behavior of the target actor based on what the target's state was when it received the first message. This makes it difficult to reason about the behavior of the system as such interleaving of messages may lead to erroneous and inconsistent states.

Instead, the target actor processes messages one at a time, in a single *atomic step* consisting of all actions taken in response to a given message [7]. By dramatically reducing the nondeterminism that must be considered, such atomicity provides a *macro-step semantics* which simplifies reasoning about actor programs. Macro-step semantics is commonly used by correctness-checking tools; it significantly reduces the state-space exploration required to check a property against an actor program's potential executions (e.g., see [32]).

Fairness

The Actor model assumes a notion of *fairness* which states that every actor makes progress if it has some computation to do, and that every message is eventually delivered to the destination actor, unless the destination actor is permanently disabled. Fairness enables modular reasoning about the liveness properties of actor programs [7]. For example, if an actor system *A* is composed with an actor system *B* where *B* includes actors that are permanently busy, the composition does not affect the progress of the actors in *A*. A familiar example where fairness would be useful is in browsers. Problems are often caused by the composition of browser components with third-party plug-ins: in the absence of fairness, such plug-ins sometimes result in browser crashes and hang-ups.

Location Transparency

In the Actor model, the actual location of an actor does not affect its name. Actors communicate by exchanging messages with other actors, which could be on the same core, on the same CPU, or on another node in the network. Location transparent naming provides an abstraction for programmers, enabling them to program without worrying about the actual physical location of actors. Location transparent naming facilitates

automatic migration in the runtime, much as indirection in addressing facilitates compaction following garbage collection in sequential programming.

Mobility is defined as the ability of a computation to migrate across different nodes. Mobility is important for load-balancing, fault-tolerance, and reconfiguration. In particular, mobility is useful in achieving scalable performance, particularly for dynamic, irregular applications [26]. Moreover, employing different distributions in different stages of a computation may improve performance. In other cases, the optimal or correct performance depends on runtime conditions such as data and workload, or security characteristics of different platforms. For example, web applications may be migrated to servers or to mobile clients depending on the network conditions and capabilities of the client [12].

Mobility may also be useful in reducing the energy consumed by the execution of parallel applications. Different parts of an application often involve different parallel algorithms and the energy consumption of an algorithm depends on how many cores the algorithm is executed on and at what frequency these cores operate [27]. Mobility facilitates dynamic redistribution of a parallel computation to the appropriate number of cores (i.e., to the number of cores that minimize energy consumption for a given performance requirement and parallel algorithm) by migrating actors. Thus, mobility could be an important feature for energy-aware programming of multicore (*manycore*) architectures. Similarly, energy savings may be facilitated by being able to migrate actors in sensor networks and clouds.

Implementations

Erlang is arguably the best-known implementation of the Actor model. It was developed to program telecom switches at Ericsson about 20 years ago. Some recent actor implementations have been listed earlier. Many of these implementations have focused on a particular domain such as the Internet (SALSA), distributed applications (Erlang and E), sensor networks (ActorNet), and, more recently multicore processors (Scala Actors library, ActorFoundry, and many others in development).

It has been noted that a faithful but naïve implementation of the Actor model can be highly inefficient [29] (at least on the current generation of architectures). Consider three examples:

1. An implementation that maps each actor to a separate process may have a high cost for actor creation.
2. If the number of cores is less than the number of actors in the program (sometimes termed *CPU over-subscription*), an implementation mapping actors to separate processes may suffer from high context switching cost.
3. If two actors are located on the same sequential node, or on a shared-memory processor, it may be an order of magnitude more efficient to pass a reference to the message contents rather than to make a copy of the actual message contents.

These inefficiencies may be addressed by compilation and runtime techniques, or through a combination of the two. The implementation of the ABCI language [45] demonstrates some early ideas for optimizing both intra-node and internode execution and communication between actors. The Thal language project [26] shows that encapsulation, fairness, and universal naming in an actor language can be implemented efficiently on commodity hardware by using a combination of compiler and runtime. The Thal implementation also demonstrates that various communication abstractions such as RPC-like communication, local synchronization constraints, and join expressions can also be supported efficiently using various compile-time program transformations.

The Kilim framework develops a clever post-compilation continuation-passing style (CPS) transform (“weaving”) on Java-based actor programs for supporting lightweight actors that can pause and resume [39]. Kilim and Scala also add type systems to support safe but efficient messages among actors on a shared node [25, 39]. Recent work suggests that *ownership transfer* between actors, which enables safe and efficient messaging, can be statically inferred in most cases [33].

On distributed platforms such as cloud computers or grids, because of latency in sending messages to remote actors, an important technique for achieving good performance is communication–computation

overlap. Decomposition into actors and the placement of actors can significantly determine the extent of this overlap. Some of these issues have been effectively addressed in the Charm++ runtime [28]. Decomposition and placement issues are also expected to show up on scalable manycore architectures since these architecture cannot be expected to support constant time access to shared memory.

Finally, note that the notion of garbage in actors is somewhat complex. Because an actor name may be communicated in a message, it is not sufficient to mark the forward acquaintances (references) of *reachable* actors as reachable. The inverse acquaintances of reachable actors that may be potentially active need to be considered as well (these actors may send a message to a reachable actor). Efficient garbage collection of distributed actors remains an open research problem because of the problem of taking efficient distributed snapshots of the reachability graph in a running system [43].

Tools

Several tools are available to aid in writing, maintaining, debugging, model checking, and testing actor programs. Both Erlang and Scala have a plug-in for the popular, open source IDE (Integrated Development Environment) called Eclipse (<http://www.eclipse.org>). A commercial testing tool for Erlang programs called QuickCheck [5] is available. The tool enables programmers to specify program properties and input generators which are used to generate test inputs.

JCute [36] is a tool for automatic unit testing of programs written in a Java actor framework. Basset [30] works directly on executable (Java bytecode) actor programs and is easily retargetable to any actor language that compiles to bytecode. Basset understands the semantic structure of actor programs (such as the macro-step semantics), enabling efficient path exploration through the Java Pathfinder (JPF) – a popular tool for model checking programs [44]. The term rewriting system Maude provides an Actor module to specify program behavior; it has been used to model check actor programs [13]. There has also been work on runtime monitoring of actor programs [41].

Extensions and Abstractions

A programming language should facilitate the process of writing programs by being close to the conceptual level at which a programmer thinks about a problem rather than at the level at which it may be implemented. Higher level abstractions for concurrent programming may be defined in interaction languages which allow patterns to be captured as first-class objects [35]. Such abstractions can be implemented through an adaptive, reflective middleware [9]. Besides programming abstractions for concurrency in the pure (asynchronous) Actor model, there are variants of the Actor model, such as for real-time, which extend the model [31, 34]. Two interaction patterns are discussed to illustrate the ideas of interaction patterns.

Pattern-Directed Communication

Recall that a sending actor must know the name of a target actor before the sending actor can communicate with the target actor. This property, called *locality*, is useful for compositional reasoning about actor programs – if it is known that only some actors can send a message to an actor A, then it may be possible to figure out what types of messages A may get and perhaps specify some constraints on the order in which it may get them. However, real-world programs generally create an open system which interacts with their external environment. This means that having ways of discovering actors which provide certain services can be helpful. For example, if an actor migrates to some environment, discovering a printer in that environment may be useful.

Pattern-directed communication allows programmers to declare properties of a group of actors, enabling the use of the properties to discover actual recipients are chosen at runtime. In the *ActorSpace* model, an actor specifies recipients in terms of patterns over properties that must be satisfied by the recipients. The sender may send the message to all actors (in some group) that satisfy the property, or to a single representative actor [1]. There are other models for pattern-based communication. In *Linda*, potential recipients specify a pattern for messages they are interested in [14]. The sending actors simply inserts a message (called *tuple* in Linda) into

a *tuple-space*, from where the receiving actors may read or remove the tuples if the tuple matches the pattern of messages the receiving actor is interested in.

Coordination

Actors help simplify programming by increasing the granularity at which programmers need to reason about concurrency, namely, they may reason in terms of the potential interleavings of messages to actors, instead of in terms the interleavings of accesses to shared variables within actors. However, developing actor programs is still complicated and prone to errors. A key cause of complexity in actor programs is the large number of possible interleaving of messages to groups of actors: if these message orderings are not suitably constrained, some possible execution orders may fail to meet the desired specification.

Recall that local synchronization constraints postpone the dispatch of a message based on the contents of the messages and the local state of the receiving actor (see section “Local Synchronization Constraints”). *Synchronizers*, on the other hand, change the order in which messages are processed by a group of actors by defining constraints on ordering of messages processed at different actors in a group of actors. For example, if a withdrawal and deposit messages must be processed atomically by two different actors, a Synchronizer can specify that they must be scheduled together. Synchronizers are described in [2].

In the standard actor semantics, an actor that knows the name of a target actor may send the latter a message. An alternate semantics introduces the notion of a *channel*; a channel is used to establish communication between a given sender and a given recipient. Recent work on actor languages has introduced *stateful channel contracts* to constrain the order of messages between two actors. Channels are a central concept for communication between actors in both Microsoft’s Singularity platform [20] and Microsoft’s Axum language [18], while they can be optionally introduced between two actors in Erlang. Channel contracts specify a protocol that governs the communication between the two end points (actors) of the channel. The contracts are stated in terms of state transitions based on observing messages on the channel.

From the perspective of each end point (actor), the channel contract specifies the *interface* of the other end point (actor) in terms of not only the type of messages but also the ordering on messages. In Erlang, contracts are enforced at runtime, while in Singularity a more restrictive notion of typed contracts make it feasible to check the constraints at compile time.

Current Status and Perspective

Actor languages have been used for parallel and distributed computing in the real world for some time (e.g., Charm++ for scientific applications on supercomputers [28], Erlang for distributed applications [8]). In recent years, interest in actor-based languages has been growing, both among researchers and among practitioners. This interest is triggered by emerging programming platforms such as multicore computers and cloud computers. In some cases, such as cloud computing, web services, and sensor networks, the Actor model is a natural programming model because of the distributed nature of these platforms. Moreover, as multicore architectures are scaled, multicore computers will also look more and more like traditional multicomputer platforms. This is illustrated by the 48-core Single-Chip Cloud Computer (SCC) developed by Intel [16] and the 100-core TILE-Gx by Tilera [19]. However, the argument for using actor-based programming languages is not simply that they are a good match for distributed computing platforms; it is that Actors is a good model in which to think about concurrency. Actors simplify the task of programming by extending object-based design to concurrent (parallel, distributed, mobile) systems.

more efficient, and it is most often related to different speeds or overheads associated with the resources of the computing node that are required by the computing task.

Discussion

Introduction

In parallel computing environments, it may be more efficient to schedule a computing task on one computing node than on another. Such affinity of a specific task for a particular node can arise from many sources, where the goal of the scheduling policy is typically to optimize a functional of response time and/or throughput. For example, the affinity might be based on how fast the computing task can be executed on a computing node in an environment comprised of nodes with heterogeneous processing speeds. As another example, the affinity might concern the resources associated with the computing nodes such that each node has a collection of available resources, each task must execute on a node with a certain set of resources, and the scheduler attempts to maximize performance subject to these imposed system constraints.

Another form of affinity scheduling is based on the state of the memory system hierarchy. More specifically, it may be more efficient in parallel computing environments to schedule a computing task on a particular computing node than on any other if relevant data, code, or state information already resides in the caches or local memories associated with the node. This is the form most commonly referred to as affinity scheduling, and it is the primary focus of this entry. The use of such affinity information in general-purpose multiprocessor systems can often improve performance in terms of functionals of response time and throughput, particularly if this information is inexpensive to obtain and exploit. On the other hand, the performance benefits of this form of affinity scheduling often depend upon a number of factors and vary over time, and thus there is a fundamental scheduling trade-off between scheduling tasks where they execute most efficiently and keeping the workload shared among nodes.

Affinity scheduling in general-purpose multiprocessor systems will be next described within its historical

Affinity Scheduling

MARK S. SQUILLANTE
IBM, Yorktown Heights, NY, USA

Synonyms

Cache affinity scheduling; Resource affinity scheduling

Definition

Affinity scheduling is the allocation, or scheduling, of computing tasks on the computing nodes where they will be executed more efficiently. Such affinity of a task for a node can be based on any aspects of the computing node or computing task that make execution

context, followed by a brief discussion of the performance trade-off between affinity scheduling and load sharing.

General-Purpose Multiprocessor Systems

Many of the general-purpose parallel computing environments introduced in the 1980s were shared-memory multiprocessor systems of modest size in comparison with the parallel computers of today. Most of the general-purpose multiprocessor operating systems at the time implemented schedulers based on simple priority schemes that completely ignored the affinity a task might have for a specific processor due to the contents of processor caches. On the other hand, as processor cycle times improved at a much faster rate than main memory access times, researchers were observing the increasingly important relative performance impact of cache misses (refer to, e.g., [12]). The relative costs of a cache miss were also increasing due to other issues including cache coherency [2] and memory bus interference. As a matter of fact, the caches in one of the general-purpose multiprocessor systems at the time were not intended to reduce the memory access time at all, but rather to reduce memory bus interference and protect the bus from most processor-memory references (refer to, e.g., [23]).

In one of the first studies of such processor-cache affinity issues, Squillante and Lazowska [18, 19] considered the performance implications of scheduling based on the affinity of a task for the cache of a particular processor. The typical behaviors of tasks in general-purpose multiprocessor systems can include alternation between executing at a processor and releasing this processor either to perform I/O or synchronization operations (in which cases the task is not eligible for scheduling until completion of the operation) or because of quantum expiration or preemption (in which cases the task is suspended to allow execution of another task). Upon returning and being scheduled on a processor, the task may experience an initial burst of cache misses and the duration of this burst depends, in part, upon the number of blocks belonging to the task that are already resident in the cache of the processor. Continual increases in cache sizes at the time further suggested that a significant portion of the working set of a task may reside in the cache of a specific processor under these scenarios. Scheduling decisions that disregard such cache reload

times may cause significant increases in the execution times of individual tasks as well as reductions in the performance of the entire system. These cache-reload effects may be further compounded by an increase in the overhead of cache coherence protocols (due to a larger number of cache invalidations resulting from modification of a task's data still resident in another processor's cache) and an increase in bus traffic and interference (due to cache misses).

To this end, Squillante and Lazowska [18, 19] formulate and analyze mathematical models to investigate fundamental principles underlying the various performance trade-offs associated with processor-cache affinity scheduling. These mathematical models represent general abstractions of a wide variety of general-purpose multiprocessor systems and workloads, ranging from more traditional time-sharing parallel systems and workloads even up through more recent dynamic coscheduling parallel systems and workloads (see, e.g., [21]). Several different scheduling policies are considered, spanning the entire spectrum from ignoring processor-cache affinity to fixing tasks to execute on specific processors. The results of this modeling analysis illustrate and quantify the benefits and limitations of processor-cache affinity scheduling in general-purpose shared-memory multiprocessor systems with respect to improving and degrading the first two statistical moments of response time and throughput. In particular, the circumstances under which performance improvement and degradation can be realized and the importance of exploiting processor-cache affinity information depend upon many factors. Some of the most important of these factors include the size of processor caches, the locality of the task memory references, the size of the set of cache blocks in active use by the task (its cache footprint), the ratio of the cache footprint loading time to the execution time of the task per visit to a processor, the time spent non-schedulable by the task between processor visits, the processor activities in between such visits, the system architecture, the parallel computing workload, the system scheduling strategy, and the need to adapt scheduling decisions with changes in system load.

A large number of empirical research studies subsequently followed to further examine affinity scheduling across a broad range of general-purpose parallel computing systems, workloads, scheduling strategies,

and resource types. Gupta et al. [10] use a detailed multiprocessor simulator to evaluate various scheduling strategies, including gang scheduling (coscheduling), two-level scheduling (space-sharing) with process control, and processor-cache affinity scheduling, with a focus on the performance impact of scheduling on cache behavior. The benefits of processor-cache affinity scheduling are shown to exhibit a relatively small but noticeable performance improvement, which can be explained by the factors identified above under the multiprocessor system and workload studied in [10]. Two-level scheduling with process control and gang scheduling are shown to provide the highest levels of performance, with process control outperforming gang scheduling when applications have large working sets that fit within a cache. Vaswani and Zahorjan [27] then developed an implementation of a space-sharing strategy (under which processors are partitioned among applications) to examine the implications of cache affinity in shared-memory multiprocessor scheduling under various scientific application workloads. The results of this study illustrate that processor-cache affinity within such a space-sharing strategy provides negligible performance improvements for the three scientific applications considered. It is interesting to note that the models in [18, 19], parameterized by the system and application measurements and characteristics in [27], also show that affinity scheduling yields negligible performance benefits in these circumstances. Devarakonda and Mukherjee [7] consider various implementation issues involved in exploiting cache affinity to improve performance, arguing that affinity is most effective when implemented through a thread package which supports the multiplexing of user-level threads on operating system kernel-level threads. The results of this study show that a simple scheduling strategy can yield significant performance improvements under an appropriate application workload and a proper implementation approach, which can once again be explained by the factors identified above. Torrellas et al. [25, 26] study the performance benefits of cache-affinity scheduling in shared-memory multiprocessors under a wide variety of application workloads, including various scientific, software development, and database applications, and under a time-sharing strategy that was in widespread use by the vast majority of parallel computing environments at the time. The authors conclude

that affinity scheduling yields significant performance improvements for a few of the application workloads and moderate performance gains for most of the application workloads considered in their study, while not degrading the performance of the rest of these workloads. These results can once again be explained by the factors identified above.

In addition to affinity scheduling in general-purpose shared-memory multiprocessors, a number of related issues have arisen with respect to other types of resources in parallel systems. One particularly interesting application area concerns affinity-based scheduling in the context of parallel network protocol processing, as first considered by Salehi et al. (see [16] and the references cited therein), where parallel computation is used for protocol processing to support high-bandwidth, low-latency networks. In particular, Salehi et al. [16] investigate affinity-based scheduling issues with respect to: supporting a large number of streams concurrently; receive-side and send-side protocol processing (including data-touching protocol processing); stream burstiness and source locality of network traffic; and improving packet-level concurrency and caching behavior. The approach taken to evaluate various affinity-based scheduling policies is based on a combination of multiprocessor system measurements, analytic modeling, and simulation. This combination of methods is used to illustrate and quantify the potentially significant benefits and effectiveness of affinity-based scheduling in multiprocessor networking. Across all of the workloads considered, the authors find benefits in managing threads and free-memory by taking affinity issues into account, with different forms of affinity-based scheduling performing best under different workload conditions.

The trends of increasing cache and local memory sizes and of processor speeds decreasing at much faster rates than memory access times continued to grow over time. This includes generations of non-uniform memory-access (NUMA) shared-memory and distributed-memory multiprocessor systems in which the remoteness of memory accesses can have an even more significant impact on performance. The penalty for not adhering to processor affinities can be considerably more significant in such NUMA and distributed-memory multiprocessor systems, where the actual cause of the larger costs depends upon the memory

management policy but are typically due to remote access or demand paging of data stored in non-local memory modules. These trends in turn have caused the performance benefits of affinity scheduling in parallel computing environments to continue to grow. The vast majority of parallel computing systems available today, therefore, often exploit various forms of affinity scheduling throughout distinct aspects of the parallel computing environment. There continues to be important differences, however, among the various forms of affinity scheduling depending upon the system architecture, application workload, and scheduling strategy, in addition to new issues arising from some more recent trends such as power management.

Affinity Scheduling and Load Sharing Trade-off

In parallel computing environments that employ affinity scheduling, the system often allocates computing tasks on the computing nodes where they will be executed most efficiently. Conversely, underloaded nodes are often inevitable in parallel computing environments due to factors such as the transient nature of system load and the variability of task service times. If computing tasks are always executed on the computing nodes for which they have affinity, then the system may suffer from load sharing problems as tasks are waiting at overloaded nodes while other nodes are underloaded. On the one hand, if processor affinities are not followed, then the system may incur significant penalties as each computing task must establish its working set in close proximity to a computing node before it can proceed. On the other hand, scheduling decisions cannot be based solely on task-node affinity, else other scheduling criteria, such as fairness, may be sacrificed. Hence, there is a fundamental scheduling trade-off between keeping the workload shared among nodes and scheduling tasks where they execute most efficiently. An adaptive scheduling policy is needed that determines, as a function of system load, the appropriate balance between the extremes of strictly balancing the workload among all computing nodes and abiding by task-node affinities blindly.

One such form of load sharing has received considerable attention with respect to distributed system environments. Static policies, namely those that use

information about the average behavior of the system while ignoring the current state, have been proposed and studied by numerous researchers including Bokhari [4], and Tantawi and Towsley [22]. These policies have been shown, in many cases, to provide better performance than policies that do not attempt to share the system workload. Other studies have shown that more adaptive policies, namely those that make decisions based on the current state of the system, have the potential to greatly improve system performance over that obtained with static policies. Furthermore, Livny and Melman [14], and Eager, Lazowska, and Zahorjan [8] have shown that much of this potential can be realized with simple methods. This potential has prompted a number of studies of specific adaptive load sharing policies, including the research conducted by Barak and Shiloh [3], Wang and Morris [28], Eager et al. [9], and Mirchandaney et al. [15].

While there are many similarities between the affinity scheduling and load sharing trade-off in distributed and shared-memory (as well as some distributed-memory) parallel computing environments, there can be several important differences due to distinct characteristics of these diverse parallel system architectures. One of the most important differences concerns the direct costs of moving a computing task. In a distributed system, these costs are typically incurred by the computing node from which the task is being migrated, possibly with an additional network delay. Subsequent to this move, the processing requirements of the computing task are identical to those at the computing node where the task has affinity. On the other hand, the major costs of task migration in a shared-memory (as well as distributed-memory) system are the result of a larger service demand at the computing node to which the computing task is migrated, reflecting the time required to either establish the working set of the task in closer proximity to this node or remotely access the working set from this node. Hence, there is a shift of the direct costs of migration from the (overloaded) computing node for which the computing task has affinity to the (underloaded) node receiving the task.

Motivated by these and related differences between distributed and shared-memory systems, Squillante and Nelson [20] investigated the fundamental trade-off between affinity scheduling and load sharing in

shared-memory (as well as some distributed-memory) parallel computing environments. More specifically, the authors consider the question of how expensive task migration must become before it is not beneficial to have an underloaded computing node migrate a computing task waiting at another node, as it clearly would be beneficial to migrate such a task if the cost to do so was negligible. Squillante and Nelson [20], therefore, formulate and analyze mathematical models to investigate this and related questions concerning the conditions under which it becomes detrimental to migrate a task away from its affinity node with respect to the costs of not adhering to these task-node affinities. The results of this modeling analysis illustrate and quantify the potentially significant benefits of migrating waiting tasks to underloaded nodes in shared-memory multiprocessors even when migration costs are relatively large, particularly at moderate to heavy loads. By sharing the collection of computing tasks among all computing nodes, a combination of affinity scheduling and threshold-based task migration can yield performance that is better than a non-migratory policy even with a larger service demand for migrated tasks, provided proper threshold values are employed. These modeling analysis results also demonstrate the potential for unstable behavior under task migration policies when improper threshold settings are employed, where optimal policy thresholds avoiding such behavior are provided as a function of system load and the relative processing time of migrated tasks.

Bibliographic Notes and Further Reading

Affinity scheduling based on the different speeds of executing tasks in heterogeneous processor environments has received considerable attention in the literature, including both deterministic models and stochastic models for which, as examples, the interested reader is referred to [5, 11] and [13, 30], respectively. Affinity scheduling based on resource requirement constraints have also received considerable

attention in the literature (see, e.g., [5, 6, 29]). Examples of shared memory multiprocessor systems from the 1980s include the DEC Firefly [23] and the Sequent Symmetry [17]. Multiprocessor operating systems of this period that completely ignored processor-cache affinity include Mach [1], DYNIX [24], and Topaz [23].

This entry primarily focuses on affinity scheduling based on the state of the memory system hierarchy where it can be more efficient to schedule a computing task on a particular computing node than on another if any relevant information already resides in caches or local memories in close proximity to the node. This entry also considers the fundamental trade-off between affinity scheduling and load sharing. A number of important references have been provided throughout, to which the interested reader is referred together with the citations provided therein. Many more references on these subjects are widely available, in addition to the wide variety of strategies that have been proposed to address affinity scheduling and related performance trade-offs.

[Ajtai–Komlós–Szemerédi sorting network](#); [AKS sorting network](#); [Logarithmic-depth sorting network](#)

Definition

AKS networks are $\mathcal{O}(\log n)$ -depth networks of 2-item sorters that sort their n input items by following the 1982 design by Miklós Ajtai, János Komlós, and Endre Szemerédi.

Discussion

Comparator Networks for Sorting

Following Knuth [9, Section 5.3.4] or Cormen et al. [8, Chapter 27], consider algorithms that reorder their input sequences I (of items, or “keys,” from some totally ordered universe) via “oblivious comparison-exchanges.” Each comparison-exchange is effected by a “comparator” from a data position i to another data

position j , which permutes $I[i]$ and $I[j]$ so that $I[i] \leq I[j]$. (So a comparator amounts to an application of a 2-item sorter.) The sequence of such comparison-exchanges depends only on the number n of input items, but not on whether items get switched. Independent comparison-exchanges, involving disjoint pairs of data positions, can be allowed to take place at the same time – up to $\lfloor n/2 \rfloor$ comparison-exchanges per parallel step.

Each such algorithm can be reformulated so that every comparison-exchange $[i : j]$ has $i < j$ (Knuth's standard form) [9, Exercise 5.3.4-16, or 8, Exercise 27.1-8]. Following Knuth, restrict attention to such algorithms and represent them by left-to-right parallel horizontal “time lines” for the n data positions (also referred to as *registers*), connecting pairs of them by vertical lines to indicate comparison-exchanges. A famous example is Batcher's family of networks for sorting “bitonic” sequences [5]. The network for $n = 16$ is depicted in Fig. 1. Since the maximum depth is 4, four steps suffice. In general, Batcher's networks sort bitonic input sequences of lengths n that are powers of 2, in $\log_2 n$ steps.

If such a network reorders *every* length- n input sequence into sorted order (i.e., so that $I[i] \leq I[j]$ holds whenever $i < j$ does), then call it a *sorting* network. Since the concatenation of a sorted sequence and the reverse of a sorted sequence is bitonic, Batcher's networks can be used to merge sorted sequences in $\Theta(\log n)$ parallel steps (using $\Theta(n \log n)$ comparators), and hence to implement merge sort in $\Theta(\log^2 n)$ parallel steps (using $\Theta(n \log^2 n)$ comparators).

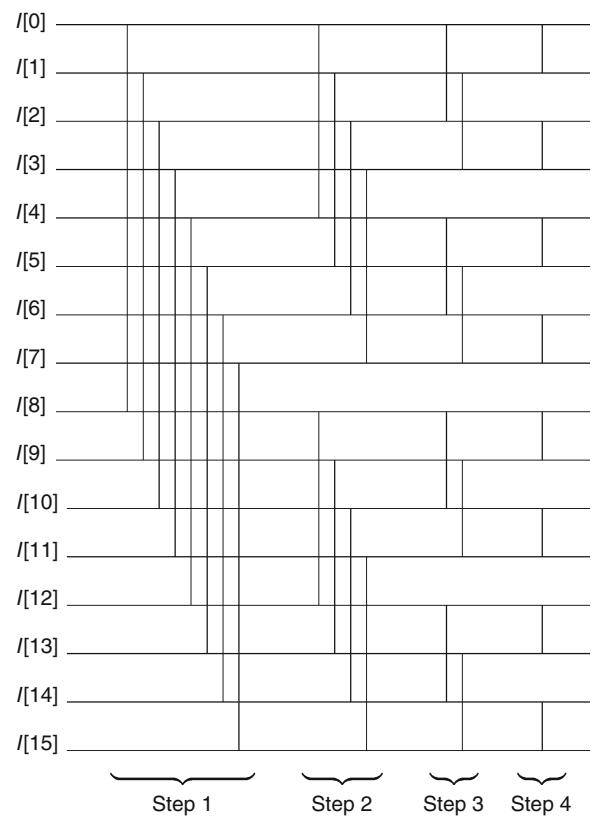

The total number $\Theta(n \log^2 n)$ of comparators used by Batcher's elegant sorting networks is worse by a factor of $\Theta(\log n)$ than the number $\Theta(n \log n) = \Theta(\log_2 n!)$ of two-outcome comparisons required for the best (nonoblivious) sorting algorithms, such as merge sort and heap sort [8, 9]. At the expense of simplicity and practical multiplicative constants, the “AKS” sorting networks of Ajtai, Komlós, and Szemerédi [1–2] close this gap, sorting in $\mathcal{O}(\log n)$ parallel steps, using $\mathcal{O}(n \log n)$ comparators.

The Sorting-by-Splitting Approach

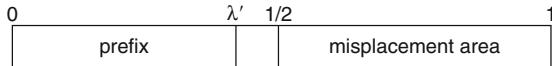

The AKS algorithm is based on a “sorting-by-splitting” or “sorting-by-classifying” approach that amounts to an ideal version of “quicksort” [8, 9]: Separate the items to be sorted into a smallest half and a largest half, and

continue recursively on each half. But the depth of just a halving network would already have to be $\Omega(\log n)$, again seeming to lead, through recursion, only to sorting networks of depth $\Omega(\log^2 n)$.

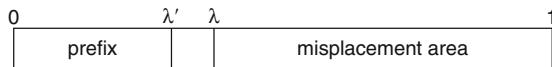

(To see that (all) the outputs of a perfect halver have to be at depth $\Omega(\log n)$, consider the computation on a sequence of n identical items, and consider any particular output item. If its depth is only d , then there are $n - 2^d$ input items that can have no effect on that output item. If this number exceeds $n/2$, then these uninvolved input items can all be made larger or smaller to make the unchanged output *wrong*. (In fact, a slightly more careful argument by Alekseev [4, 9] shows also that the total number of comparators has to be $\Omega(n \log n)$, again seeming to leave no room for a good recursive result.))

AKS Network. Fig. 1 Batcher's bitonic merger for $n = 16$ elements. Each successive comparator (vertical line) reorders its inputs (top and bottom endpoints) into sorted order

AKS Network. Fig. 2 Setting for approximate halving (prefix case)

AKS Network. Fig. 3 Setting for approximate λ -separation (prefix case)

The 1982, AKS breakthrough [1] was twofold: to notice that there *are* shallow *approximate* separators, and to find a way to tolerate their errors in sorting by classification.

Approximate Separation via Approximate Halving via Bipartite Expander Graphs

The approximate *separators* defined, designed, and used are based on the simpler definition and existence of approximate *halvers*. The criterion for approximate halving is a relative bound (ε) on the number of misplacements from each prefix or suffix (of relative length λ' up to $\lambda = 1/2$) of a completely sorted result to the wrong *half* of the result actually produced (see Fig. 2). For approximate *separation*, the “wrong fraction” one-half is generalized to include even larger fractions $1 - \lambda$. (See Fig. 3.)

Definition 1 For each $\varepsilon > 0$ and $\lambda \leq 1/2$, the criterion for ε -approximate λ -separation of a sequence of n input elements is that, for each $\lambda' \leq \lambda$, at most $\varepsilon\lambda'n$ of the $\lfloor \lambda'n \rfloor$ smallest (respectively, largest) elements do not get placed among the $\lfloor \lambda n \rfloor$ first (respectively, last) positions. For $\lambda = 1/2$, this is called ε -halving.

Although these definitions do not restrict n , they will be needed and used only for *even* n .

The AKS construction will use constant-depth networks that perform *both* ε -halving and ε -approximate λ -separation for some λ *smaller* than $1/2$. Note that neither of these quite implies the other, since the former constrains more prefixes and suffixes (all the way up to half the length), while the latter counts more misplacements (the ones to a longer “misplacement area”) as significant.

Lemma 1 For each $\varepsilon > 0$, ε -halving can be performed by comparator networks (one for each even n) of constant depth (depending on ε , but independent of n).

Proof From the study of “expander graphs” [14, e.g.], using the fact that $\frac{1-\varepsilon}{\varepsilon}\varepsilon < 1$, start with a constant d , determined by ε , and a d -regular $n/2$ -by- $n/2$ bipartite graph with the following expansion property: Each subset S of either part, with $|S| \leq \varepsilon n/2$, has more neighbors than $\frac{1-\varepsilon}{\varepsilon}|S|$.

The ε -halver uses a first-half-to-second-half comparator corresponding to each edge in the d -regular bipartite expander graph. This requires depth only d , by repeated application of a minimum-cut argument, to extract d matchings [8, Exercise 26.3-5, for example].

To see that the result is indeed an ε -halver, consider, in any application of the network, the final positions of the strays from the $m \leq n/2$ smallest elements. Those positions *and all their neighbors* must finally contain elements among the m smallest. If the fraction of strays were more than ε , then this would add up to more than $\varepsilon m + \frac{1-\varepsilon}{\varepsilon}\varepsilon m = m$, a contradiction. \square

Using approximate halvers in approximate separation and exact sorting resembles such mundane tasks as sweeping dirt with an imperfect broom or clearing snow with an imperfect shovel. There has to be an efficient, converging strategy for cleaning up the relatively few imperfections. Subsequent strokes should be aimed at where the concentrations of imperfections are currently known to lie, rather than again at the full job – something like skimming spilled oil off the *surface* of the Gulf of Mexico.

The use of approximate halvers in approximate separation involves relatively natural shrinkage of “stroke size” to sweep more extreme keys closer to the ends.

Lemma 2 For each $\varepsilon > 0$ and $\lambda \leq 1/2$, ε -approximate λ -separation and simultaneous ε -halving can be performed by comparator networks (one for each even n) of constant depth (depending on ε and λ , but independent of n).

Proof For ε_0 small in terms of ε and λ , make use of the ε_0 -halvers already provided by Lemma 1 (the result for $\lambda = 1/2$):

First apply the ε_0 -halver for length n to the whole sequence, and then work separately on each resulting half, so that the final result will remain an ε_0 -halver.

The halves are handled symmetrically, in parallel; so focus on the first half. In terms of $m = \lfloor \lambda n \rfloor$ (assuming $n \geq 1/\lambda$), apply ε_0 -halvers to the $\lceil \log_2(n/m) \rceil - 1$ prefixes of lengths $2m, 4m, 8m, \dots, 2^{\lceil \log_2(n/m) - 1 \rceil} m$, in reverse order, where the last one listed (first one performed) is simplified as if the inputs beyond the first $n/2$ were all some very large element. Then the total number of elements from the smallest $\lfloor \lambda' n \rfloor$ (for any $\lambda' \leq \lambda$) that do not end up among the first $\lfloor \lambda n \rfloor = m$ positions is at most $\varepsilon_0 \lambda' n$ in each of the $\lceil \log_2(n/m) \rceil$ intervals $(m, 2m], (2m, 4m], (4m, 8m], \dots, (2^{\lceil \log_2(n/m) - 2 \rceil} m, n/2],$ and $(n/2, n]$, for a total of at most $\lceil \log_2(n/m) \rceil \varepsilon_0 \lambda' n$.

For any chosen $c < 1$ (close to 1, making $\log_2(1/c)$ close to 0), the following holds: Unless n is small ($n < (1/\lambda)(1/(1-c))$),

$$\begin{aligned} 2^{1+\log_2(n/m)} &= 2(n/m) = 2n/\lfloor \lambda n \rfloor < 2n/(\lambda n - 1) \\ &\leq 2n/(c\lambda n) = (2/c)(1/\lambda), \end{aligned}$$

so that $\log_2(n/m)$ is less than $\log_2(1/c) + \log_2(1/\lambda)$, and the number of misplaced elements above is at most $\lceil \log_2(1/c) + \log_2(1/\lambda) \rceil \varepsilon_0 \lambda' n$. This is bounded by $\varepsilon \lambda' n$ as required, provided $\varepsilon_0 \leq \varepsilon / [\log_2(1/c) + \log_2(1/\lambda)]$. \square

Sorting with Approximate Separators

Without loss of generality, assume the n items to be sorted are distinct, and that n is a power of 2 larger than 1. To keep track of the progress of the recursive classification, and the (now not necessarily contiguous) sets of registers to which approximate halvers and separators should be applied, consider each of the registers always to occupy one of $n-1 = 1+2+4+\dots+n/2$ bags – one bag corresponding to each nonsingleton *binary subinterval* of the length- n index sequence: one whole, its first and second halves (two halves), their first and second halves (four quarters), ..., their first and second halves ($n/2$ contiguous pairs). These binary subintervals, and hence the associated bags, correspond nicely to the nodes of a complete binary tree, with each nontrivial binary subinterval serving as *parent* for its first and second halves, which serve respectively as its *left child* and *right child*. (The sets, and even the numbers, of registers corresponding to these bags will change with time, according to time-determined baggings and rebaggings by the algorithm.)

Based on its actual *rank* (position in the actual sorted order), each register's current item can be considered *native* to one bag at each level of the tree. For example, if it lies in the second quartile, it is native to the second of the four bags that are grandchildren of the root. Sometimes an item will occupy a bag to which it is *not native*, where it is a *stranger*; more specifically, it will be *j-strange* if its bag is *at least j* steps off its native path down from the root. (So the 1-strangers are *all* the strangers; and the *additional* 0-strangers are actually native, and not strangers at all.)

Initially, consider all n registers to be in the root bag (the one corresponding to the whole sequence of indices), to which all contents are native. The strategy is to design and follow a schedule, oblivious to the particular data, of applications of certain comparator networks and conceptual rebaggings of the results, that is guaranteed to leave all items in the bags of constant-height subtrees to which they are native. Then to finish, it will suffice to apply a separate sorting network to the $\mathcal{O}(1)$ registers in the bags of each of these constant-size subtrees.

The Structure of the Bagging Schedule

Each stage of the network acts separately on the contents of each nonempty bag, which is an inductively predictable subsequence of the n registers. In terms of the bag's current "capacity" b (an upper bound on its number of registers), a certain fixed "skimming" fraction λ , and other parameters to be chosen later (in retrospect), it applies an approximate separator from Lemma 2 to that sequence of registers, and it evacuates the results to the parent and children bags as follows: If there is a parent, then "kick back" to it $\lfloor \lambda b \rfloor$ items (or as many as are available, if there are not that many) from each end of the results, where too-small and too-large items will tend to accumulate. If the excess (between these ends) is odd (which will be inductively impossible at the root), then kick back any one additional register (the middle one, say) to the parent. Send the first and second halves of any remaining excess down to the respective children. Note that this plan can fail to be feasible in only one case: the number of registers to be evacuated exceeds $2\lfloor \lambda b \rfloor + 1$, but the bag has no children (i.e., it is a leaf).

The parameter b is an imposed *capacity* that will increase (exponentially) with the depth of the bag in the tree but decrease (also exponentially) with time, thus

“squeezing” all the items toward the leaves, as desired. Aim to choose the parameters so that the squeezing is slow enough that the separators from Lemma 2 have time to successfully skim and reroute all strangers back to their native paths.

To complete a (not yet proved) *description* of a network of depth $\mathcal{O}(\log n)$ to sort n items, here is a preview of one set of adequate parameters:

$$\lambda = \varepsilon = 1/99 \text{ and } b = n \cdot 10^d (.65)^t,$$

where $d \geq 0$ is the depth and $t \geq 0$ is the number of previous stages. It turns out that adopting these parameters enables iteration until $b_{\text{leaf}} < 99$, and that at that time every item will be in a height-1 subtree to which it is native, so that the job can be finished with disjoint 4-sorters.

A Suitable Invariant

In this and the next section, the parameters are carefully reintroduced, and constraints on them are accumulated, sufficient for the analysis to work out. For A comfortably larger than 1 (10 in the preview above) and v less than but close to 1 (.65 in the preview above), define the *capacity* (b above) of a depth- d bag after t stages to be $nv^t A^d$. (Again note the dynamic reduction with time, so that this capacity eventually becomes small even compared to the number of items native to the bag.) Let $\lambda < 1$ be chosen as indicated later, and let $\varepsilon > 0$ be small.

Subject to the constraints accumulated in section “Argument that the Invariant is Maintained”, it will be shown there that each successful iteration of the separation–rebagging procedure described in section “The Structure of the Bagging Schedule” (i.e., each stage of the network) preserves the following four-clause invariant.

1. Alternating levels of the tree are entirely empty.
2. On each level, the number of registers currently in each bag (or in the entire subtree below) is the same (and hence at most the size of the corresponding binary interval).
3. The number of registers currently in each bag is bounded by the current capacity of the bag.
4. For each $j \geq 1$, the number of j -strangers currently in the registers of each bag is bounded by $\lambda \varepsilon^{j-1}$ times the bag’s current capacity.

How much successful iteration is enough? Until the leaf capacities b dip below the constant $1/\lambda$. At that point, the subtrees of smallest height k such that $(1/\lambda)(1/A)^{k+1} < 1$ contain all the registers, because higher-level capacities are at most $b/A^{k+1} < (1/\lambda)(1/A)^{k+1} < 1$. And the contents are correctly classified, because the number of $(k-i+1)$ -strangers in each bag at each height $i \leq k$ is bounded by $\lambda \varepsilon^{k-i} b/A^i \leq \lambda b < 1$. So the job can be finished with independent 2^{k+1} -sorters, of depth at most $(k+1)(k+2)/2$ [5]. In fact, for the right choice of parameters (holding $1/\lambda$ to less than A^2), k as small as 1 can suffice, so that the job can be finished with mere 4-sorters, of depth just 3. Therefore, the number t of successful iterations need only exceed $((1+\log_2 A)/\log_2(1/v)) \log_2 n - \log_2(A/\lambda)/\log_2(1/v) = \mathcal{O}(\log n)$, since that is (exactly) enough to get the leaf capacity $nv^t A^{(\log_2 n)-1}$ down to $1/\lambda$.

As noted in the previous section, only one thing can prevent successful iteration of the proposed procedure for each stage: $2\lfloor \lambda b \rfloor + 1$ being less than the number of items to be evacuated from a bag with current capacity b but with no children. Since such a bag is a leaf, it follows from Clause 2 of the invariant that the number of items is at most 2. Thus the condition is $2\lfloor \lambda b \rfloor + 1 < 2$, implying the goal $b < 1/\lambda$ has already been reached.

Therefore, it remains only to choose parameters such that each successful iteration does preserve the entire invariant.

Argument that the Invariant Is Maintained

Only Clauses 3 and 4 are not immediately clear. First consider the former – that capacity will continue after the next iteration to bound the number of registers in each bag. This is nontrivial only for a bag that is currently empty. If the current capacity of such a bag is $b \geq A$, then the next capacity can safely be as low as

$$\begin{aligned} & (\text{number of registers from below}) \\ & + (\text{number of registers from above}) \\ & \leq (4\lambda b A + 2) + b/(2A) \\ & = b(4\lambda A + 1/(2A)) + 2 \\ & \leq b(4\lambda A + 1/(2A) + 2/A), \text{ since } b \geq A. \end{aligned}$$

In the remaining Clause 3 case, the current capacity of the empty bag is $b < A$. Therefore, all higher bags’ capacities are bounded by $b/A < 1$, so that the n registers are equally distributed among the subtrees rooted

on the level below, an even number of registers per subtree. Since each root on that level has passed down an equal net number of registers to each of its children, it currently holds an even number of registers and will not kick back an odd register to the bag of interest. In this case, therefore, the next capacity can safely be as low as just $4\lambda bA$.

In either Clause 3 case, therefore, any $v \geq 4\lambda A + 5/(2A)$ will work.

Finally, turn to restoration of Clause 4. First, consider the relatively easy case of $j > 1$. Again, this is nontrivial only for a bag that is currently empty. Suppose the current capacity of such a bag is b . What is a bound on the number of j -strangers after the next step? It is at most

$$\begin{aligned} & (\text{all } (j+1)\text{-strangers currently in children}) \\ & + ((j-1)\text{-strangers currently in parent, and not} \\ & \quad \text{filtered out by the separation}) \\ & < 2bA\lambda\varepsilon^j + \varepsilon((b/A)\lambda\varepsilon^{j-2}) \\ & \leq \lambda\varepsilon^{j-1}vb, \text{ provided } [2A\varepsilon + 1/A \leq v]. \end{aligned}$$

Note that the bound $\varepsilon((b/A)\lambda\varepsilon^{j-2})$ exploits the “filtering” performance of an approximate separator: At most fraction ε of the “few” smallest (or largest) are permuted “far” out of place.

All that remains is the more involved Clause 4 case of $j = 1$. Consider any currently empty bag B , of current capacity b . At the root there are always *no* strangers; so assume B has a parent, D , and a sibling, C . Let d be the number of registers in D .

There are three sources of 1-strangers in B after the next iteration, two previously strange, essentially as above, and one newly strange:

1. Current 2-strangers at children (at most $2\lambda\varepsilon bA$).
2. Unfiltered current 1-strangers in D (at most $\varepsilon(\lambda(b/A))$, as above).
3. Items in D that are native to C but that now get sent to B instead.

For one of these last items to get sent down to B , it must get permuted by the approximate separator of Lemma 2 into “ B ’s half” of the registers. The number that do is at most the number of C -native items in excess of $d/2$, plus the number of “halving errors” by the approximate separator. By the approximate halving behavior, the latter is at most $\varepsilon b/(2A)$, leaving only the former to estimate.

For this remaining estimate, compare the current “actual” distribution with a more symmetric “benchmark” distribution that has an unchanged number of registers in each bag, but that, for each bag C' on the same level as B , has only C' -native items below C' and has $d/2$ C' -native items in the parent D' of C' . (If d is odd, then the numbers of items in D' native to its two children will be $[d/2]$ and $\lceil d/2 \rceil$, in either order.) That there *is* such a redistribution follows from Clause 2 of the invariant: Start by partitioning the completely sorted list among the bags on B ’s level, and then move items down and up in appropriate numbers to fill the budgeted vacancies.

In the benchmark distribution, the number of C -native items in excess of $d/2$ is 0. If the actual distribution is to have an excess, where can the excess C -native items come from, in terms of the benchmark distribution? They can come only from C -native items on levels above D ’s and from a net reduction in the number of C -native items in C ’s subtree. The latter can only be via the introduction into C ’s subtree of items *not* native to C . By Clause 4 of the invariant, the number of these can be at most

$$\begin{aligned} & 2\lambda\varepsilon bA + 8\lambda\varepsilon^3 bA^3 + 32\lambda\varepsilon^5 bA^5 + 128\lambda\varepsilon^7 bA^7 + \dots \\ & = 2\lambda\varepsilon bA(1 + (2\varepsilon A)^2 + ((2\varepsilon A)^2)^2 \\ & \quad + ((2\varepsilon A)^2)^3 + \dots) < 2\lambda\varepsilon bA/(1 - (2\varepsilon A)^2). \end{aligned}$$

If 2^i is the number of bags C' on the level of C , then the total number of items on levels above D ’s is at most

$$2^{i-3}b/A^3 + 2^{i-5}b/A^5 + 2^{i-7}b/A^7 + \dots$$

Since the number native to each such C' is the same, the number native to C is at most $1/2^i$ times as much:

$$\begin{aligned} & b/(2A)^3 + b/(2A)^5 + b/(2A)^7 + \dots \\ & < b/\left((2A)^3(1 - 1/(2A)^2)\right) \\ & = b/(8A^3 - 2A). \end{aligned}$$

So the total number of 1-strangers from all sources is at most

$$\begin{aligned} & 2\lambda\varepsilon bA + \varepsilon(\lambda(b/A)) + \varepsilon b/(2A) + 2\lambda\varepsilon bA/(1 - (2\varepsilon A)^2) \\ & + b/(8A^3 - 2A). \end{aligned}$$

This total is indeed bounded, as needed, by λvb (λ times the new capacity), provided

$$2\lambda\varepsilon A + \varepsilon\lambda/A + \varepsilon/(2A) + 2\lambda\varepsilon A/(1 - (2\varepsilon A)^2) \\ + 1/(8A^3 - 2A) \leq \lambda v.$$

This completes the argument, subject to the following accumulated constraints:

$$\begin{aligned} A &> 1, \\ v &< 1, \\ \varepsilon &> 0, \\ \lambda &< 1, \\ v &\geq 4\lambda A + 5/(2A), \\ v &\geq 2A\varepsilon + 1/A, \\ \lambda v &\geq 2\lambda\varepsilon A + \varepsilon\lambda/A + \varepsilon/(2A) + 2\lambda\varepsilon A/(1 - (2\varepsilon A)^2) \\ &\quad + 1/(8A^3 - 2A). \end{aligned}$$

Here is one choice order and strategy that works out neatly:

1. Choose A big
2. Choose λ between $1/(8A^3 - 2A)$ and $1/(8A)$
3. Choose ε small
4. Choose v within the resulting allowed range

For example, $A = 10$, $\lambda = 1/100$, $\varepsilon = 1/100$, and $v = 13/20$. In fact, perturbing λ and ε to $1/99$ makes it possible to hold the parameter “ k ” of section “A Suitable Invariant” to 1 and get by with 4-sorters at the very end, as previewed in section “The Structure of the Bagging Schedule”.

Concluding Remarks

Thus the AKS networks are remarkable sorting algorithms, one for each n , that sort their n inputs in just $\mathcal{O}(\log n)$ oblivious compare-exchange steps that involve no concurrent reading or writing.

The amazing kernel of this celebrated result is that the number of such steps for the problem of *approximate halving* (in provable contrast to the problem of *perfect halving*) does not have to grow with n at all. This is yet another (of many) reasons to marvel at the existence of constant-degree expander graphs. And it is another reason to consider approximate solutions to fundamental algorithms. (Could some sort of approximate *merging* algorithm similarly lead to a fast sorting algorithm based on *merge sort*?)

Algorithmically most interesting is the measured use of approximate halvers to clean up their own errors

in a design originally conceived for perfect halvers. The “one-step-backward, two-steps-forward” approach is a valuable one that should and indeed does show up in many other settings. This benefit holds regardless of whether the constant hidden in the big- \mathcal{O} for this particular result can ever be reduced to something practical.

Bibliographic Notes and Further Reading

Ajtai, Komlós, and Szemerédi submitted the first version of their design and argument directly to a journal [1]. Inspired by Joel Spencer’s ideas for a more accessible exposition, they soon published a quite different conference version [2]. The most influential version, on which most other expositions are based, was the one eventually published by Paterson [12]. The version presented here is based on a much more recent simplification [13], with fewer distinct parameters, but thus with less potential for fine-tuning more quantitative results.

The embedded expander graphs, and thus the constant hidden in the $\mathcal{O}(\log n)$ depth estimate, make these networks impractical to build or use. The competition for the constant is Batcher’s extra $\log_2 n$ factor [5], which is relatively quite small for any remotely practical value of n .

The shallowest approximate halvers can be produced by more direct arguments rather than via expander graphs. By a direct and careful counting argument, Paterson [12] (the theorem in his appendix, specialized to the case $\alpha = 1$) proves that the depth of an ε -halver need be no more than $\lceil(2\log \varepsilon)/\log(1 - \varepsilon) + 2/\varepsilon - 1\rceil$. Others [3, 11] have less precisely sketched or promised asymptotically better results.

Even better, one can focus on the construction of approximate separators. Paterson [12], for example, notes the usefulness in that construction (as presented above, for Lemma 2) of somewhat weaker (and thus shallower) halvers, which perform well only on extreme sets of sizes bounded in terms of an additional parameter $\alpha \leq 1$. Tailoring the parameters to the different levels

of approximate halvers in the construction, he manages to reduce the depth of separators enough to reduce the depth of the resulting sorting network to less than $6100 \log_2 n$.

Ajtai, Komlós, and Szemerédi [3] announce that design in terms of generalized, *multi-way* comparators (i.e., M -sorter units) can lead to drastically shallower approximate halvers and “near-sorters” (their original version [2] of separators). Chvátal [7] pursues this idea carefully and arrives at an improved final bound less than $1830 \log_2 n$, although still somewhat short of the $100 \log_2 n$ privately claimed by Komlós. To date, the tightest analyses have appeared only as sketches in preliminary conference presentations or mere promises of future presentation [3], or as unpublished technical reports [7].

Leighton [10] shows, as a corollary of the AKS result (regardless of the networks), that there is an n -node degree-3 network that can sort n items in $\mathcal{O}(\log n)$ steps.

Considering the VLSI model of parallel computation, Bilardi and Preparata [6] show how to lay out the AKS sorting networks to sort n $\mathcal{O}(\log n)$ -bit numbers in optimal area $\mathcal{O}(n^2)$ and time $\mathcal{O}(\log n)$.

Definition

Multigrid refers to a family of iterative algorithms for solving large sparse linear systems associated with a broad class of integral and partial differential equations [13, 22, 36]. The key to its success lies in the use of efficient coarse scale approximations to dramatically accelerate the convergence so that an accurate approximation is obtained in only a few iterations at a cost that is linearly proportional to the problem size. *Algebraic multigrid* methods construct these coarse scale approximations utilizing only information from the finest resolution matrix. Use of algebraic multigrid solvers has become quite common due to their optimal execution time and relative ease-of-use.

Discussion

Introduction

Multigrid algorithms are used to solve large sparse linear systems

$$Ax = b \quad (1)$$

where A is an $n \times n$ matrix, b is a vector of length n , and one seeks a vector x also of length n . When these

matrices arise from elliptic partial differential equations (PDEs), multigrid algorithms are often provably optimal in that they obtain a solution with $O(n/p + \log p)$ floating point operations where p is the number of processes employed in the calculation. Their rapid convergence rate is a key feature. Unlike most simpler iterative methods, the number of iterations required to reach a given tolerance does not degrade as the system becomes larger (e.g., when A corresponds to a PDE and the mesh used in discretization is refined).

Multigrid development started in the 1970s with the pioneering works of Brandt [6] and Hackbusch [21, 23], though the basic ideas first appeared in the 1960s [4, 18, 19]. The first methods would now be classified as geometric multigrid (GMG). Specifically, applications supply a mesh hierarchy, discrete operators corresponding to the PDE discretization on all meshes, interpolation operators to transfer solutions from a coarse resolution mesh to the next finer one, and restriction operators to transfer solutions from a fine resolution mesh to the next coarsest level. In geometric multigrid, the inter-grid transfers are typically based on a geometrical relationship of a coarse mesh and its refinement, such as using linear interpolation to take a solution on a coarse mesh and define one on the next finer mesh. While early work developed, proved, and demonstrated optimally efficient algorithms, it was the development of algebraic multigrid (AMG) that paved the way for non-multigrid experts to realize this optimal behavior across a broad range of applications including combustion calculations, computational fluid dynamics, electromagnetics, radiation transfer, semiconductor device modeling, structural analysis, and thermal calculations. While better understood for symmetric positive definite (SPD) systems, AMG methods have achieved notable success on other types of linear systems such as those involving strongly convective flows [11, 34] or drift diffusion equations.

The first algebraic multigrid scheme appeared in the mid-1980s and is often referred to as classical algebraic multigrid [7, 33]. This original technique is still one of the most popular, and many improvements have helped extend its applicability on both serial and parallel computers. Although classical algebraic multigrid is frequently referred to as just *algebraic multigrid*, the notation C-AMG is used here to avoid confusion with other algebraic multigrid methods. The list of alternative

AMG methods is quite extensive, but this entry only addresses one alternative referred to as smoothed aggregation [38, 39], denoted here as SA. Both C-AMG and SA account for the primary AMG use by most scientists. Some publicly available AMG codes include [12, 20, 25, 31, 32]. A number of commercial software products also contain algebraic multigrid solvers. Today, research continues on algebraic multigrid to further expand applicability and robustness.

Geometric Multigrid

Although multigrid has been successfully applied to a wide range of problems, its basic principles are easily understood by first studying the two-dimensional Poisson problem

$$-u_{xx} - u_{yy} = f \quad (2)$$

defined over the unit square with homogeneous Dirichlet conditions imposed on the boundary. Discretization leads to an SPD matrix problem

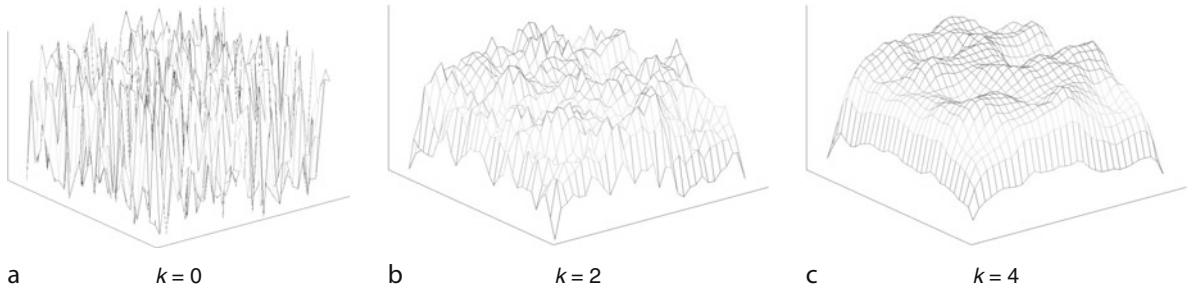

$$Ax = b. \quad (3)$$

The Gauss–Seidel relaxation method is one of the oldest iterative solution techniques for solving (3). It can be written as

$$\mathbf{x}^{(k+1)} \leftarrow (D + L)^{-1}(\mathbf{b} - U\mathbf{x}^{(k)}) \quad (4)$$

where $\mathbf{x}^{(k)}$ denotes the approximate solution at the k^{th} iteration, D is the diagonal of A , L is the strictly lower triangular portion of A , and U is the strictly upper triangular portion of A . While the iteration is easy to implement and economical to apply, a prohibitively large number of iterations (which increases as the underlying mesh is refined) are often required to achieve an accurate solution [40].

Figure 1 depicts errors ($\mathbf{e}^{(k)} = \mathbf{x}^{(*)} - \mathbf{x}^{(k)}$, where $\mathbf{x}^{(*)}$ is the exact solution) over the problem domain as a function of iteration number k for a typical situation on a 32×32 mesh. Notice that while the error remains quite large after four iterations, it has become locally much smoother. Denoting by $\mathbf{r}^{(k)} = \mathbf{b} - Ax^{(k)}$ the residual, the error is found by solving $A\mathbf{e}^{(k)} = \mathbf{r}^{(k)}$. Of course, solving this residual equation appears to be no easier than solving the original system. However, the basic multigrid idea is to recognize that smooth error is well represented

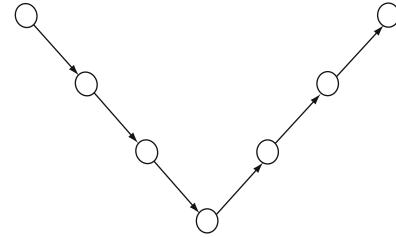

Algebraic Multigrid. Fig. 1 Errors as a function of k , the Gauss–Seidel iteration number

```

MGV( $A_\ell, \mathbf{x}_\ell, \mathbf{b}_\ell, \ell$ ):
  if  $\ell \neq \ell_{max}$ 
     $\mathbf{x}_\ell \leftarrow S_\ell^{pre}(A_\ell, \mathbf{x}_\ell, \mathbf{b}_\ell)$ 
     $\mathbf{r}_\ell \leftarrow \mathbf{b}_\ell - A_\ell \mathbf{x}_\ell$ 
     $\mathbf{x}_{\ell+1} \leftarrow 0$ 
     $\mathbf{x}_{\ell+1} \leftarrow MGV(A_{\ell+1}, \mathbf{x}_{\ell+1}, I_\ell^{\ell+1} \mathbf{r}_\ell, \ell+1)$ 
     $\mathbf{x}_\ell \leftarrow \mathbf{x}_\ell + I_{\ell+1}^\ell \mathbf{x}_{\ell+1}$ 
     $\mathbf{x}_\ell \leftarrow S_\ell^{post}(A_\ell, \mathbf{x}_\ell, \mathbf{b}_\ell)$ 
  else  $\mathbf{x}_\ell \leftarrow A_\ell^{-1} \mathbf{b}_\ell$ 

```

Algebraic Multigrid. Fig. 2 Multigrid V-cycle

on a mesh with coarser resolution. Thus, a coarse version can be formed and used to obtain an approximation with less expense by inverting a smaller problem. This approximation is then used to perform the update $\mathbf{x}^{(*)} \approx \mathbf{x}^{(k+1)} = \mathbf{x}^{(k)} + \mathbf{e}_c^{(k)}$ where $\mathbf{e}_c^{(k)}$ is defined by interpolating to the fine mesh the solution of the coarse resolution version of $A\mathbf{e}^{(k)} = \mathbf{r}^{(k)}$. This is referred to as *coarse-grid correction*. Since the coarse-level correction may introduce oscillatory components back into the error, it is optionally followed by application of a small number of simple relaxation steps (the post-relaxation). If the size of the coarse discretization matrix is small enough, Gaussian elimination can be applied to directly obtain a solution of the coarse level equations. If the size of the coarse system matrix remains large, the multigrid idea can be applied recursively.

Figure 2 illustrates what is referred to as multigrid V-cycle for solving the linear system $A_\ell \mathbf{x}_\ell = \mathbf{b}_\ell$. Subscripts are introduced to distinguish different resolution approximations. $A_1 = A$ is the operator on the finest level, where one seeks a solution while $A_{\ell_{max}}$ denotes the coarsest level system where Gaussian elimination

can be applied without incurring prohibitive cost. $I_\ell^{\ell+1}$ restricts residuals from level ℓ to level $\ell + 1$, and $I_{\ell+1}^\ell$ prolongates from level $\ell+1$ to level ℓ . $S_\ell^{pre}()$ and $S_\ell^{post}()$ denote a basic iterative scheme (e.g., Gauss–Seidel) that is applied to smooth the error. It will be referred to as *relaxation* in the remainder of the entry, although it is also commonly called *smoothing*. The right side of Fig. 2 depicts the algorithm flow for a four-level method. The lowest circle represents the direct solver. The circles to the left of this represent pre-relaxation while those to the right indicate post-relaxation. Finally, the downward arrows indicate restriction while the upward arrows correspond to interpolation or prolongation, followed by correction of the solution. Each relaxation in the hierarchy effectively damps errors that are oscillatory with respect to the mesh at that level. The net effect is that for a well-designed multigrid, errors at all frequencies are substantially reduced by one sweep of a V-cycle iteration.

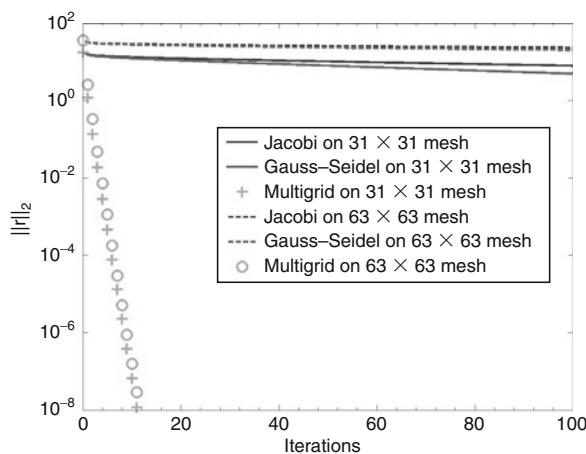

Different multigrid variations visit coarse meshes more frequently. The V-cycle (depicted here) and a W-cycle are the most common. The W-cycle is obtained

by adding a second $\mathbf{x}_{\ell+1} \leftarrow \text{MGV}()$ invocation immediately after the current one in Fig. 2. In terms of cost, grid transfers are relatively inexpensive compared to relaxation. The relaxation cost is typically proportional to the number of unknowns or ck^3 on a $k \times k \times k$ mesh where c is a constant. Ignoring the computational expense of grid transfers and assuming that coarse meshes are defined by halving the resolution in each coordinate direction, the V-cycle cost is

$$\begin{aligned} \text{V-cycle cost} &\approx c \left(k^3 + \frac{k^3}{8} + \frac{k^3}{64} + \frac{k^3}{512} + \dots \right) \\ &\approx \frac{8}{7} \text{ fine-level relaxation cost.} \end{aligned}$$

That is, the extra work associated with the coarse level computations is almost negligible.

In addition to being inexpensive, coarse-level computations dramatically accelerate convergence so that a solution is obtained in a few iterations. Figure 3 illustrates convergence histories for a Jacobi iteration, a Gauss-Seidel iteration, and a multigrid V-cycle iteration where $S_\ell^{pre}()$ and $S_\ell^{post}()$ correspond to one Gauss-Seidel sweep. These experiments use a standard finite difference discretization of (2) on four different meshes with a zero initial guess and a random right hand. Figure 3 clearly depicts the multigrid advantage. *The key to this rapid convergence lies in the complementary nature of relaxation and the coarse level corrections.* Relaxation eliminates high frequency errors while the coarse level correction eliminates low frequency errors

Algebraic Multigrid. Fig. 3 Residuals as a function of k , the Gauss-Seidel iteration number

on each level. Furthermore, errors that are relatively low frequency on a given level appear oscillatory on some coarser level, and will be efficiently eliminated by relaxation on that level.

For complex PDE operators, it can sometimes be challenging to define multigrid components in a way that preserves this complementary balance. Jacobi and Gauss-Seidel relaxations, for example, do not effectively smooth errors in directions of weak coupling when applied to highly anisotropic diffusion PDEs. This is easily seen by examining a damped Jacobi iteration

$$\mathbf{x}^{(k+1)} \leftarrow \mathbf{x}^{(k)} + \omega D^{-1}(\mathbf{b} - A\mathbf{x}^{(k)}) \quad (5)$$

where D is the diagonal matrix associated with A and ω is a scalar damping parameter typically between zero and one. The error propagation is governed by

$$e^{(k+1)} = (I - \omega D^{-1}A)e^{(k)} = (I - \omega D^{-1}A)^{k+1}e^{(0)} \quad (6)$$

where $e^{(k)} = \mathbf{x}^{(*)} - \mathbf{x}^k$. Clearly, error components in eigenvector directions associated with small eigenvalues of $D^{-1}A$ are almost unaffected by the Jacobi iteration. Gauss-Seidel exhibits similar behavior, though the analysis is more complex. When A corresponds to a standard Poisson operator, these eigenvectors are all low frequency modes, and thus effectively attenuated through the coarse-grid correction process. However, when applied to $u_{xx} + \epsilon u_{yy}$ (with $\epsilon \ll 1$), eigenvectors associated with low eigenvalues are smooth functions in the x direction, but may be oscillatory in the y direction. Within geometric multigrid schemes, where coarsening is dictated by geometrical considerations, these oscillatory error modes are not reduced, and multigrid convergence suffers when based on a simple point-wise relaxation, such as Jacobi. It may thus be necessary to employ more powerful relaxation (e.g., line relaxation) to make up for deficiencies in the choice of coarse grid representations.

Algebraic Multigrid

Algebraic multigrid differs from geometric multigrid in that $I_\ell^{\ell+1}$ and $I_{\ell+1}^\ell$ are not defined from geometric information. They are constructed using only A_ℓ and, optionally, a small amount of additional information (to be discussed). Once grid transfers on a given level are defined, a Galerkin projection is employed to obtain a coarse level discretization:

$$A_{\ell+1} \leftarrow I_\ell^{\ell+1} A_\ell I_{\ell+1}^\ell.$$

Further, $I_\ell^{\ell+1}$ is generally taken as the transpose of the prolongation operator for symmetric problems. In this case, an algebraic V-cycle iteration can be completely specified by a procedure for generating prolongation matrices along with a choice of appropriate relaxation method. In contrast to geometric multigrid, the relaxation process is typically selected upfront, but the prolongation is automatically tailored to the problem at hand. This is referred to as *operator-dependent prolongation*, and can overcome problems such as anisotropies of which geometric multigrid coarsening may not be aware.

Recalling the Jacobi error propagation formula (6), components associated with large eigenvalues of A are easily damped by relaxation while those associated with small eigenvalues remain. (Without loss of generality, one can assume that A has been scaled so that its diagonal is identically one. Thus, A as opposed to $D^{-1}A$ is used to simplify the discussion.) In geometric multigrid, the focus is on finding a relaxation scheme such that all large eigenvalues of its error propagation operator correspond to low frequency eigenvectors. In algebraic multigrid, one assumes that a simple (e.g., Gauss-Seidel) relaxation is employed where the error propagation satisfies

$$\begin{aligned}\|S_\ell e\|_{A_\ell}^2 &\leq \|e\|_{A_\ell}^2 - \alpha \|e\|_{A_\ell}^2 \\ &= \|e\|_{A_\ell}^2 - \alpha \|r\|^2\end{aligned}\quad (7)$$

where α is a positive constant independent of the mesh size. Equation (7) indicates that errors associated with a large A_ℓ -norm are reduced significantly while those associated with small residuals are relatively unchanged by relaxation. The focus is now on constructing $I_\ell^{\ell+1}$ and $I_{\ell+1}^\ell$ such that eigenvectors associated with small eigenvalues of A_ℓ are transferred between grid levels accurately. That is, error modes that are not damped by relaxation on a given level must be transferred to another level so that they can be reduced there. Note that these components need not be smooth in the geometric sense, and are therefore termed *algebraically smooth*.

More formally, the general principle for grid transfers applied to symmetric problems is that they satisfy an approximation property, for example,

$$\|e - I_{\ell+1}^\ell \hat{e}\|^2 \leq \frac{\beta}{\|A_\ell\|} \|e\|_{A_\ell}^2 \quad (8)$$

where \hat{e} is a coarse vector minimizing the left side and β is a constant independent of mesh size and e . Basically, (8) requires that vectors with smaller A_ℓ -norm be more accurately captured on coarse meshes. That is, high and low energy, measured by the A_ℓ -norm, replaces the geometric notions of high and low frequency.

It is possible to show that a two-level method that employs a coarse grid correction satisfying (8) followed by a relaxation method S_ℓ satisfying (7) is itself convergent, *independent of problem size*. The error propagation operator associated with the coarse-grid correction is given by

$$T_\ell = I - I_{\ell+1}^\ell (I_\ell^{\ell+1} A_\ell I_{\ell+1}^\ell)^{-1} I_\ell^{\ell+1} A_\ell. \quad (9)$$

Note that (9) moves fine error to the coarse level, performs an exact solve, interpolates the result back to the fine level, and differences it with the original fine error. Assuming that the grid transfer $I_{\ell+1}^\ell$ is full-rank, the following estimate for a two-level multigrid method can be proved using (8) and (7):

$$\|S_\ell T_\ell\|_{A_\ell} \leq \sqrt{1 - \frac{\alpha}{\beta}}, \quad (10)$$

where post-relaxation only is assumed to simplify the discussion. That is, a coarse-grid correction followed by relaxation converges at a rate independent of the mesh size. Given the general nature of problems treated with algebraic multigrid, however, sharp multilevel convergence results (as opposed to two-level results) are difficult to obtain. The best known multilevel AMG convergence bounds are of the form, $1 - \frac{1}{C(L)}$, where the constant $C(L)$ depends polynomially on the number of multigrid levels [38].

In addition to satisfying some approximation property, grid transfers must be practical. The sparsity patterns of $I_{\ell+1}^\ell$ and $I_\ell^{\ell+1}$ effectively determine the number of nonzeros in $A_{\ell+1}$. If prohibitively large, the method is impractically expensive. Most AMG methods construct grid transfers in several stages. The first stage defines a graph associated with A_ℓ . The second stage coarsens this graph. Coarsening fixes the dimensions of $I_{\ell+1}^\ell$ and $I_\ell^{\ell+1}$. Coarsening may also effectively determine the sparsity pattern of the grid transfer matrices or, within some AMG methods, the sparsity pattern may be constructed separately. Finally, the actual grid transfer

coefficients are determined so that the approximation property is satisfied and that relaxation on the coarse grid is effective.

One measure of expense is the *operator complexity*, $\sum_i(nnz(A_i)/nnz(A_1)$, which compares number of nonzeros on all levels to the number of nonzeros in the finest grid matrix. The operator complexity gives an indication both of the amount of memory required to store the AMG preconditioner and the cost to apply it. Another measure of complexity is the matrix stencil size, which is the average number of coefficients in a row of A_ℓ . Increases in matrix stencil size can lead to increases in communication and matrix evaluation costs. In general, AMG methods must carefully balance accuracy with both types of complexity. Increasing the complexity of an AMG method often leads to better convergence properties, at the cost of each iteration being more expensive. Conversely, decreasing the complexity of a method tends to lead to a method that converges more slowly, but is cheaper to apply.

Within C-AMG, a matrix graph is defined with the help of a strength-of-connection measure. In particular, each vector unknown corresponds to a vertex. A graph edge between vertex i and j is only added if i is strongly influenced by j or if $-a_{ij} \geq \epsilon \max_{i \neq k} (-a_{ik})$, where $\epsilon > 0$ is independent of i and j . The basic idea is to ignore weak connections when defining the matrix graph in order to coarsen only in directions of strong connections (e.g., to avoid difficulties with anisotropic applications). The structure of $I_{\ell+1}^\ell$ is determined by selecting a subset of vertices, called *C-points*, from the fine graph. The *C-points* constitute the coarse graph vertices; the remaining unknowns are called *F-points* and will interpolate from the values at *C-points*. If *C-points* are too close to each other, the resulting complexities are high. If they are too far apart, convergence rates tend to suffer. To avoid these two situations, the selection process attempts to satisfy two conditions. The first is that if point j strongly influences an *F-point* i , then j should either be a *C-point* or j and i should be strongly influenced by a common *C-point*. The second is that the set of *C-points* should form a maximal independent set such that no two *C-points* are strongly influenced by each other. For isotropic problems, the aforementioned C-AMG algorithm tends to select every other unknown as a *C-point*. This yields a *coarsening rate* of roughly 2^d , where d is the spatial problem dimension. With the

C-points identified, the interpolation coefficients are calculated. *C-points* themselves are simply interpolated via injection. The strong influence of an *F-point* j on a different *F-point* i is given by the weighted interpolation from the *C-points* common to i and j . The latter is done in such a manner so as to preserve interpolation of constants. Additionally, it is based on the assumption that residuals are small after relaxation. That is, $A_\ell \mathbf{e} \approx 0$, or, equivalently, modes associated with small eigenvalues should be accurately interpolated. Further details can be found in [36].

SA also coarsens based on the graph associated with matrix A_ℓ . In contrast to C-AMG, however, the coarse grid unknowns are formed from disjoint groups, or *aggregates*, of fine grid unknowns. Aggregates are formed around initially-selected unknowns called root points. An unknown i is included in an aggregate if it is strongly coupled to the root point j . More precisely, unknowns i and j are said to be strongly coupled if $|a_{ij}| > \theta \sqrt{|a_{ii}||a_{jj}|}$, where $\theta \geq 0$ is a tuning parameter independent of i and j . Because the aggregates produced by SA tend to have a graph diameter 3, SA generally coarsens at a rate of 3^d , where d is the geometric problem dimension. After aggregate identification, a tentative prolongator is constructed so that it exactly interpolates a set of user-defined vectors. For scalar PDEs this is often just a single vector corresponding to the constant function. For more complex operators, however, it may be necessary to provide several user-defined vectors. In three-dimensional elasticity, it is customary to provide six vectors that represent the six rigid body modes (three translations and three rotations). In general, these vectors should be near-kernel vectors that are generally problematic for the relaxation. The tentative prolongator is defined by restricting the user-defined vectors to each aggregate. That is, each column of the tentative prolongator is nonzero only for degrees of freedom within a single aggregate, and the values of these nonzeros correspond to one of the user-defined vectors. The columns are locally orthogonalized within an aggregate by a QR algorithm to improve linear independence. The final result is that the user-defined modes are within the range space of the tentative prolongator, the prolongator columns are orthonormal, and the tentative prolongator is quite sparse because each column's nonzeros are associated with a single aggregate. Unfortunately, individual tentative prolongator columns have a high energy

(or large A -norm). This essentially implies that some algebraically smooth modes are not accurately represented throughout the mesh hierarchy even though the user-defined modes are accurately represented. To rectify this, one step of damped Jacobi is applied to all columns of the tentative prolongator:

$$I_{\ell+1}^\ell = (I - \omega D_\ell^{-1} A_\ell) I_\ell^\ell$$

where ω is the Jacobi damping parameter and D_ℓ is the diagonal of A_ℓ . This reduces the energy in each of the columns while preserving the interpolation of user-defined low energy modes. Further details can be found in [38, 39].

Parallel Algebraic Multigrid

Distributed memory parallelization of most simulations based on PDEs is accomplished by dividing the computational domain into subdomains, where one subdomain is assigned to each processor. A processor is then responsible for updating unknowns associated within its subdomain only. To do this, processors occasionally need information from other processors; that information is obtained via communication. Partitioning into boxes or cubes is straightforward for logically rectangular meshes. There are several tools that automate the subdivision of domains for unstructured meshes [5, 26, 27]. A general goal during subdivision is to assign an equal amount of work to each processor and to reduce the amount of communication between processors by minimizing the surface area of the subdomains.

Multigrid parallelization follows in a similar fashion. For example, V-cycle computations within a mesh are performed in parallel, but each mesh in the hierarchy is addressed one at a time as in standard multigrid. A multigrid cycle (see Fig. 2) consists almost entirely of relaxation and sparse matrix–vector products. This means that the parallel performance depends entirely on these two basic kernels. Parallel matrix–vector products are quite straightforward, as are parallel Jacobi and parallel Chebyshev relaxation (which are often preferred in this setting [3]). Chebyshev relaxation requires an estimate of the largest eigenvalue of A_ℓ (which is often available or easily estimated) but not that of the smallest eigenvalue, as relaxation need only damp the high end of the spectrum. Unfortunately, construction of efficient parallel Gauss–Seidel algorithms

is challenging and relies on sophisticated multicoloring schemes on unstructured meshes [2]. As an alternative, most large parallel AMG packages support an option to employ Processor Block (or local) Gauss–Seidel. Here, each processor performs Gauss–Seidel as a subdomain solver for a block Jacobi method. While Processor Block Gauss–Seidel is easy to parallelize, the overall multigrid convergence rate usually suffers and can even lead to divergence if not suitably damped [41].

Given a multigrid hierarchy, the main unique aspect associated with parallelization boils down to partitioning all the operators in the hierarchy. As these operators are associated with matrix graphs, it is actually the graphs that must be partitioned. The partitioning of the finest level graph is typically provided by an outside application and so it ignores the coarse graphs that are created during multigrid construction. While coarse graph partitioning can also be done in this fashion, it is desirable that the coarse and fine graph partitions “match” in some way so that inter-processor communication during grid transfers is minimized. This is usually done by deriving coarse graph partitions from the fine graph partition. For example, when the coarse graph vertices are a subset of fine vertices, it is natural to simply use the fine graph partitioning on the coarse graph. If the coarse graph is derived by agglomerating elements and the fine graph is partitioned by elements, the same idea holds. In cases without a simple correspondence between coarse and fine graphs, it is often natural to enforce a similar condition that coarse vertices reside on the same processors that contain most of the fine vertices that they interpolate [30]. Imbalance can result if the original matrix A_1 itself is poorly load-balanced, or if the coarsening rate differs significantly among processes, leading to imbalance on coarse levels. Synchronization occurs within each level of the multigrid cycle, so the time to process a level is determined by the slowest process. Even when work is well balanced, processors may have only a few points as the total number of graph vertices can diminish rapidly from one level to a coarser level. In fact, it is quite possible that the total number of graph vertices on a given level is actually less than the number of cores/processors on a massively parallel machine. In this case some processors are forced to remain idle while more generally if processes have only a few points, computation time can be dominated by communication. A partial solution

is to redistribute and load-balance points on a subset of processes. While this certainly leaves processes idle during coarse level relaxation, this can speed up run times because communication occurs among fewer processes and expensive global all-to-all communication patterns are avoided. A number of alternative multigrid algorithms that attempt to process coarse level corrections in parallel (as opposed to the standard sequential approach) have been considered [15]. Most of these, however, suffer drawbacks associated with convergence rates or even more complex load balancing issues.

The parallel cost of a simple V-cycle can be estimated to help understand the general behavior. In particular, assume that run time on a single level is modeled by

$$T_{sl} = c_0 \left(\frac{k}{q} \right)^3 + c_1 \left(\alpha + \beta \left(\frac{k}{q} \right)^2 \right)$$

where k^3 is the number of degrees of freedom on the level, q^3 is the number of processors, and $\alpha + \beta w$ measures the cost of sending a message of length w from one processor to another on a distributed memory machine. The constants c_0 and c_1 reflect the ratio of computation to communication inherent in the smoothing and matrix-vector products. Then, if the coarsening rate per dimension in 3D is γ , it is easy to show that the run time of a single AMG V-cycle with several levels, ℓ , is approximately

$$T_{amg} = c_0 \left(\frac{k}{q} \right)^3 \left(\frac{\gamma^3}{\gamma^3 - 1} \right) + c_1 \beta \left(\frac{k}{q} \right)^2 \left(\frac{\gamma^2}{\gamma^2 - 1} \right) + c_1 \alpha \ell$$

where now k^3 is the number of degrees of freedom on the finest mesh. For $\gamma = 2$, a standard multigrid coarsening rate, this becomes

$$T_{amg} = \frac{8}{7} c_0 \left(\frac{k}{q} \right)^3 + \frac{4}{3} c_1 \beta \left(\frac{k}{q} \right)^2 + c_1 \alpha \ell.$$

Comparing this with the single level execution time, we see that the first term is pure computation and it increases by 1.14 to account for the hierarchy of levels. The second term reflects communication bandwidth and it increases by 1.33. The third term is communication latency and it increases by ℓ . Thus, it is to be expected that parallel multigrid spends a higher percentage of time communicating than a single level method. However, if $(k/q)^3$ (the number of degrees of freedom per processor) is relatively large, then the first term dominates and so inefficiencies associated

with the remaining terms are not significant. However, when this first term is not so dominant, then inefficiencies associated with coarse level computations are a concern. Despite a possible loss of efficiency, the convergence benefits of multigrid far outweigh these concerns and so, generally, multilevel methods remain far superior to single level methods, even on massively parallel systems.

The other significant issue associated with parallel algebraic multigrid is parallelizing the construction phase of the algorithm. In principle this construction phase is highly parallel due to the locality associated with most algorithms for generating grid transfers and setting up smoothers. The primary challenge typically centers on the coarsening aspect of algebraic multigrid. For example, the smoothed aggregation algorithm requires construction of aggregates, then a tentative prolongator, followed by a prolongator smoothing step. Prolongator smoothing as well as Galerkin projection (to build coarse level discretizations) require only an efficient parallel matrix–matrix multiplication algorithm. Further, construction of the tentative prolongator only requires that the near-null space be injected in a way consistent with the aggregates followed by a series of independent small QR computations. It is, however, the aggregation phase that can be difficult. While highly parallel in principle, it is difficult to get the same quality of aggregates without having some inefficiencies. Aggregation is somewhat akin to placing floor tiles in a room. If several workers start at different locations and lay tile simultaneously, the end result will likely lead to the trimming of many interior tiles so that things fit. Unfortunately, a large degree of irregularity in aggregates can either degrade the convergence properties of the overall method or significantly increase the cost per iteration. Further, once each process (or worker in our analogy) has only a few rows of the relatively coarse operator A_ℓ , the rate of coarsening slows, thus leading to more multigrid levels. Instead of naively allowing each process to coarsen its portion of the graph independently, several different aggregation-based strategies have been proposed in the context of SA, based on parallel maximal independent sets [1, 37] or using graph-partitioning algorithms [20]. The latter can increase the coarsening rate and decrease the operator complexity. In both cases, an aggregate can span several processors. Parallel variants of C-AMG coarsening

have also been developed to minimize these effects. The ideas are quite similar to the smoothed aggregation context, but the details tend to be distinct due to differences in coarsening rates and the fact that one is based on aggregation while the other centers on identifying vertex subsets. Subdomain blocking [28] coarsens from the process boundary inward, and CLJP coarsening [16, 25] is based on selecting parallel maximal independent sets. A more recently developed aggressive coarsening variant, PMIS [35], addresses the high complexities sometimes seen with CLJP.

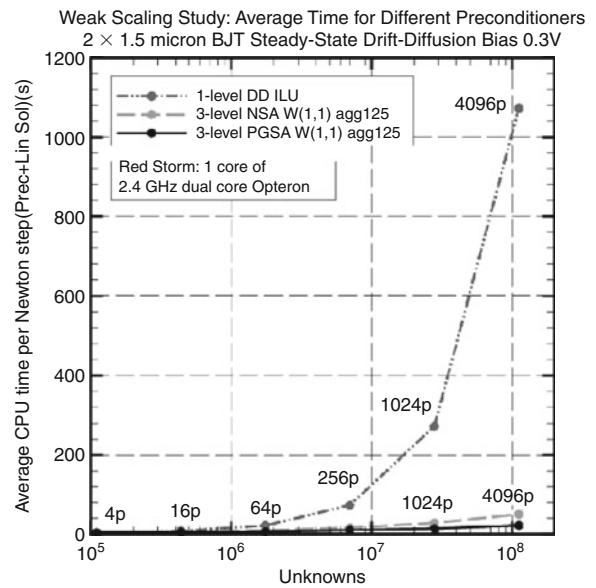

We conclude this section with some performance figures associated with the ML multigrid package that is part of the Trilinos framework. ML implements parallel smoothed aggregation along the lines just discussed. [Figure 4](#) illustrates weak parallel scaling on a semiconductor simulation. Each processor has approximately 27,000 degrees of freedom so that the problem size increases as more processors are used. In an ideal situation, one would like that the total simulation time remains constant as the problem size and processor count increase. Examination of [Fig. 4](#) shows that execution times rise only slightly due to relatively constant run time per iteration.

The emergence of very large scale multi-core architectures presents increased stresses on the underlying multigrid parallelization algorithms and so research must continue to properly take advantage of these new architectures.

Related Multigrid Approaches

When solving difficult problems, it is often advantageous to “wrap” the multigrid solver with a Krylov method. This amounts to using a small number of AMG iterations as a preconditioner in a Krylov method. The additional cost per iteration amounts to an additional residual computation and a small number of inner products, depending on Krylov method used. Multigrid methods exhibiting a low-dimensional deficiency can have good convergence rates restored this way.

Standard implementations of C-AMG and SA base their coarsening on assumptions of smoothness. For C-AMG, this is that an algebraically smooth error behaves locally as a constant. When this is not the case, convergence will suffer. One advantage of SA is that it is possible to construct methods capable of approximating *any* prescribed user-defined error component accurately on coarse meshes. Thus, in principle, if one knows

Algebraic Multigrid. Fig. 4 Weak scaling timings for a semiconductor parallel simulation. The *left image* is the steady-state electric potential; *red* represents high potential, *blue* indicates low potential. The scaling results compare GMRES preconditioned by domain-decomposition, a nonideal AMG method, and an AMG method intended for nonsymmetric problems, respectively. Results courtesy of [29]

difficult components for relaxation, suitable grid transfers can be defined that accurately transfer these modes to coarse levels. However, there are applications where such knowledge is lacking. For instance, QCD problems may have multiple difficult components that are not only oscillatory, but are not *a priori* known. *Adaptive multigrid* methods have been designed to address such problems [9, 10]. The key feature is that they determine the critical components and modify coarsening to ensure their attenuation. These methods can be intricate, but are based on the simple observation that an iteration process applied to the homogeneous problem, $A_\ell \mathbf{x}_\ell = \mathbf{0}$, will either converge with satisfactory rate, or reveal, as its solution, the error that the current method does not attenuate. As the method improves, any further components are revealed more rapidly. The adaptive methods are currently more extensively developed within the SA framework, but progress has also been made within the context of C-AMG, [10].

Another class of methods that attempt to take advantage of additional available information are known as AMGe [8, 14]. These utilize local finite element information, such as local stiffness matrices, to construct inter-grid transfers. Although this departs from the AMG framework, variants related to the methodology have been designed that do not explicitly require local element matrices [17, 24].

AMG methods have been successfully applied directly to high-order finite element discretizations. However, given the much denser nature of a matrix, A^H , obtained from high-order discretization, it is usually advantageous to precondition the high-order system by an inverse of the low-order discretization, A^L , corresponding to the problem over the same nodes that are used to define the high-order Lagrange interpolation. One iteration of AMG can then be used to efficiently approximate the action of $(A^L)^{-1}$, and the use of A^H is limited to computing a fine-level residual, which may be computed in a matrix-free fashion.

[Experimental parallel algorithmics](#)

Definition

Algorithmics is the subdiscipline of computer science that studies the systematic development of efficient algorithms. Algorithm Engineering (AE) is a methodology for algorithmic research that views design, analysis, implementation, and experimental evaluation of algorithms as a cycle driving algorithmic research. Further components are realistic models, algorithm libraries, and a multitude of interrelations to applications. Fig. 1 gives an overview. A more detailed definition can be found in [6]. This article is concerned with particular issues that arise in engineering parallel algorithms.

Discussion

Introduction

The development of algorithms is one of the core areas of computer science. After the early days of the 1940s–1960s, in the 1970s and 1980s, algorithmics was largely viewed as a subdiscipline of computer science that is concerned with “paper-and-pencil” theoretical work – design of algorithms with the goal to prove worst-case performance guarantees. However, in the 1990s it became more and more apparent that this purely theoretical approach delays the transfer of algorithmic results into applications. Therefore, in *algorithm engineering* implementation and experimentation are viewed as equally important as design and analysis of algorithms. Together these four components form a feedback cycle: Algorithms are designed, then analyzed and implemented. Together with experiments using *realistic inputs*, this process induces new insights that lead to modified and new algorithms. The methodology of algorithm engineering is augmented by using *realistic models* that form the basis of algorithm descriptions, analysis, and implementation and by *algorithm libraries* that give high quality reusable implementations.

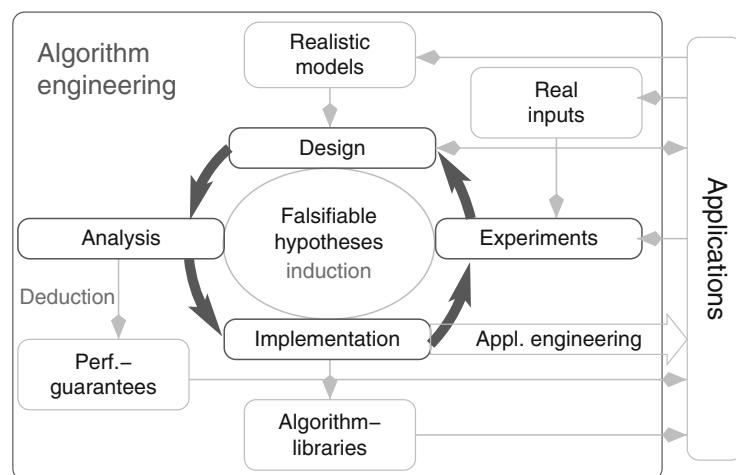

The history of parallel algorithms is exemplary for the above development, where many clever algorithms were developed in the 1980s that were based on the Parallel Random Access Machine (PRAM) model of computation. While this yielded interesting insights into the

basic aspects of parallelizable problems, it has proved quite difficult to implement PRAM algorithms on mainstream parallel computers.

The remainder of this article closely follows Fig. 1, giving one section for each of the main areas’ models, design, analysis, implementation, experiments, instances/benchmarks, and algorithm libraries.

Models

Parallel computers are complex systems containing processors, memory modules, and networks connecting them. It would be very complicated to take all these aspects into account at all times when designing, analyzing, and implementing parallel algorithms. Therefore we need simplified models. Two families of such models have proved very useful: In a *shared memory* machine, all processors access the same global memory. In a *distributed memory* machine, several sequential computers communicate via an interconnection network. While these are useful abstractions, the difficulty is to make these models more concrete by specifying what operations are supported and how long they take. For example, shared memory models have to specify how long it takes to access a memory location. From sequential models we are accustomed to constant access time and this also reflects the best case behavior of many parallel machines. However, in the worst case, most real world machines will exhibit severe contention

Algorithm Engineering. Fig. 1 Algorithm engineering as a cycle of design, analysis, implementation, and experimental evaluation driven by falsifiable hypotheses

when many processors access the same memory module. Hence, despite many useful models (e.g., QRQW PRAM – Queue Read Queue Write Parallel Random Access Machine [3]), there remains a considerable gap to reality when it comes to large-scale shared memory systems.

The situation is better for distributed memory machines, in particular, when the sequential machines are connected by a powerful switch. We can then assume that all processors can communicate with an arbitrary partner with predictable performance. The LogP model [2] and the Bulk Synchronous Parallel model [10] put this into a simple mathematical form. Equally useful are folklore models where one simply defines the time needed for exchanging a message as the sum of a startup overhead and a term proportional to the message length. Then the assumption is usually that every processor can only communicate with a single other processor at a time, or perhaps it can receive from one processor and send to another one. Also note that algorithms *designed* for a distributed memory model often yield efficient *implementations* on shared memory machines.

Design

As in algorithm theory, we are interested in efficient algorithms. However, in algorithm engineering, it is equally important to look for simplicity, implementability, and possibilities for code reuse. In particular, since it can be very difficult to debug parallel code, the algorithms should be designed for simplicity and testability. Furthermore, efficiency means not just asymptotic worst-case efficiency, but we also have to look at the constant factors involved. For example, we have to be aware that operations where several processors interact can be a large constant factor more expensive than local computations. Furthermore, we are not only interested in worst-case performance but also in the performance for real-world inputs. In particular, some theoretically efficient algorithms have similar best-case and worst-case behavior whereas the algorithms used in practice perform much better on all but contrived examples.

Analysis

Even simple and proven practical algorithms are often difficult to analyze and this is one of the main reasons

for gaps between theory and practice. Thus, the analysis of such algorithms is an important aspect of AE.

For example, a central problem in parallel processing is partitioning of large graphs into approximately equal-sized blocks such that few edges are cut. This problem has many applications, for example, in scientific computing. Currently available algorithms with performance guarantees are too slow for practical use. Practical methods iteratively contract the graph while preserving its basic structure until only few nodes are left, compute an initial solution on this coarse representation, and then improve by local search on each level. These algorithms are very fast and yield good solutions in many situations, yet no performance guarantees are known (see [11] for a recent overview).

Implementation

Despite huge efforts in parallel programming languages and in parallelizing compilers, implementing parallel algorithms is still one of the main challenges in the algorithm engineering cycle. There are several reasons for this. First, there are huge semantic gaps between the abstract algorithm description, the programming tools used, and the actual hardware. In particular, really efficient codes often use fairly low-level programming interfaces such as MPI or atomic memory operations in order to keep the overheads for processor interaction manageable. Perhaps more importantly, *debugging* parallel programs is notoriously difficult.

Since performance is the main reason for using parallel computers in the first place, and because of the complexity of parallel hardware, performance tuning is an important part of the implementation phase. Although the line between implementation and experimentation is blurred here, there are differences. In particular, performance tuning is less systematic. For example, there is no need for reproducibility, detailed studies of variances, etc., when one finds out that sequential file I/O is a prohibitive bottleneck or when it turns out that a collective communication routine of a particular MPI implementation has a performance bug.

Experiments

Meaningful experiments are the key to closing the cycle of the AE process. Compared to the natural sciences, AE is in the privileged situation where it can perform many experiments with relatively little effort.

However, the other side of the coin is highly nontrivial planning, evaluation, archiving, postprocessing, and interpretation of results. The starting point should always be falsifiable hypotheses on the behavior of the investigated algorithms, which stem from the design, analysis, implementation, or from previous experiments. The result is a confirmation, falsification, or refinement of the hypothesis. The results complement the analytic performance guarantees, lead to a better understanding of the algorithms, and provide ideas for improved algorithms, more accurate analysis, or more efficient implementation.

Experiments with parallel algorithms are challenging because the number of processors (let alone other architectural parameters) provide another degree of freedom for the measurements, because even parallel programs without randomization may show nondeterministic behavior on real machines, and because large parallel machines are an expensive resource.

Experiments on comparing the quality of the computed results are not so much different from the sequential case. In the following, we therefore concentrate on performance measurements.

Measuring Running Time

The *CPU time* is a good way to characterize the time used by a sequential process (without I/Os), even in the presence of some operating system interferences. In contrast, in parallel programs we have to measure the actual elapsed time (*wall-clock time*) in order to capture all aspects of the parallel program, in particular, communication and synchronization overheads. Of course, the experiments must be performed on an otherwise unloaded machine, by using dedicated job scheduling and by turning off unnecessary components of the operating system on the processing nodes. Usually, further aspects of the program, like startup, initialization, and shutdown, are not interesting for the measurement. Thus timing is usually done as follows: All processors perform a barrier synchronization immediately before the piece of program to be timed; one processor x notes down its local time and all processors execute the program to be measured. After another barrier synchronization, processor x measures the elapsed time. As long as the running time is large compared to the time for a barrier synchronization, this is an easy way to measure wall-clock time. To get reliable results,

averaging over many repeated runs is advisable. Nevertheless, the measurements may remain unreliable since rare delays, for example, due to work done by the operating system, can become quite frequent when they can independently happen on any processor.

Speedup and Efficiency

In parallel computing, running time depends on the number of processors used and it is sometimes difficult to see whether a particular execution time is good or bad considering the amount of resources used. Therefore, derived measures are often used that express this more directly. The *speedup* is the ratio of the running time of the fastest known sequential implementation to that of the parallel running time. The speedup directly expresses the impact of parallelization. The *relative speedup* is easier to measure because it compares with the parallel algorithm running on a single processor. However, note that the relative speedup can significantly overstate the actual usefulness of the parallel algorithm, since the sequential algorithm may be much faster than the parallel algorithm run on a single processor.

For a fixed input and a good parallel algorithm, the speedup will usually start slightly below one for a single processor, and initially goes up linearly with the number of processors. Eventually, the speedup curve gets more and more flat until parallelization overheads become so large that the speedup goes down again. Clearly, it makes no sense to add processors beyond the maximum of the speedup curve. Usually it is better to stop much earlier in order to keep the parallelization cost-effective. *Efficiency*, the ratio of the speedup to the number of processors, more directly expresses this. Efficiency usually starts somewhere below one and then slowly decreases with the number of processors. One can use a threshold for the minimum required efficiency to decide on the maximum number of efficiently usable processors.

Often, parallel algorithms are not really used to decrease execution time but to increase the size of the instances that can be handled in reasonable time. From the point of view of speedup and efficiency, this is good news because for a scalable parallel algorithm, by sufficiently increasing the input size, one can efficiently use any number of processors. One can check this experimentally by scaling the input size together with the number of processors. An interesting property of an

algorithm is *how much* one has to increase the input size with the number of processors. The *isoefficiency function* [4] expresses this relation analytically, giving the input size needed to achieve some given, constant efficiency. As usual in algorithmics, one uses asymptotic notation to get rid of constant factors and lower order terms.

Speedup Anomalies

Occasionally, efficiency exceeding one (also called *superlinear speedup*) causes confusion. By Brent's principle (a single processor can simulate a p -processor algorithm with a uniform slowdown factor of p) this should be impossible. However, genuine superlinear absolute speedup can be observed if the program relies on resources of the parallel machine not available to a simulating sequential machine, for example, main memory or cache.

A second reason is that the computations done by an algorithm can be done in many different ways, some leading to a solution fast, some more slowly. Hence, the parallel program can be “lucky” to find a solution more than p times earlier than the sequential program. Interestingly, such effects do *not* always disappear when averaging over all inputs. For example, Schöning [7] gives a randomized algorithm for finding satisfying assignments to formulas in propositional calculus that are in conjunctive normal form. This algorithm becomes exponentially faster when run in parallel on many (possibly simulated) processors. Moreover, its worst-case performance is better than any sequential algorithm. Brent's principle is not violated since the best sequential algorithm turns out to be the emulation of the parallel algorithm.

Finally, there are many cases where superlinear speedup is not genuine, mostly because the sequential algorithm used for comparison is not really the best one for the inputs considered.

Instances and Benchmarks

Benchmarks have a long tradition in parallel computing. Although their most visible use is for comparing different machines, they are also helpful within the AE cycle. During implementation, benchmarks of basic operations help to select the right approach. For example, SKaMPI [5] measures the performance of most MPI

calls and thus helps to decide which of several possible calls to use, or whether a manual implementation could help.

Benchmark suites of input instances for an important computational problem can be key to consistent progress on this problem. Compared to the alternative that each working group uses its own inputs, this has obvious advantages: there can be wider range of inputs, results are easier to compare, and bias in instance selection is less likely. For example, Chris Walshaw's graph partitioning archive [9] has become an important reference point for graph partitioning.

Synthetic instances, though less realistic than real-world inputs can also be useful since they can be generated in any size and sometimes are good as stress tests for the algorithms (though it is often the other way round – naively constructed random instances are likely to be unrealistically easy to handle). For example, for the graph partitioning problem, one can generate graphs that almost look like random graphs but have a pre-designed structure that can be more or less easy to detect according to tunable parameters.

Algorithm Libraries

Algorithm libraries are made by assembling implementations of a number of algorithms using the methods of software engineering. The result should be efficient, easy to use, well documented, and portable. Algorithm libraries accelerate the transfer of know-how into applications. Within algorithmics, libraries simplify comparisons of algorithms and the construction of software that builds on them. The software engineering involved is particularly challenging, since the applications to be supported are *unknown* at library implementation time and because the separation of interface and (often highly complicated) implementation is very important. Compared to an application-specific reimplementation, using a library should save development time without leading to inferior performance. Compared to simple, easy to implement algorithms, libraries should improve performance. To summarize, the triangle between generality, efficiency, and ease of use leads to challenging trade-offs because often optimizing one of these aspects will deteriorate the others. It is also worth mentioning that *correctness* of algorithm libraries is even more important than for other softwares because it is extremely difficult for a user to debug a library code

that has not been written by his team. All these difficulties imply that implementing algorithms for use in a library is several times more difficult than implementations for experimental evaluation. On the other hand, a good library implementation might be *used* orders of magnitude more frequently. Thus, in AE there is a natural mechanism leading to many exploratory implementations and a few selected library codes that build on previous experimental experience.

In parallel computing, there is a fuzzy boundary between software libraries whose main purpose is to shield the programmer from details of the hardware and genuine algorithm libraries. For example, the basic functionality of MPI (message passing) is of the first kind, whereas its collective communication routines have a distinctively algorithmic flavor. The Intel Thread Building Blocks (<http://www.threadingbuildingblocks.org>) offers several algorithmic tools including a load balancer hidden behind a task concept and distributed data structures such as hash tables. The standard libraries of programming languages can also be parallelized. For example, there is a parallel version of the C++ STL in the GNU distribution [8].

The Computational Geometry Algorithms Library (CGAL, <http://www.cgal.org>) is a very sophisticated example of an algorithms library that is now also getting partially parallelized [1].

Conclusion

This article explains how algorithm engineering (AE) provides a methodology for research in parallel algorithmics that allows to bridge gaps between theory and practice. AE does not abolish theoretical analysis but contains it as an important component that, when applicable, provides particularly strong performance and robustness guarantees. However, adding careful implementation, well-designed experiments, realistic inputs, algorithm libraries, and a process coupling all of this together provides a better way to arrive at algorithms useful for real-world applications.

Definition

Among a group of processing elements (nodes) each node has a data item that is to be transferred to *all* other nodes, such that all nodes in the group end up having all of the data items. The allgather operation accomplishes this total data exchange.

Discussion

The reader may consider first visiting the entry on *collective communication*.

It is assumed that the p nodes in the group of nodes participating in the allgather operation are indexed consecutively, each having an index i with $0 \leq i < p$. It is furthermore assumed that the data items are to be collected in some fixed order determined by the node indices; each node may apply a different order. Assume that each node i initially has a vector of data x_i of some number of elements n_i with $n = \sum_{i=0}^{p-1} n_i$ being the total number of subvector elements. Upon completion of the allgather operation each node i will have the full vector x consisting of the subvectors x_i , $i = 0, \dots, p - 1$. This is shown in Fig. 1.

All nodes in the group are assumed to explicitly take part in the allgather communication operation. If all subvectors x_i have the same number of elements $n_i = n/p$ the allgather operation is said to be *regular*, otherwise *irregular*. It is

Before			After		
Node 0	Node 1	Node 2	Node 0	Node 1	Node 2
x_0			x_0	x_0	x_0
	x_1		x_1	x_1	x_1
		x_2	x_2	x_2	x_2

Allgather. Fig. 1 Allgather on three nodes

commonly assumed that all nodes know the size of all subvectors in advance. The Message Passing Interface (MPI), for instance, makes this assumption for both its regular MPI_Allgather and its irregular MPI_Allgatherv collective operations. Other collective interfaces that support the operation make similar assumptions. This can be assumed without loss of generality. If it is not the case, a special, one item per node allgather operation can be used to collect the subvector sizes at all nodes.

The allgather operation is a symmetric variant of the broadcast operation in which all nodes concurrently broadcast their data item, and is therefore often referred to as *all-to-all broadcast*. It is semantically equivalent to a gather operation that collects data items from all nodes at a specific *root* node, followed by a broadcast from that root node, or to p concurrent gather operations with each node serving as root in one such operation. This explains the term *allgather*. The term *concatenation* can be used to emphasize that the data items are gathered in increasing index order at all nodes if such is the case. When concerned with the operation for specific communication networks (graphs) the term *gossiping* has been used. The problem has, like broadcast, been extensively studied in the literature, and other terminology is occasionally found.

Lower Bounds

To obtain lower bounds for the allgather operation a *fully connected, k -ported, homogeneous* communication system with *linear communication cost* is assumed. This means that

- All nodes can communicate directly with all other nodes, at the same communication cost,
- In each communication operation, a node can send up to k distinct messages to k other nodes, and simultaneously receive k messages from k possibly different nodes, and
- The cost of transmitting a message of size n (in some unit) between any two nodes is modeled by a simple, linear function $\alpha + n\beta$. Here α is a start-up latency and β the transfer cost per unit.

With these approximations, lower bounds on the number of communication rounds during which nodes are involved in k -ported communication, and the total

amount of data that have to be transferred along a critical path of any algorithm, can be easily established:

- Since the allgather operation implies a broadcast of a data item from each node, the number of communication rounds is at least $\lceil \log_{k+1} p \rceil$. This follows because the number of nodes to which this particular item has been broadcast can at most increase by a factor of $k + 1$ per round, such that the number of nodes to which the item has been broadcast after d rounds is at most $(k + 1)^d$.
- The total amount of data to be received by node j is $n - n_j$, and since this can be received over k simultaneously active ports, a lower bound is $\max_{0 \leq j < p} \lceil \frac{n-n_j}{k} \rceil$. For the regular case this is $\lceil \frac{n-n/p}{k} \rceil = \lceil \frac{(p-1)n}{pk} \rceil$.

In the linear cost model, a lower bound for the allgather operation is therefore $\lceil \log_{k+1} p \rceil \alpha + \max_{0 \leq j < p} \lceil \frac{(n-n_j)}{k} \rceil \beta$. For regular allgather problems this simplifies to

$$\lceil \log_{k+1} p \rceil \alpha + \lceil \frac{(p-1)n}{pk} \rceil \beta.$$

The model approximations abstract from any specific network topology, and for specific networks, including networks with a hierarchical communication structure, better, more precise lower bounds can sometimes be established. The network diameter will for instance provide another lower bound on the number of communication rounds.

Algorithms

At first it is assumed that $k = 1$ and that the allgather is regular, that is, the size n_i of each subvector x_i is equal to n/p . A brief survey of practically useful, common algorithmic approaches to the problem follows.

Ring, Mesh, and Hypercube

A flexible class of algorithms can be described by first viewing the nodes as connected as a ring where node i sends to node $(i + 1) \bmod p$ and receives from node $(i - 1) \bmod p$. An allgather operation can be accomplished in $p - 1$ communication rounds. In round j , $0 \leq j < p - 1$, node i sends subvector $x_{(i-j) \bmod p}$ and receives subvector $x_{(i-1-j) \bmod p}$.

The cost of this algorithm is

$$(p - 1) \left(\alpha + \frac{n}{p} \beta \right) = (p - 1)\alpha + \frac{(p - 1)n}{p} \beta.$$

This simple algorithm achieves the lower bound in the second term, and is useful when the vector size n is large. The linear, first term is far from the lower bound.

If the p nodes are instead organized in a $r_0 \times r_1$ mesh, with $p = r_0 r_1$, the complete allgather operation can be accomplished by first gathering (simultaneously) along the first dimension, and secondly gathering the larger subvectors along the second dimension. The cost of this algorithm becomes

$$\begin{aligned} & (r_1 - 1) \left(\alpha + \frac{n}{p} \beta \right) + (r_0 - 1) \left(\alpha + r_1 \frac{n}{p} \beta \right) \\ &= (r_1 + r_0 - 2)\alpha + \frac{(r_1 - 1)n + (r_0 - 1)r_1 n}{p} \beta \\ &= (r_1 + r_0 - 2)\alpha + \frac{(p - 1)n}{p} \beta. \end{aligned}$$

Generalizing the approach, if the p nodes are organized in a d -dimension with $p = r_0 \times r_1 \times \dots \times r_{d-1}$, the complete allgather operation can be accomplished by d successive allgather operations along the d dimensions. The cost of this algorithm becomes

$$\begin{aligned} & (r_{d-1} - 1) \left(\alpha + \frac{n}{p} \beta \right) + (r_{d-2} - 1) \left(\alpha + r_{d-1} \frac{n}{p} \beta \right) + \dots \\ &= \left(\sum_{j=0}^{d-1} (r_j - 1)\alpha \right) + \frac{(p - 1)n}{p} \beta. \end{aligned}$$

Notice that as the number of dimensions increases, the α term decreases while the (optimal) β term does not change.

If $p = 2^d$ so that $d = \log_2 p$ this approach yields an algorithm with cost

$$\left(\sum_{j=0}^{\log_2 p - 1} (2 - 1)\alpha \right) + \frac{(p - 1)n}{p} \beta = (\log_2 p)\alpha + \frac{(p - 1)n}{p} \beta.$$

The allgather in each dimension now involves only two nodes, and becomes a bidirectional exchange of data. This algorithm maps easily to hypercubes, and conversely a number of essentially identical algorithms were originally developed for hypercube systems. For fully connected networks it is restricted to the situation where p is a power of two, and does not easily,

```

 $j \leftarrow 1$ 
 $j' \leftarrow 2$ 
while  $j' < p$  do
    /* next round */
    par/* simultaneous send-receive */
        Send subvector  $(x_i, x_{(i+1) \bmod p}, \dots, x_{(i+j-1) \bmod p})$  to node  $(i-j) \bmod p$ 
        Receive subvector  $(x_{(i+j) \bmod p}, x_{(i+j+1) \bmod p}, \dots, x_{(i+j+j'-1) \bmod p})$  from node  $(i+j) \bmod p$ 
    endpar
     $j \leftarrow j'$ 
     $j' \leftarrow 2j'$ 
endwhile
/* last subvector */
 $j' \leftarrow p-j$ 
par/* simultaneous send-receive */
    Send subvector  $(x_i, x_{(i+1) \bmod p}, \dots, x_{(i+j'-1) \bmod p})$  to node  $(i-j) \bmod p$ 
    Receive subvector  $(x_{(i+j+1) \bmod p}, x_{(i+j+1) \bmod p}, \dots, x_{(i+j+j'-1) \bmod p})$  from node  $(i+j) \bmod p$ 
endpar

```

Allgather. Fig. 2 The dissemination allgather algorithm for node i , $0 \leq i < p$, and $1 < p$

without loss of theoretical performance, generalize to arbitrary values of p . It is sometimes called the *bidirectional exchange* algorithm, and relies only on restricted, *telephone-like* bidirectional communication. For this algorithm both the α and the β terms achieve their respective lower bounds. In contrast to, for instance, the broadcast operation, optimality can be achieved without the use of pipelining techniques.

Dissemination Allgather

On networks supporting bidirectional, fully connected, single-ported communication the allgather problem can be solved in the optimal $\lceil \log_2 p \rceil$ number of communication rounds for any p as shown in Fig. 2. In round k , node i communicates with nodes $(i + 2^k) \bmod p$ and $(i - 2^k) \bmod p$, and the size of the subvectors sent and received doubles in each round, with the possible exception of the last. Since each node sends and receives $p-1$ subvectors each of n/p elements the total cost of the algorithm is

$$\lceil \log_2 p \rceil \alpha + \frac{(p-1)n}{p} \beta,$$

for any number of nodes p , and meets the lower bound for single-ported communication systems. It can be generalized optimally (for some k) to k -ported communication systems.

This scheme is useful in many settings for implementation of other collective operations. The

$\lceil \log_2 p \rceil$ -regular communication pattern is an instance of a so-called *circulant* graph.

Composite Algorithms

Different, sometimes practically efficient algorithms for the allgather operation can be derived by combinations of algorithms for *broadcast* and *gather*. The full vector can be gathered at a chosen root node and broadcast from this node to all other nodes. This approach is inherently a factor of two off from the optimal number of communication rounds, since both gather and broadcast requires at least $\lceil \log p \rceil$ communication rounds even for fully connected networks. Other algorithms can be derived from broadcast or gather, by doing these operations simultaneously with each of the p nodes acting as either broadcast or gather root node.

Bibliographic Notes and Further Reading

The allgather operation is a symmetric variant of the broadcast operation, and together with this, one

of the most studied collective communication operations. Early theoretical surveys under different communication assumptions can be found in [5, 7, 8, 11]. For (near-)optimal algorithms for hypercubes, meshes, and tori, see [10, 18]. Practical implementations, for instance, for MPI for a variety of parallel systems have frequently been described, see, for instance, [1, 2, 12, 16]. Algorithms and implementations that exploit multi-port communication capabilities can be found in [2, 4, 14]. Algorithms based on ring shifts are sometimes called cyclic or bucket algorithms; in [3, 13] it is discussed how to create hybrid algorithms for meshes of lower dimension and fully connected architectures where the number of nodes is not a power of two. The ideas behind these algorithms date back to the early days of distributed memory architectures [6, 15]. The dissemination allgather algorithm is from the fundamental work of Bruck et al. [2], although the term is not used in that paper [1, 9]. Attention has almost exclusively been given to the regular variant of the problem. A pipelined algorithm for very large, *irregular* allgather problems was given in [17]. More general bibliographic notes can be found in the entry on collective communication.

Definition

Among a set of processing elements (nodes) each node has distinct (personalized) data items destined for each of the other nodes. The all-to-all operation accomplishes this total data exchange among the set of

nodes, such that each node ends up having an individual data item from each of the other nodes.

Discussion

The reader may consider first visiting the entry on *collective communication*.

Let the p nodes be indexed consecutively, $0, 1, \dots, p - 1$. Initially each node i has a (column)vector of data $x^{(i)}$ that is further subdivided into subvectors $x_j^{(i)}$ for $j = 0, \dots, p - 1$. The subvector $x_j^{(i)}$ is to be sent to node j from node i . Upon completion of the all-to-all exchange operation node i will have the vector consisting of the subvectors $x_i^{(j)}$ for $j = 0, \dots, p - 1$. In effect, the matrix consisting of the i columns $x^{(i)}$ is *transposed* with the i th row consisting of subvectors $x_i^{(j)}$ originally distributed over the p nodes $j = 0, \dots, p - 1$ now transferred to node i . This *transpose* all-to-all operation is illustrated in Fig. 1. The subvectors $x_i^{(i)}$ do not have to be communicated, but for symmetry reasons it is convenient to think of the operation as if each node also contributes a subvector to itself.

The all-to-all exchange can be interpreted as an actual matrix transpose operation in the case where all subvectors $x_i^{(j)}$ have the same number of elements n . In that case the all-to-all problem is called *regular* and the operation is also sometimes termed *index*. The all-to-all operation is, however, also well defined in cases where subvectors have different number of elements. Subvectors could for instance differ for each row index j , e.g., $n_j = |x_j^{(i)}|$ for all nodes i , or each subvector could have a possibly different number of elements $n_{ij} = |x_j^{(i)}|$ without any specified relation between the subvector sizes. In all such cases, the all-to-all problem is called *irregular*. Likewise, the subvectors $x_j^{(i)}$ can be structured objects, for instance matrix blocks. It is common to assume that for both regular and irregular all-to-all problems each

Before			After		
Node 0	Node 1	Node 2	Node 0	Node 1	Node 2
$x_0^{(0)}$	$x_0^{(1)}$	$x_0^{(2)}$	$x_0^{(0)}$	$x_1^{(0)}$	$x_2^{(0)}$
$x_1^{(0)}$	$x_1^{(1)}$	$x_1^{(2)}$	$x_0^{(1)}$	$x_1^{(1)}$	$x_2^{(1)}$
$x_2^{(0)}$	$x_2^{(1)}$	$x_2^{(2)}$	$x_0^{(2)}$	$x_1^{(2)}$	$x_2^{(2)}$

All-to-All. Fig. 1 All-to-all communication for three nodes

node knows not only the number of elements of all subvectors it has to send to other nodes, but also the number of elements in all subvectors it has to receive from other nodes. This can be assumed without loss of generality, since a regular all-to-all operation with subvectors of size one can be used to exchange and collect the required information on number of elements to be sent and received.

All-to-all communication is the most general and most communication intensive collective data-exchange communication pattern. Since it is allowed that some $|x_j^{(i)}| = 0$ and that some subvectors $x_j^{(i)}$ are identical for some i and j , the irregular all-to-all operation subsumes other common *collective communication* patterns like broadcast, gather, scatter, and allgather. Algorithms for specific patterns are typically considerably more efficient than general, all-to-all algorithms, which motivates the inclusion of a spectrum of collective communication operations in collective communication interfaces and libraries. The *Message-Passing Interface* (MPI), for instance, has both regular MPI_Alltoall and irregular MPI_Alltoallv and MPI_Alltoallw operations in its repertoire, as well as operations for the specialized operations broadcast, gather, scatter, and allgather, and structured data can be flexibly described by so-called user-defined datatypes.

All-to-all communication is required in FFT computations, matrix transposition, generalized permutations, etc., and is thus a fundamental operation in a large number of scientific computing applications.

Lower Bounds

The (regular) all-to-all communication operation requires that each node exchanges data with each other node. Therefore, a lower bound on the all-to-all communication time will be determined by a minimal *bisection* and the *bisection bandwidth* of the communication system or network. The number of subvectors that have to cross any bisection of the nodes (i.e., partition into two roughly equal-sized subsets) is $p^2/2$ (for even p), namely $p/2 \times p/2 = p^2/4$ subvectors from each subset of the partition. The number of communication links that can be simultaneously active in a minimal partition determines the number of communication rounds that are at the least needed to transfer all subvectors across the bisection assuming that subvectors are

not combined. A d -dimensional, symmetric torus with unidirectional communication has a bisection of $2k^{d-1}$ with $k = \sqrt[d]{p}$, and the number of required communication rounds is therefore $p\sqrt[d]{p}/4$. A hypercube (which can also be construed as a $\log_2 p$ dimensional mesh) has bisection $p/2$. The low bisection of the torus limits the bandwidth that can be achieved for all-to-all communication. If the bisection bandwidth is B vector elements per time unit, any all-to-all algorithms requires at least $np^2/2B$ units of time.

Assume now a fully connected, homogeneous, k -ported, bidirectional send-receive communication network. Each node can communicate directly with any other node at the same cost, and can at the same time receive data from at most k nodes and send distinct data to at most k , possibly different nodes. In this model, the following general lower bounds on the number of communication rounds and the amount of data transferred in sequence per node can be proved. Here n is the amount of data per subvector for each node.

- A complete all-to-all exchange requires at least $\lceil \log_{k+1} p \rceil$ communication rounds and transfers at least $\lceil \frac{n(p-1)}{k} \rceil$ units of data per node.
- Any all-to-all algorithm that uses $\lceil \log_{k+1} p \rceil$ communication rounds must transfer at least $\Omega(\frac{np}{k+1} \log_{k+1} p)$ units of data per node.
- Any all-to-all algorithm that transfers exactly $\frac{n(p-1)}{k}$ units of data per node requires at least $\frac{p-1}{k}$ communication rounds.

These lower bounds bound the minimum required time for the all-to-all operation. In contrast to, for instance, allgather communication, there is a trade-off between the number of communication rounds and the amount of data transferred. In particular, it is not possible to achieve a logarithmic number of communication rounds *and* a linear number of subvectors per node. Instead, fewer rounds can only be achieved at the expense of combining subvectors and sending the same subvector several times. As a first approximation, communication cost is modeled by a linear cost function such that the time to transfer n units of data is $\alpha + n\beta$ for a start-latency α and cost per unit β . All-to-all communication time is then at least α times the number of communication rounds plus β times the units of data transferred in sequence by a node.

Algorithms

In the following, the regular all-to-all operation is considered. Each node i has a subvector $x_j^{(i)}$ to transfer to each other node j , and all subvectors have the same number of elements $n = |x_i^{(j)}|$.

Fully Connected Systems

In a *direct algorithm* each node i sends each subvector directly to its destination node j . It is assumed that communication takes place in rounds, in which all or some nodes send and/or receive data. The difficulty is to organize the communication in such a way that no node stays idle for too many rounds, and that in the same round no node is required to send or receive more than the k subvectors permitted by the k -ported assumption.

For one-ported, bidirectional systems the simplest algorithm takes $p-1$ communication rounds. In round r , $1 \leq r < p$, node i sends subvector $x_{(i+r) \bmod p}^{(i)}$ to node $(i+r) \bmod p$, and receives subvector $x_i^{((i-r) \bmod p)}$ from node $(i-r) \bmod p$. If required, subvector $x_i^{(i)}$ is copied in a final noncommunication round. This algorithm achieves the lower bound on data transfer, at the expense of $p-1$ communication rounds, and trivially generalizes to k -ported systems. In this case, the last round may not be able to utilize all k communication ports.

For single-ported systems ($k = 1$) with weaker bidirectional communication capabilities allowing only that each node i sends and receives from the same node j (often referred to as the *telephone model*) in a communication round, or even unidirectional communication capabilities allowing each node to only either send or receive in one communication round, a different algorithm solves the problem. Such an algorithm is described in the following.

A fully connected communication network can be viewed as a complete, undirected graph with processing nodes modeled as graph nodes. For even p the complete graph can be partitioned into $p-1$ disjoint 1-factors (perfect matchings), each of which associates each node i with a different node j . For odd p this is not possible, but the formula $j = (r - i) \bmod p$ for $r = 0, \dots, p-1$ associates a different node j with i for each round r such that if i is associated with j in round r , then j is associated with i in the same round. In each round there is exactly one node that becomes associated with itself.

This can be used to achieve the claimed 1-factorization for even p . Let the last node $i = p - 1$ be *special*. Perform the $p - 1$ rounds on the $p - 1$ non-special nodes. In the round where a non-special node becomes associated with itself, it instead performs an exchange with the special node. It can be shown that p and $p - 1$ communication rounds for odd and even p , respectively, is *optimal*. The algorithm is depicted in Fig. 2. It takes $p - 1$ communication rounds for even p , and p rounds for odd p . If a self-copy is required it can for odd p be done in the round where a node is associated with itself and for even p either before or after the exchange. Note that in the case where p is even the formula $j = (r - i) \bmod p$

```

if odd( $p$ ) then
    for  $r \leftarrow 0, 1, \dots, p - 1$  do
         $j \leftarrow (r - i) \bmod p$ 
        if  $i \neq j$  then
            par/* simultaneous send-receive */
            Send subvector  $x_j^{(i)}$  to node  $j$ 
            Receive subvector  $x_i^{(j)}$  from node  $j$ 
        end par
    end if
    end for
else if  $i < p - 1$  then /*  $p$  even */
    /* non-special nodes */
    for  $r \leftarrow 0, 1, \dots, p - 2$  do
         $j \leftarrow (r - i - 1) \bmod (p - 1)$ 
        if  $i = j$  then  $j \leftarrow p - 1$ 
        par/* simultaneous send-receive */
        Send subvector  $x_j^{(i)}$  to node  $j$ 
        Receive subvector  $x_i^{(j)}$  from node  $j$ 
    end par
    end for
else /* special node */
    for  $r \leftarrow 0, 1, \dots, p - 2$  do
        if even ( $r$ ) then  $j \leftarrow r/2$  else  $j \leftarrow (p-1+r)/2$ 
        par/* simultaneous send-receive */
        Send subvector  $x_j^{(i)}$  to node  $j$ 
        Receive subvector  $x_i^{(j)}$  from node  $j$ 
    end par
    end for
end if

```

All-to-All. Fig. 2 Direct, telephone-like all-to-all communication based on 1-factorization of the complete p node graph. In each communication round r each node i becomes associated with a unique node j with which it performs an exchange. The algorithm falls into three special cases for odd and even p , respectively, and for the latter for nodes $i < p - 1$ and the special node $i = p - 1$. For odd p the number of communication rounds is p , and $p - 1$ for even p . In both cases, this is optimal in the number of communication rounds

also pairs node i with itself in some round, and the self-exchange could be done in this round. This would lead to an algorithm with p rounds, in some of which some nodes perform the self-exchange. If bidirectional communication is not supported, each exchange between nodes i and j can be accomplished by the smaller numbered node sending and then receiving from the larger numbered node, and conversely the larger numbered node receiving and then sending to the smaller numbered node.

If p is a power of two the pairing $j = i \oplus r$, where \oplus denotes the bitwise exclusive-or operation, likewise produces a 1-factorization and this has often been used.

Hypercube

By combining subvectors the number of communication rounds and thereby the number of message start-ups can be significantly reduced. The price is an increased communication volume because subvectors will have to be sent multiple times via intermediate nodes. Such *indirect* algorithms were pioneered for hypercubes and later extended to other networks and communication models. In particular for the fully connected, k -ported model algorithms exist that give the optimal trade-off (for many values of k and p) between the number of communication rounds and the amount of data transferred per node.

A simple, indirect algorithm for the d -dimensional hypercube that achieves the lower bound on the number of communication rounds at the expense of a logarithmic factor more data is as follows. Each hypercube node i communicates with each of its d neighbors, and the nodes pair up with their neighbors in the same fashion. In round r , node i pairs up and performs an exchange with neighbor $j = i \oplus 2^{d-r}$ for $r = 1, \dots, d$. In the first round, node i sends in one message the 2^{d-1} subvectors destined to the nodes of the $d - 1$ -dimensional subcube to which node j belongs. It receives from node j the 2^{d-1} subvectors for the $d - 1$ -dimensional subcube to which it itself belongs. In the second round, node i pairs up with a neighbor of a $d - 2$ -dimensional subcube, and exchanges the 2^{d-2} own subvectors and the additional 2^{d-2} subvectors for this subcube received in the first round. In general, in each round r node i receives and sends $2^r 2^{d-1-r} = 2^{d-1} = p/2$ subvectors.

Total cost of this algorithm in the linear cost model is $\log_2 p(\alpha + \beta \frac{p}{2} n)$.

Irregular All-to-All Communication

The irregular all-to-all communication problem is considerably more difficult both in theory and in practice. In the general case with no restrictions on the sizes of the subvectors to be sent and received, finding communication schedules that minimize the number of communication rounds and/or the amount of data transferred is an NP-complete optimization problem. For problem instances that are not too irregular a decomposition into a sequence of more regular problems and other collective operations sometimes work, and such approaches have been used in practice. Heuristics and approximation algorithms for many variations of the problem have been considered in the literature. For concrete communication libraries, a further practical difficulty is that full information about the problem to be solved, that is the sizes of *all* subvectors for all the nodes is typically not available to any single node. Instead each node knows only the sizes of the subvectors it has to send (and receive). To solve the problem this information has to be centrally gathered entailing a sequential bottleneck, or distributed algorithms or heuristics for computing a communication schedule must be employed.

Bibliographic Notes and Further Reading

All-to-all communication has been studied since the early days of parallel computing, and many of the results presented here can be found in early, seminal work [6, 15]. Classical references on indirect all-to-all communication for hypercubes are [7, 16], see also later [2] for combinations of different approaches leading to *hybrid* algorithms. The generalization to arbitrary node counts for the k -ported, bidirectional communication model was developed in [3], which also proves

the lower bounds on number of rounds and the trade-off between amount of transferred data and required number of communication rounds. Variants and combinations of these algorithms have been implemented in various MPI like libraries for collective communication [1, 14, 19].

A proof that a 1-factorization of the p node complete graph exists when p is even can be found in [6] and elsewhere.

All-to-all algorithms not covered here for meshes and tori can be found in [17, 18, 20, 21], and algorithms for multistage networks in [11, 22]. Lower bounds for tori and meshes based on counting link load can be found in [9]. Implementation considerations for some of these algorithms for MPI for the Blue Gene systems can be found in [8].

Irregular all-to-all exchange algorithms and implementations have been considered in [12, 13] (decomposition into a series of easier problems) and later in [5, 10], the former summarizing many complexity results.

Definition

The AMD Opteron™ processor codenamed “Barcelona” was introduced in September 2007 and was notable as the industry’s first “native” quad-core x86 processor, containing four cores on single piece of silicon. The die also featured an integrated L3 cache which was accessible by all four cores, Rapid Virtualization Indexing to improve virtualization performance, new power management features including split power planes for the integrated memory controller and the cores, and a higher-IPC (Instructions per Clock) core including significantly higher floating-point performance. Finally, the product was a plug-in replacement for the previous-generation AMD Opteron processor – “Barcelona” used the same Direct Connect system architecture, the same physical socket including commodity DDR2 memory, and fit in approximately the same thermal envelope.

Discussion

Previous Opteron Generations

The first-generation AMD Opteron processor was introduced in April of 2003. AMD Opteron introduced the AMD64 instruction set architecture, which was an evolutionary extension to the x86 instruction set that provided additional registers and 64-bit addressing [1]. An important differentiating feature of AMD64 was that it retained compatibility with the large library of 32-bit x86 applications which had been written over the 30-year history of that architecture – other 64-bit architectures at that time either did not support the x86 ISA or supported it only through a slow emulation mode. The first-generation AMD Opteron also introduced Direct Connect architecture which featured a memory controller integrated on the same die as the

All-to-All Broadcast

Altivec

► [IBM Power Architecture](#)

► [Vector Extensions, Instruction-Set Architecture \(ISA\)](#)

processor, and HyperTransport™ Technology bus links to directly connect the processors and enable glueless two-socket and four-socket multiprocessor systems.

The second-generation AMD Opteron processor was introduced two years later in April of 2005 and enhanced the original offering by integrating two cores (Dual-Core) with the memory controller. The dual-core AMD Opteron was later improved with DDR2 memory for higher bandwidth, and introduced AMD-V™ hardware virtualization support.

“Barcelona” introduced the third generation of the AMD Opteron architecture, in September of 2007.

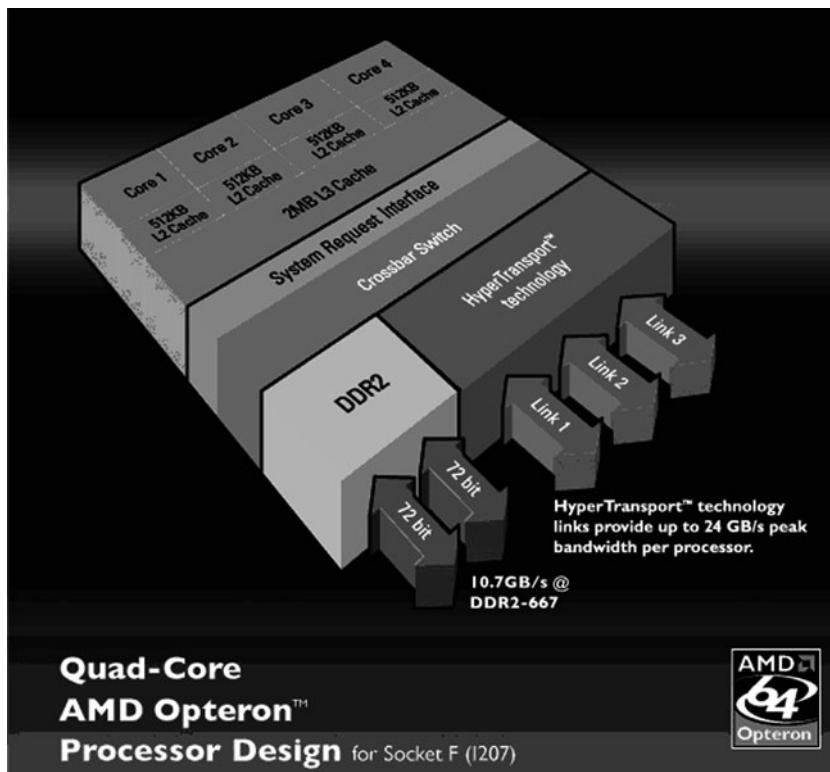

System-on-a-Chip

“Barcelona” was the industry’s first native quad-core processor – as shown in Fig. 1, the processor contained four processing cores (each with a private 512 k L2 cache), a shared 2 MB L3 cache, an integrated crossbar which enabled efficient multiprocessor communication, and DDR2 memory controller and three HyperTransport links. The tight integration on a single die enabled efficient communication between all four cores, notably

through an improved power management flexibility and the shared L3 cache.

The L3 cache was a non-inclusive architecture – the contents of the L2 caches were independent and typically not replicated in the L3, enabling more efficient use of the cache hierarchy. The L2 and L3 caches were designed as a victim-cache architecture. A newly retrieved cache line would initially be written to the L1 cache. Eventually, the processor would evict the line from the L1 cache and would then write it into the L2 cache. Finally, the line would be evicted from the L2 cache and the processor would write it to the L3 cache.

The shared cache used a “sharing-aware” fill and replacement policy. Consider the case where a line-fill request hits in the L3 cache: The processor has the option of leaving a copy of the line in the L3 (predicting that other cores are likely to want that line in the future) or moving the line to the requesting core, invalidating it from the L3 to leave a hole which could be used by another fill. Lines which were likely to be shared (for example, instruction code or lines which had been shared in the past) would leave a copy of the line in

AMD Opteron Processor Barcelona. Fig. 1 Quad-Core AMD Opteron™ processor design

the L3 cache for other cores to access. Lines which were likely to be private (for example, requested with write permission or which had never been previously shared in the past) would move the line from the L3 to the L1. The L3 cache maintained a history of which lines had been shared to guide the fill policy. Additionally, the sharing history information influenced the L3 replacement policy – the processor would preferentially keep lines which had been shared in the past by granting them an additional trip through the replacement policy.

In Client CPUs, AMD later introduced a “Triple-Core” product based on the same die used by “Barcelona” – this product served an important product category (for users who valued an affordable product with more than dual-core processing power). The Triple-Core product was targeted at the consumer market and was based on the same die used by “Barcelona” with three functional cores rather than four.

Socket Compatibility

“Barcelona” was socket-compatible with the previous-generation Dual-Core AMD OpteronTM product: “Barcelona” had the same pinout, used the same two channels of DDR2 memory, and also fit in a similar thermal envelope enabling the use of the same cooling and thermal solution. Even though “Barcelona” used four cores (rather than two) and each core possessed twice the peak floating-point capability of the previous generation, “Barcelona” was able to fit in the same thermal envelope through the combination of a smaller process (“Barcelona” was the first AMD server product based on 65 nm SOI technology) and a reduction in peak operating frequency (initially “Barcelona” ran at 2.3 GHz). The doubling of core density in the same platform was appealing and substantially increased performance on many important server workloads compared to the previous-generation AMD Opteron product. Customers could upgrade their AMD Opteron products to take advantage of quad-core “Barcelona,” and OEMs could leverage much of their platform designs from the previous generation.

Delivering More Memory Bandwidth

As mentioned above, the “Barcelona” processor’s socket-compatibility eased its introduction to the marketplace. However, the four cores on a die placed additional load on the memory controller – the platform had the

same peak bandwidth as the previous generation: Each socket still had two channels of DDR2 memory, running at up to 667 MHz and delivering a peak bandwidth of 10.7 GB/s (per socket). To feed the additional cores, the memory controller in “Barcelona” included several enhancements which improved the *delivered* bandwidth.

One notable feature was the introduction of “independent” memory channels. In the second-generation AMD Opteron product, each memory channel serviced half of a 64-byte memory request – i.e., in parallel the memory controller would read 32 bytes from each channel. This was referred to as a “ganged” controller organization and has the benefit of perfectly balancing the memory load between the two memory channels. However, this organization also effectively reduces the number of available dram banks by a factor of two – when a dram page is opened on the first channel, the controller opens the same page on the other channel at the same time. Effectively, the ganged organization creates pages which are twice as big, but provides half as many dram pages as a result.

With four cores on a die all running four different threads, the memory accesses tend to be unrelated and more random. DRAMs support only a small number of open banks, and requests which map to the same bank but at different addresses create a situation called a “page conflict.” The page conflict can dramatically reduce the efficiency and delivered bandwidth of the DRAM, because the DRAM has to repeatedly switch between the multiple pages which are competing for the same open bank resources. Additionally, write traffic coming from the larger multi-level “Barcelona” cache hierarchy created another level of mostly random memory traffic which had to be efficiently serviced. All of these factors led to a new design in which the two memory channels were controlled independently – i.e., each channel could independently service an entire 64-byte cache line rather than using both channels for the same cache line. This change enabled the two channels to independently determine which pages to open, effectively doubling the number of banks and enabling the design to better cope with the more complex memory stream coming from the quad-core processor.

A low-order address bit influenced the channel selection, which served to spread the memory traffic between the two controllers and avoid overloading

one of the channels. The design hashed the low-order address bit with other higher-order address bit to spread the traffic more evenly, and in practice, applications showed an near-equal allocation between the two channels, enabling the benefits of the extra banks provided by the independent channels along with equal load balancing. The independent channels also resulted in a longer burst length (twice as long as the ganged organization), which reduced pressure on the command bus; essentially each Read or Write command performed twice as much work with the independent organization. This was especially important for some DIMMs which required commands to be sent for two consecutive cycles (“2T” mode).

“Barcelona” continued to support a dynamic open-page policy, in which the memory controller leaves dram pages in the “open” state if the pages are likely to be accessed in the future. As compared to a closed-page design (which always closes the dram pages), the dynamic open-page design can improve latency and bandwidth in cases where the access stream has locality to the same page (by leaving the page open), and also deliver best-possible bandwidth when the access stream contains conflicts (by recognizing the page-conflict stream and closing the page). “Barcelona” introduced a new predictor which examined the history of accesses to each bank to determine whether to leave the page open or to close it. The predictor was effective at increasing the number of page hits (delivering lower latency) and reducing the number of page conflicts (improving bandwidth).

“Barcelona” also introduced a new DRAM prefetcher which monitored read traffic and prefetched the next cache line when it detected a pattern. The prefetcher had sophisticated pattern detection logic which could detect both forward and backward patterns, unit and non-unit strides, as well as some more complicated patterns. The prefetcher targeted a dedicated buffer to store the prefetched data (rather than a cache) and thus the algorithm could aggressively exploit unused dram bandwidth without concern for generating cache pollution. The prefetcher also had a mechanism to throttle the prefetcher if the prefetches were inaccurate or if the dram bandwidth was consumed by non-prefetch requests. Later generations of the memory controller would improve on both the prefetch and the throttling mechanisms.

The DRAM controller was also internally re-plumbed with wider busses (the main busses were increased from 64-bits to 128-bits) and with additional buffering. Many of these changes served to prepare the controller to support future higher-speeds memory technologies. One notable change was the addition of write-bursting logic, which buffered memory writes until a watermark level was achieved, at which time the controller would burst all the writes to the controller. As compared to trickling the writes to the DRAM as they arrived at the memory controller, the write-bursting mode was another bandwidth optimization. Typically, the read and write requests address different banks, so switching between a read mode and a write mode both minimizes the number of read/write bus turnarounds and minimizes the associated page open/close traffic.

“Barcelona” Core Architecture

The “Barcelona” core was based on the previous “K8” core design but included comprehensive IPC (Instruction-Per-Clock) improvements throughout the entire pipeline. One notable feature was the “Wide Floating-Point Accelerator,” which doubled the raw computational floating-point data paths and floating-point execution units from 64-bits to 128-bits. A 2.5 GHz “Barcelona” core possessed a peak rate of 20 GFlops of single-precision computation; the quad-core “Barcelona” could then deliver 80 GFlops at peak (twice as many cores, each with twice as much performance). This doubling of each core’s raw computation bandwidth was accompanied by a doubling of the instruction fetch bandwidth (from 16-bytes/cycle to 32-bytes/cycle) and a doubling of the data cache bandwidth (two 128-bit loads could be serviced each clock cycle), enabling the rest of the pipeline to feed the new higher-bandwidth floating-point units. Notably, SSE instructions include one or more prefix bytes, frequently use the REX prefix to encode additional registers, and can be quite large. The increased instruction fetch bandwidth was therefore important to keep the pipeline balanced and able to feed the high-throughput wide floating-point units.

“Barcelona” introduced a new “unaligned SSE mode,” which allowed a single SSE instruction to both load and execute an SSE operation, without concern for alignment. Previously, users had to use two instructions

(an unaligned load followed by an execute operation). This new mode further reduced pressure on the instruction decoders and also reduced register pressure. The mode relaxed a misguided attempt to simplify the architecture by penalizing unaligned operations and was later adopted as the x86 standard. Many important algorithms such as video decompression can benefit from vector instructions but cannot guarantee alignment in the source data (for example, if the input data is compressed).

The “Barcelona” pipeline included an improved branch predictor, using more bits for the global history to improve the accuracy and also doubling the size of the return stack. “Barcelona” added a dedicated predictor for indirect branches to improve performance when executing virtual functions commonly used in modern programming styles. The wider 32-byte instruction fetch improved both SSE instruction throughput as well as higher throughput in codes with large integer instructions, particularly when using some of the more complicated addressing modes.

“Barcelona” added a Sideband Stack Optimizer feature which executed common stack operations (i.e., the PUSH and POP instructions) with dedicated stack adjustment logic. The logic broke the serial dependence chains seen in consecutive strings of PUSH and POP instructions (common at function entry and exit), and also freed the regular functional units to execute other operations.

“Barcelona” also improved the execution core with a data-dependent divide, which provided an early out for the common case where the dividend was small. “Barcelona” introduced the SSE4a instruction set, which added a handful of instructions including leading-zero count and population count, bit INSERT and EXTRACT, and streaming single-precision store operations.

“Barcelona” core added an out-of-order load feature, which enabled loads to bypass other loads in the pipeline. Other memory optimizations included a wider L2 bus, larger data and instruction TLBs, 1GB page size, and 48-bit physical address to support large server database footprints. The L1 data TLB was expanded to 48 entries, and each entry could hold any of the three page sizes in the architecture (4K, 2M, or 1GB); this provided flexibility for the architecture to efficiently run applications with both legacy and newer page sizes.

Overall the “Barcelona” core was a comprehensive but evolutionary improvement over the previous design. The evolutionary improvement provided a consistent optimization strategy for compilers and software developers: optimizations for previous-generation AMD Opteron™ processors were largely effective on the “Barcelona” core as well.

Virtualization and Rapid Virtualization Indexing

In 2007, virtualization was an emerging application class driven by customer desire to more efficiently utilize multi-core server systems and thus was an important target for the quad-core “Barcelona.” One performance bottleneck in virtualized applications was the address translation performed by the hypervisor – the hypervisor virtualizes the physical memory in the system and thus has to perform an extra level of address translation between the guest physical and the actual host physical address. Effectively, the hypervisor creates another level of page tables for this final level of translation. Previous-generation processors performed this translation with a software-only technique called “shadow paging.” Shadow paging required a large number of hypervisor intercepts (to maintain the page tables) which slowed performance and also suffered from an increase in the memory footprint. “Barcelona” introduced Rapid Virtualization Indexing (also known as “nested paging”) which provided hardware support for performing the final address translation; effectively, the hardware was aware of both the host and guest page tables and could walk both as needed [2]. “Barcelona” also provided translation caching structures to accelerate the nested table walk.

“Barcelona” continued to support AMD-V™ hardware virtualization support, tagged TLBs to reduce TLB flushing when switching between guests, and the Device Exclusion Vector for security. Additionally, well-optimized virtualization applications typically demonstrate a high degree of local memory accesses, i.e., accesses to the integrated memory controller rather than to another socket in the multi-socket system. AMD’s Direct Connect architecture, which provided lower latency and higher bandwidth for local memory accesses, was thus particularly well suited for running virtualization applications.

Power Reduction Features

The “Barcelona” design included dedicated power supplies for the CPU cores and the memory controller, allowing the voltage for each to be separately controlled. This allowed the cores to operate at reduced power consumption levels while the memory controller continued to run at full speed and service memory requests from other cores in the system. In addition, the core design included the use of fine-gaters to reduce the power to logic on the chip which was not currently in use. One example was the floating-point unit – for integer code, when the floating-point unit was not in use, “Barcelona” would gate the floating-point unit and significantly reduce the consumed power. The fine-gaters could be re-enabled in a single cycle and did not cause any visible increased latency.

The highly integrated “Barcelona” design also reduced the overall system chip count and thus reduced system power. Notably the AMD Opteron™ system architecture integrated the northbridge on the same die as the processor (reducing system chip count by one device present in some legacy system architectures), and also used commodity DDR2 memory (which consumed less power than the competing FB-DIMM standard).

Future Directions

The AMD Opteron™ processor codenamed “Barcelona” was the third generation in the AMD Opteron processor line. “Barcelona” was followed by the AMD Opteron processor codenamed “Shanghai,” which was built in 45 nm SOI process technology, included a larger 6 M shared L3 cache, further core and northbridge performance improvements, faster operating frequencies, and faster DDR2 and HT interconnect frequencies. “Shanghai” was introduced in November of 2008.

“Shanghai” was followed by the AMD Opteron processor codenamed “Istanbul,” which integrated six cores onto a single die, and again plugged into the same socket as “Barcelona” and “Shanghai.” “Istanbul” also included an “HT Assist” feature which substantially reduced probe traffic in the system. HT Assist adds cache directory to each memory controller; the directory tracks lines in the memory range serviced by the memory controller which are cached somewhere in the system. Frequently, a memory access misses the directory (indicating the line is not cached anywhere in the

system) and thus the system can immediately return the requested data without having to probe the system. HT Assist enables the AMD Opteron platform to efficiently scale bandwidth to 4-socket and 8-socket server systems.

The next AMD Opteron™ product is on the near horizon as well. Codenamed “Magny-Cours,” this processor is planned for introduction in the first quarter of 2010, includes up to 12-cores in each socket, and introduces a new G34 platform. Each G34 socket contains 4 DDR3 channels and 4 HyperTransport links. “Magny-Cours” continues to use evolved versions of the core and memory controller that were initially introduced in “Barcelona.”

“Barcelona” broke new ground as the industry’s first native quad-core device, including a shared L3 cache architecture and leadership memory bandwidth. The “Barcelona” core was designed with an evolutionary approach, and delivered higher core performance (especially on floating-point codes), and introduced new virtualization technologies to improve memory translation performance and ease Hypervisor implementation. Finally, “Barcelona” was plug-compatible with the previous-generation AMD Opteron processors, leveraging the stable AMD Direct Connect architecture and cost-effective commodity DDR2 memory technology.

Amdahl's Argument

- [Amdahl's Law](#)

Amdahl's Law

JOHN L. GUSTAFSON
Intel Labs, Santa Clara, CA, USA

Synonyms

Amdahl's argument; Fixed-size speedup; Law of diminishing returns; Strong scaling

Definition

Amdahl's Law says that if you apply P processors to a task that has serial fraction f , the predicted net speedup is

$$\text{Speedup} = \frac{1}{f + \frac{1-f}{P}}.$$

More generally, it shows the speedup that results from applying any performance enhancement by a factor of P to only one part of a given workload.

A corollary of Amdahl's Law, often confused with the law itself, is that even when one applies a very large number of processors P (or other performance enhancement) to a problem, the net improvement in speed cannot exceed $1/f$.

Discussion

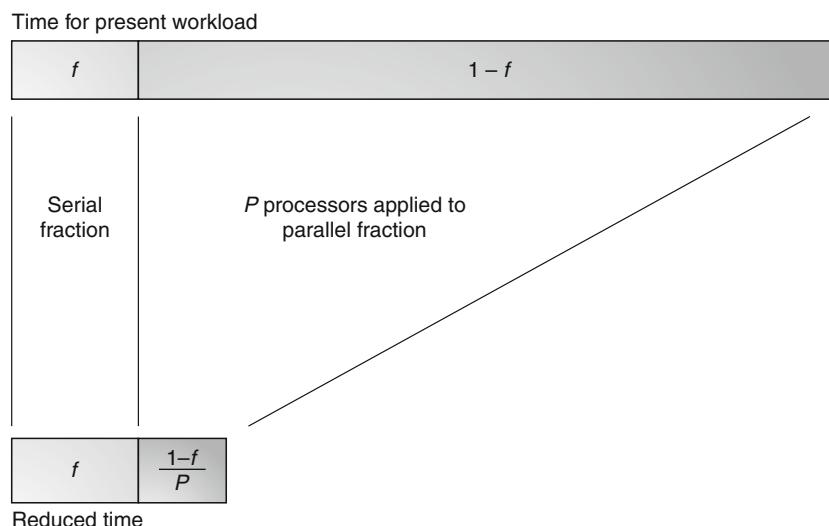

Graphical Explanation

The diagram in Fig. 1 graphically explains the formula in the definition.

The model sets the time required to solve the present workload (top bar) to unity. The part of the workload that is serial, f , is unaffected by parallelization. (See discussion below for the effect of including the time for interprocessor communication.) The model assumes that the remainder of the time, $1 - f$, parallelizes perfectly so that it takes only $1/P$ as much time as on the serial processor. The ratio of the top bar to the bottom bar is thus $1/(f + (1-f)/P)$.

History

In the late 1960s, research interest increased in the idea of achieving higher computing performance by using many computers working in parallel. At the Spring 1967 meeting of the American Federation of Information Processing Societies (AFIPS), organizers set up a session entitled "The best approach to large computing capability – A debate." Daniel Slotnick presented "Unconventional Systems," a description of a 256-processor ensemble controlled by a single instruction stream, later known as the ILLIAC IV [12]. IBM's chief architect, Gene Amdahl, presented a counterargument entitled "Validity of the single processor approach to achieving large scale computing capabilities" [1]. It

Amdahl's Law. Fig. 1 Graphical explanation of Amdahl's Law

was in this presentation that Amdahl made a specific argument about the merits of serial mainframes over parallel (and pipelined) computers.

The formula known as Amdahl's Law does *not* appear anywhere in that paper. Instead, the paper shows a hand-drawn graph that includes the performance speedup of a 32-processor system over a single processor, as the fraction of parallel work increases from 0% to 100%. There are no numbers or labels on the axes in the original, but Fig. 2 reproduces his graph more precisely.

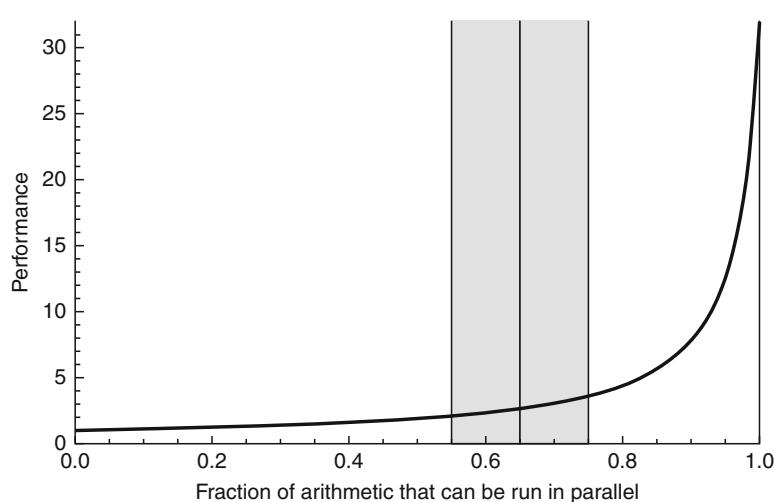

Amdahl estimated that about 10% of an algorithm was inherently serial, and data management imposed another 25% serial overhead, which he showed as the gray area in the figure centered about 65% parallel content. He asserted this was the most probable region of operation. From this, he concluded that a parallel system like the one Slotnick described would only yield from about 2X to 4X speedup. At the debate, he presented the formula used to produce the graph, but did not include it in the text of the paper itself.

This debate was so influential that in less than a year, the computing community was referring to the argument against parallel computing as "Amdahl's Law." The person who first coined the phrase may have been Willis H. Ware, who in 1972 first put into print the phrase "Amdahl's Law" and the usual form of the formula, in a RAND report titled "The Ultimate Computer" [14].

The argument rapidly became part of the commonly accepted guidelines for computer design, just as the Law

of Diminishing Returns is a classic guideline in economics and business. In the early 1980s, computer users attributed the success of Cray Research vector computers over rivals such as those made by CDC to Cray's better attention to Amdahl's Law. The Cray designs did not take vector pipelining to such extreme levels relative to the rest of their system and often got a higher fraction of peak performance as a result. The widely used textbook on computer architecture by Hennessy and Patterson [7] harkens back to the traditional view of Amdahl's Law as guidance for computer designers, particularly in its earlier editions.

The formula Amdahl used was simply the use of elementary algebra to combine two different speeds, here defined as *work* per unit time, not *distance* per unit time: it simply compares two cases of the net speed as the total work divided by the total time. This common result is certainly not due to Amdahl, and he was chagrined at receiving credit for such an obvious bit of mathematics. "Amdahl's Law" really refers to the argument that the formula (along with its implicit assumptions about typical serial fractions and the way computer costs and workloads scale) predicts harsh limits on what parallel computing can achieve. For those who wished to avoid the change to their software that parallelism would require, either for economic or emotional reasons, Amdahl's Law served as a technical defense for their preference.

Amdahl's Law. Fig. 2 Amdahl's original 32-processor speedup graph (reconstructed)

Estimates of the “Serial Fraction” Prove Pessimistic

The algebra of Amdahl's Law is unassailable since it describes the fundamental way speeds add algebraically, for a fixed amount of work. However, the estimate of the serial fraction f (originally 35%, give or take 10%) was only an estimate by Amdahl and was not based on mathematics.

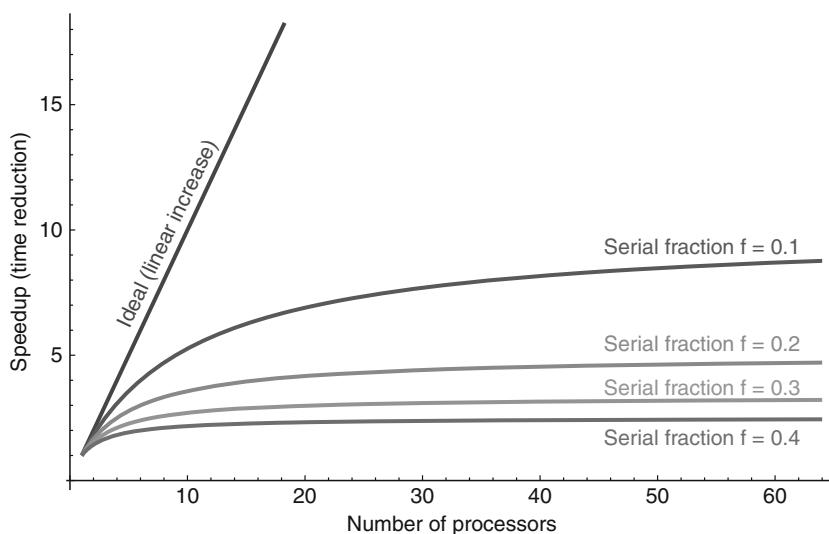

There exist algorithms that are inherently almost 100% serial, such as a time-stepping method for a physics simulation involving very few spatial variables. There are also algorithms that are almost 100% parallel, such as ray tracing methods for computer graphics, or computing the Mandelbrot set. It therefore seems *reasonable* that there might be a rather even distribution of serial fraction from 0 to 1 over the entire space of computer applications. The following figure shows another common way to visualize the effects of Amdahl's Law, with speedup as a function of the number of processors. Figure 3 shows performance curves for serial fractions 0.1, 0.2, 0.3, and 0.4 for a 64-processor computer system.

The limitations of Amdahl's Law for performance prediction were highlighted in 1985, when IBM scientist Alan Karp publicized a skeptical challenge (and a token award of \$100) to anyone who could demonstrate a speedup of over 200 times on three real computer applications [9]. He had just returned from a conference at which startup companies nCUBE and Thinking

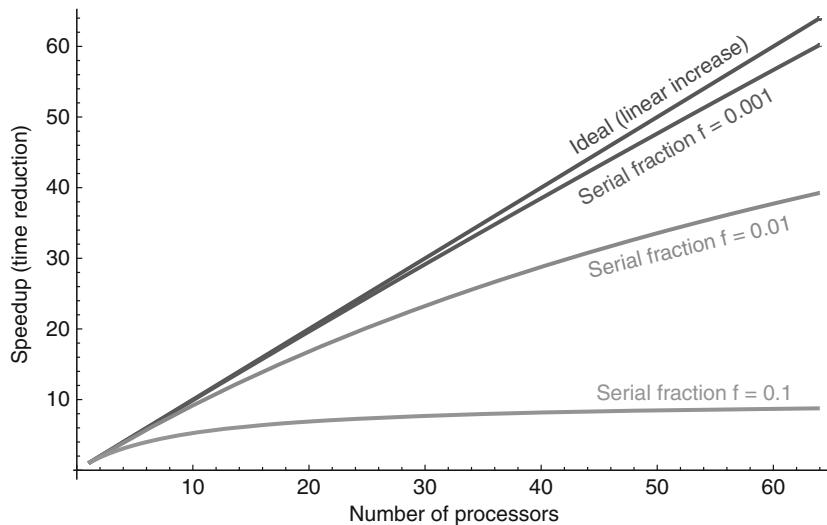

Machines had announced systems with over 1,000 processors, and Karp gave the community 10 years to solve the problem putting a deadline at the end of 1995 to achieve the goal. Karp suggested fluid dynamics, structural analysis, and econometric modeling as the three application areas to draw from, to avoid the use of contrived and unrealistic applications. The published speedups of the 1985 era tended to be less than tenfold and used applications of little economic value (like how to place N queens on a chessboard so that no two can attack each other).

The Karp Challenge was widely distributed by e-mail but received no responses for years, suggesting that if 200-fold speedups were possible, they required more than a token amount of effort. C. Gordon Bell, also interested in promoting the advancement computing, proposed a similar challenge but with two alterations: He raised the award to \$1,000, and said that it would be given annually to the greatest parallel speedup achieved on three real applications, but only awarded if the speedup was at least twice that of the previous award. This definition was the original Gordon Bell Prize [2], and Bell envisioned that the first award might be for something close to tenfold speedup, with increasingly difficult advances after that.

By late 1987, Sandia scientists John Gustafson, Gary Montry, and Robert Benner undertook to demonstrate high parallel speedup on applications from fluid

Amdahl's Law. Fig. 3 Speedup curves for large serial fractions

Amdahl's Law. Fig. 4 Speedup curves for smaller serial fractions

dynamics, structural mechanics, and acoustic wave propagation. They recognized that an Amdahl-type speedup (now called “strong scaling”) was more challenging to achieve than some of the speedups claimed for distributed memory systems like Caltech’s Cosmic Cube [5] that altered the problem according to the number of processors in use. However, using a 1,024-processor nCUBE 10, the three Sandia researchers were able to achieve performance on 1,024 processors ranging from 502X to 637X that of a single processor running the same size problem, implying the Amdahl serial fraction was only 0.0006–0.001 for those applications. This showed that the historical estimates of values for the serial fraction in Amdahl’s formula might be far too high, at least for some applications. While the mathematics of Amdahl’s Law is unassailable, it was a poorly substantiated opinion that the actual values of the serial fraction for computing workloads would always be too high to permit effective use of parallel computing.

Figure 4 shows Amdahl’s Law, again for a 64-processor system, but with serial fractions of 0.1, 0.01, and 0.001.

The TOP500 list ranks computers by their ability to solve a dense system of linear equations. In November 2009, the top-ranked system (Jaguar, Oak Ridge National Laboratories) achieved over 75% parallel efficiency using 224,256 computing cores. For Amdahl’s Law to hold, the serial fraction must be about *one part per million* for this system.

Observable Fraction and Superlinear Speedup

For many scientific codes, it is simple to instrument and measure the amount of time f spent in serial execution. One can place timers in the program around serial regions and obtain an estimate of f that might or might not strongly depend on the input data. One can then apply this fraction for Amdahl’s Law estimates of time reduction, or Gustafson’s Law estimates of scaled speedup. Neither law takes into account communication costs or intermediate degrees of parallelism.

A more common practice is to measure the parallel speedup as the number of processors is varied, and fit the resulting curve to derive f . This approach may yield some guidance for programmers and hardware developers, but it confuses serial fraction with communication overhead, load imbalance, changes in the relative use of the memory hierarchy, and so on. The term “strong scaling” refers to the requirement to keep the problem size the same for any number of processors. A common phenomenon that results from “strong scaling” is that when spreading a problem across more and more processors, the *memory per processor* goes down to the point where the data fits entirely in cache, resulting in *superlinear speedup* [4]. Sometimes, the superlinear speedup effects and the communication overheads partially cancel out, so what appears to be a low value of f is actually the result of the combination of the two effects. In modern parallel systems, performance

analysis with Amdahl's original law alone will usually be inaccurate, since so many other parallel processing phenomena have large effects on the speedup.

Impact on Parallel Computing

Even at the time of the 1967 AFIPS conference, there was already enough investment in serial computing software that the prospect of rewriting all of it to use parallelism was quite daunting. Amdahl's Law served as a strong defense against having to rewrite the code to exploit multiple processors. Efforts to create experimental parallel computer systems proceeded in the decades that followed, especially in academic or research laboratory settings, but the major high-performance computer companies like IBM, Digital, Cray, and HP did not create products with a high degree of parallelism, and cited Amdahl's Law as the reason. It was not until the 1988 solution to the Karp Challenge, which made clear that Amdahl's Law need not limit the utility of highly parallel computing, that vendors began developing commercial parallel products in earnest.

Implicit Assumptions, and Extensions to the Law

Fixed Problem Size

The assumption that the computing community overlooked for 20 years was that the problem size is fixed. If one applies many processors (or other performance enhancement) to a workload, it is not necessarily true that users will keep the workload fixed and accept shorter times for the execution of the task. It is common to increase the workload on the faster machine to the point where it takes the same amount of time as before.

In comparing two things, the scientific approach is to control all but one variable. The natural choice when comparing the performance of two computations is to run the same problem in both situations and look for a change in the execution time. If speed is w/t where w is work and t is time, then speedup for two situations is the ratio of the speeds: $(w_1/t_1)/(w_2/t_2)$. By keeping the work the same, that is, $w_1 = w_2$, the speedup simplifies to t_2/t_1 , and this avoids the difficult problem of defining "work" for a computing task. Amdahl's Law uses this "fixed-size speedup" assumption. While the assumption is reasonable for small values of speedup, it

is less reasonable when the speeds differ by many orders of magnitude. Since the execution time of an application tends to match human patience (which differs according to application), people might scale the problem such that the *time* is constant and thus is the controlled variable. That is, $t_1 = t_2$, and the speedup simplifies to w_1/w_2 . See *Gustafson's Law*.

System Cost: Linear with the Number of Processors?

Another implicit assumption is that system cost is linear in the number of processors, so anything less than perfect speedup implies that cost-effectiveness goes down every time an approach uses more processors. At the time Amdahl made his argument in 1967, this was a reasonable assumption: a system with two IBM processors would probably have cost almost exactly twice that of an individual IBM processor. Amdahl's paper even states that "... by putting two processors side by side with shared memory, one would find approximately 2.2 times as much hardware," where the additional 0.2 hardware is for sharing the memory with a crossbar switch. He further estimated that memory conflicts would add so much time that net price performance of a dual-processor system would be 0.8 that of a single processor.

His cost assumptions are not valid for present-era system designs. As Moore's Law has decreased the cost of transistors to the point where a single silicon chip holds many processors in the same package that formerly held a single processor, it is apparent that system costs are far below linear in the number of processors. Processors share software and other facilities that can cost much more than individual processor cores. Thus, while Amdahl's algebraic formula is true, the implications it provided in 1967 for optimal system design have changed. For example, it might be that increasing the number of processors by a factor of 4 only provides a net speedup of 1.3X for the workload, but if the quadrupling of processors only increases system cost by 1.2X, the cost-effectiveness of the system increases with parallelism. Put another way, the point of diminishing returns for adding processors in 1967 might have been a single processor. With current economics, it might be a very large number of processors, depending on the application workload.

All-or-None Parallelism

In the Amdahl model, there are only two levels of concurrency for the use of N processors: N -fold parallel or serial. A more realistic and detailed model recognizes that the amount of exploitable parallelism might vary from one to N processors through the execution of a program [13]. The speedup is then

$$\text{Speedup} = 1 / (f_1 + f_2/2 + f_3/3 + \dots + f_N/N),$$

where f_j is the fraction of the program that can be run on j processors in parallel, and $f_1 + f_2 + \dots + f_N = 1$.

Sharing of Resources

Because the parallelism model was that of multiple processors controlled by a single instruction stream, Amdahl formulated his argument for the parallelism of a single job, not the parallelism of multiple users running multiple jobs. For parallel computers with multiple instruction streams, if the duration of a serial section is longer than the time it takes to swap in another job in the queue, there is no reason that $N - 1$ of the N processors need to go idle as long as there are users waiting for the system. As the previous section mentions, the degree of parallelism can vary throughout a program. A sophisticated queuing system can allocate processing resources to other users accordingly, much as systems partition memory dynamically for different jobs.

Communication Cost

Because Amdahl formulated his argument in 1967, he treated the cost of *communication* of data between processors as negligible. At that time, computer arithmetic took so much longer than data motion that the data motion was overlapped or insignificant. Arithmetic speed has improved much more than the speed of interprocessor communication, so many have improved Amdahl's Law as a performance model by incorporating communication terms in the formula.

Some have suggested that communication costs are part of the serial fraction of Amdahl's Law, but this is a misconception. Interprocessor communication can be serial or parallel just as the computation can. For example, a communication algorithm may ask one processor to send data to all others in sequence (completely serial) or it may ask each processor j to send data to

processor $j - 1$, except that processor 1 sends to processor N , forming a communication ring (completely parallel).

Analogies

Without mentioning Amdahl's Law by name, others have referred, often humorously, to the limitations of parallel processing. Fred Brooks, in *The Mythical Man-Month* (1975), pointed out the futility of trying to complete software projects in less time by adding more people to the project [3]. "Brooks' Law" is his observation that adding engineers to a project can actually make the project take longer. Brooks quoted the well-known quip, "Nine women can't have a baby in one month," and may have been the first to apply that quip to computer technology.

From 1898 to 1906, Ambrose Bierce wrote a collection of cynical definitions called *The Devil's Dictionary*. It includes the following definition:

- ▶ Logic, *n.* The art of thinking and reasoning in strict accordance with the limitations and incapacities of human misunderstanding. The basis of logic is the syllogism, consisting of a major and a minor premise and a conclusion – thus:

Major Premise: Sixty men can do a piece of work 60 times as quickly as one man.

Minor Premise: One man can dig a post-hole in 60s; therefore –

Conclusion: Sixty men can dig a post-hole in 1s.

This may be called the syllogism arithmetical, in which, by combining logic and mathematics, we obtain a double certainty, and are twice blessed.

In showing the absurdity of using 60 processors (men) for an inherently serial task, he predated Amdahl by almost 70 years.

Transportation provides accessible analogies for Amdahl's Law. For example, if one takes a trip at 30 miles per hour and immediately turns around, how fast does one have to go to average 60 miles per hour? This is a trick question that many people incorrectly answer, "90 miles per hour." To average 60 miles per hour, one would have to travel back at infinite speed and *instantly*. For a fixed travel distance, just as for a fixed workload, speeds do not combine as a simple

arithmetic average. This is contrary to our intuition, which may be the reason some consider Amdahl's Law such a profound observation.

Perspective

Amdahl's 1967 argument became a justification for the avoidance of parallel computing for over 20 years. It was appropriate for many of the early parallel computer designs that shared an instruction stream or the memory fabric or other resources. By the 1980s, hardware approaches emerged that looked more like collections of autonomous computers that did not share anything yet were capable of cooperating on a single task. It was not until Gustafson published his alternative formulation for parallel speedup in 1988, along with several examples of actual 1,000-fold speedups from a 1024-processor system, that the validity of the parallel-computing approach became widely accepted outside the academic community. Amdahl's Law still is the best rule-of-thumb when the goal of the performance improvement is to reduce execution time for a fixed task, whereas Gustafson's Law is the best rule-of-thumb when the goal is to increase the problem size for a fixed amount of time. Amdahl's and Gustafson's Laws do not contradict one another, nor is either a corollary or equivalent of the other. They are for different assumptions and different situations.

Gene Amdahl, in a 2008 personal interview, stated that he never intended his argument to be applied to the case where each processor had its own operating system and data management, and would have been far more open to the idea of parallel computing as a viable approach had it been posed that way. He is now a strong advocate of parallel architectures and sits on the technical advisory board of Massively Parallel Technologies, Inc.

With the commercial introduction of single-image systems with over 100,000 processors such as Blue Gene, and clusters with similar numbers of server processor cores, it becomes increasingly unrealistic to use a fixed-size problem to compare the performance of a single processor with that of the entire system. Thus, scaled speedup (Gustafson's Law) applies to measure performance of the largest systems, with Amdahl's Law applied mainly where the number of processors changes over a narrow range.

Bibliographic Notes and Further Reading

Amdahl's original 1967 paper is short and readily available online, but as stated in the Discussion section, it has neither the formula nor any direct analysis. An objective analysis of the Law and its implications can be found in [8] or [10]. The series of editions of the textbook on computer architecture by Hennessey and Patterson [7] began in 1990 with a strong alignment to Amdahl's 1967 debate position against parallel computing, and has evolved a less strident stance in more recent editions.

For a rigorous mathematical treatment of Amdahl's Law that covers many of the extensions and refinements mentioned in the Discussion section, see [13]. One of the first papers to show how fixed-sized speedup measurement is prone to superlinear speedup effects is [4].

A classic 1989 work on speedup and efficiency is "Speedup versus efficiency in parallel systems" by D. L. Eager, J. Zahorjan, and E. D. Lazowska, in *IEEE Transactions*, March 1989, 408–423. DOI=10.1109/12.21127.

²Columbia University, New York, NY, USA

Definition

Anton is a special-purpose supercomputer architecture designed by D. E. Shaw Research to dramatically

accelerate molecular dynamics (MD) simulations of biomolecular systems. Anton performs massively parallel computation on a set of identical MD-specific ASICs that interact in a tightly coupled manner using a specialized high-speed communication network. Anton enabled, for the first time, the simulation of proteins at an atomic level of detail for periods on the order of a millisecond – about two orders of magnitude beyond the previous state of the art – allowing the observation of important biochemical phenomena that were previously inaccessible to both computational and experimental study.

Discussion

Introduction

Classical molecular dynamics (MD) simulations give scientists the ability to trace the motions of biological molecules at an atomic level of detail. Although MD simulations have helped yield deep insights into the molecular mechanisms of biological processes in a way that could not have been achieved using only laboratory experiments [17, 18], such simulations have historically been limited by the speed at which they can be performed on conventional computer hardware.

A particular challenge has been the simulation of functionally important biological events that often occur on timescales ranging from tens of microseconds to a millisecond, including the “folding” of proteins into their native three-dimensional shapes, the structural changes that underlie protein function, and the interactions between two proteins or between a protein and a candidate drug molecule. Such long-timescale simulations pose a much greater challenge than simulations of larger chemical systems at more moderate timescales: the number of processors that can be used effectively in parallel scales with system size but not with simulation length, because of the sequential dependencies within a simulation.

Anton, a specialized, massively parallel supercomputer developed by D. E. Shaw Research, accelerated such calculations by several orders of magnitude compared with the previous state of the art, enabling the simulation of biological processes on timescales that might otherwise not have been accessible for many years. The first 512-node Anton machine (Fig. 1), which became operational in late 2008, completed an all-atom

protein simulation spanning more than a millisecond of biological time in 2009 [30]. By way of comparison, the longest such simulation previously reported in the literature, which was performed on general-purpose computer hardware using the MD code NAMD, was 10 microseconds (μ s) in length [9]; at the time, few other published simulations had reached 2 μ s (Table 1).

An Anton machine comprises a set of identical processing nodes, each containing a specialized MD computation engine implemented as a single ASIC (Fig. 2). These processing nodes are connected through a specialized high-performance network to form a three-dimensional torus. Anton was designed to use both novel parallel algorithms and special-purpose logic to dramatically accelerate those calculations that dominate the time required for a typical MD simulation [29]. The remainder of the simulation algorithm

is executed by a programmable portion of each chip that achieves a substantial degree of parallelism while preserving the flexibility necessary to accommodate anticipated advances in physical models and simulation methods.

Anton was created to attack a somewhat different problem than the ones addressed by several other projects that have deployed significant computational resources for MD simulations. The Folding@Home project [24], for example, uses hundreds of thousands of PCs (made available over the Internet by volunteers) to simulate a very large number of *separate* molecular trajectories, each of which is limited to the timescale accessible on a single PC. While a great deal can be learned from a large number of independent MD trajectories, many other important problems require the examination of a single, very long trajectory – the principal

Anton, A Special-Purpose Molecular Simulation Machine. Fig. 2 Block diagram of a single Anton ASIC, comprising the specialized high-throughput interaction subsystem, the more general-purpose flexible subsystem, six inter-chip torus links, an intra-chip communication ring, and two memory controllers

task for which Anton was designed. Other projects have produced special-purpose hardware (e.g., FAST-RUN [7], MDGRAPE [33], and MD Engine [34]) to accelerate the most computationally expensive elements of an MD simulation. Such hardware reduces the effective *cost* of simulating a given period of biological time, but Amdahl's law and communication bottlenecks prevent the efficient use of enough such chips in parallel to extend individual simulations beyond timescales of a few microseconds.

Anton was named after Anton van Leeuwenhoek, often referred to as the “father of microscopy.” In the seventeenth century, van Leeuwenhoek built high-precision optical instruments that allowed him to visualize bacteria and other microorganisms, as well as blood cells and spermatozoa, revealing for the first time an entirely new biological world. In pursuit of an

analogous goal, Anton (the machine) was designed as a sort of “computational microscope,” providing contemporary biological and biomedical researchers with a tool for understanding organisms and their diseases at previously inaccessible spatial and temporal scales. Anton has enabled substantial advances in the study of the processes by which proteins fold, function, and interact with drugs [26, 31].

Structure of a Molecular Dynamics Computation

An MD simulation computes the motion of a collection of atoms – for example, a protein surrounded by water – over a period of time according to the laws of classical physics. Time is broken into a series of discrete *time steps*, each representing a few femtoseconds of simulated time. For each time step, the simulation

performs a computationally intensive force calculation for each atom, followed by a less expensive integration operation that advances the positions and velocities of the atoms.

Forces are evaluated based on a model known as a *force field*. Anton supports a variety of commonly used biomolecular force fields, which express the total force on an atom as a sum of three types of component forces: (1) bonded forces, which involve interactions between small groups of atoms connected by one or more covalent bonds; (2) van der Waals forces, which include interactions between all pairs of atoms in the system, but which fall off quickly with distance and are typically only evaluated for nearby pairs of atoms; and (3) electrostatic forces, which include interactions between all pairs of charged atoms, and fall off slowly with distance.

Electrostatic forces are typically computed by one of several fast, approximate methods that account for long-range effects without requiring the explicit interaction of all pairs of atoms. Anton, like most MD codes for general-purpose hardware, divides electrostatic interactions into two contributions. The first decays rapidly with distance, and is thus computed directly for all atom pairs separated by less than some cutoff radius. This contribution and the van der Waals interactions together constitute the *range-limited interactions*. The second contribution (*long-range interactions*) decays more slowly, but can be expressed as a convolution and efficiently computed using fast Fourier transforms (FFTs) [27]. This process requires the mapping of charges from atoms to nearby mesh points before the FFT computations (*charge spreading*), and the calculation of forces on atoms based on values associated with nearby mesh points after the FFT computations (*force interpolation*).

The Role of Specialization in Anton

During the five years spent designing and building Anton, the number of transistors on a chip increased by roughly tenfold, as predicted by Moore's law. Anton, on the other hand, enabled simulations approximately 1,000 times faster than was possible at the beginning of that period, providing access to biologically critical millisecond timescales significantly sooner than would have been possible on commodity hardware. Achieving this performance required reengineering

how MD is done, simultaneously considering changes to algorithms, software, and, especially, hardware.

Hardware specialization allows Anton to redeploy resources in ways that benefit MD. Compared to other high-performance computing applications, MD uses much computation and communication but surprisingly little memory. Anton exploits this property by using only SRAMs and small first-level caches on the ASIC, constraining all code and data to fit on-chip in normal operation (for chemical systems that exceed SRAM size, Anton pages state to each node's local DRAM). The area that would have been spent on large caches and aggressive memory hierarchies is instead dedicated to computation and communication. Each Anton ASIC contains dedicated, specialized hardware datapaths to evaluate the range-limited interactions and perform charge spreading and force interpolation, packing much more computational logic on a chip than is typical of general-purpose architectures. Each ASIC also contains programmable processors with specialized instruction set architectures tailored to the remainder of the MD computation. Anton's specialized network fabric not only delivers bandwidth and latency two orders of magnitude better than Gigabit Ethernet, but also sustains a large fraction of peak network bandwidth when delivering small packets and provides hardware support for common MD communication patterns such as multicast [5].

The most computationally intensive parts of an MD simulation – in particular, the electrostatic interactions – are also the most well established and unlikely to change as force field models evolve, making these calculations particularly amenable to hardware acceleration. Dramatically speeding up MD, however, requires that one accelerates more than just an “inner loop.” Calculation of electrostatic and van der Waals forces accounts for roughly 90% of the computational time for a representative MD simulation on a single general-purpose processor. Amdahl's law states that no matter how much one accelerates this calculation, the remaining computations, left unaccelerated, would limit the maximum speedup to a factor of 10. Hence, Anton dedicates a significant fraction of silicon area to accelerating other tasks, such as bonded force computation and integration, incorporating programmability as appropriate to accommodate a variety of force fields and simulation features.

System Architecture

The building block of an Anton system is a node, which includes an ASIC with two major computational subsystems (Fig. 2). The first is the *high-throughput interaction subsystem* (HTIS), designed for computing massive numbers of range-limited pairwise interactions of various forms. The second is the *flexible subsystem*, which is composed of programmable cores used for the remaining, less structured part of the MD calculation. The Anton ASIC also contains a pair of high-bandwidth DRAM controllers (augmented with the ability to accumulate forces and other quantities), six high-speed (50.6 Gbit/s per direction) channels that provide communication to neighboring ASICs, and a host interface that communicates with an external host computer for input, output, and general control of the Anton system. The ASICs are implemented in 90-nm technology and clocked at 485 MHz, with the exception of the arithmetically intensive portion of the HTIS, which is clocked at 970 MHz.

An Anton machine may incorporate between 1 and 32,768 nodes, each of which is responsible for updating the position of particles within a distinct region of space during a simulation. One 2048-node machine, one 1024-node machine, ten 512-node machines, and several smaller machines were operational as of June 2010. For a given machine size, the nodes are connected to form a three-dimensional torus (i.e., a three-dimensional mesh that wraps around in each dimension, which maps naturally to the periodic boundary conditions used during most MD simulations). Four nodes are incorporated in each node board, and 32 node boards fit in a 19-inch rack; larger machines are constructed by linking racks together.

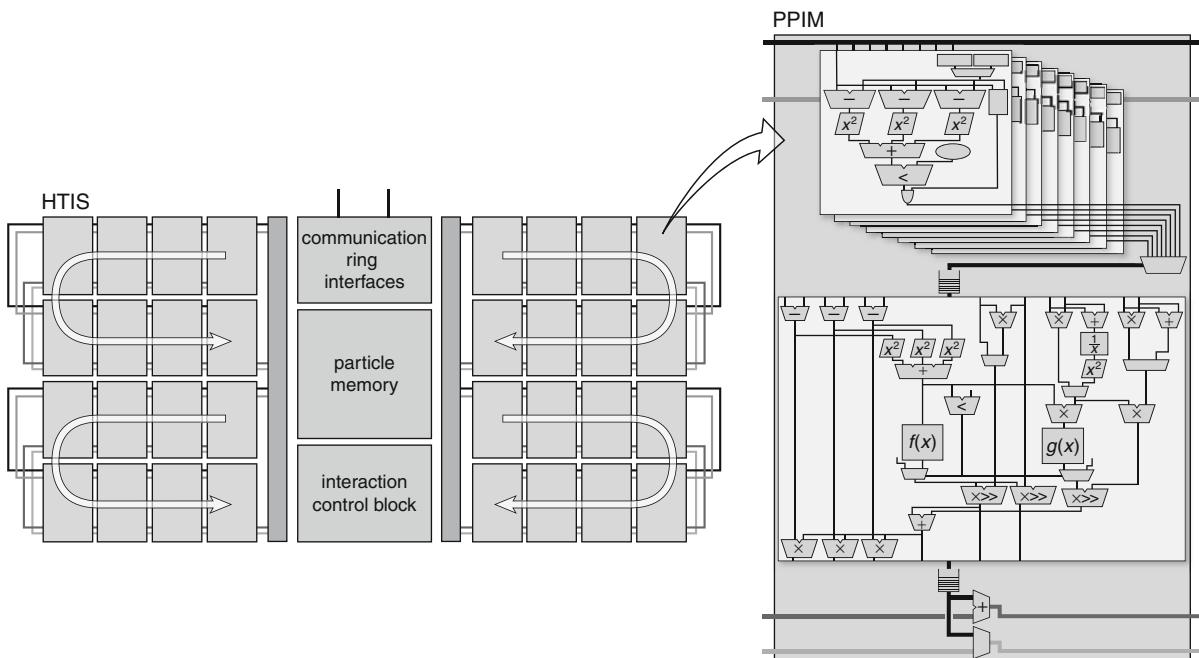

Almost all computation on Anton uses fixed-point arithmetic, which can be thought of as operating on twos-complement numbers in the range $[-1, 1]$. In practice, most of the quantities handled in an MD simulation fall within well-characterized, bounded ranges (e.g., bonds are between 1 and 3 Å in length), so there is no need for software or hardware to dynamically normalize fixed-point values. Use of fixed-point arithmetic reduces die area requirements and facilitates the achievement of certain desirable numerical properties: for example, repeated Anton simulations will produce bitwise identical results even when performed on different numbers of nodes, and molecular trajectories

produced by Anton in certain modes of operation are exactly reversible (a physical property guaranteed by Newton's laws but rarely achieved in numerical simulation) [30].

The High-Throughput Interaction Subsystem (HTIS)

The HTIS is the largest computational accelerator in Anton, handling the range-limited interactions, charge spreading, and force interpolation. These tasks account for a substantial majority of the computation involved in an MD simulation and require several hundred microseconds per time step on general-purpose supercomputers. The HTIS accelerates these computations such that they require just a few microseconds on Anton, using an array of 32 hardwired *pairwise point interaction modules* (PPIMs) (Fig. 3). The heart of each PPIM is a force calculation pipeline that computes the force between a pair of particles; this is a 26-stage pipeline (at 970 MHz) of adders, multipliers, function evaluation units, and other specialized datapath elements. The functional units of this pipeline use customized numerical precisions: bit width varies across the different stages to minimize die area while ensuring an accurate 32-bit result. The HTIS keeps these pipelines operating at high utilization through careful choreography of data flow both between chips and within a chip. A single HTIS can perform 25,600 interactions per microsecond; a modern x86 core, by contrast, can perform about 60 interactions per microsecond [20]. Despite its name, the HTIS also addresses latency: a 512-node Anton performs the entire range-limited interaction computation of a 23,000-atom MD time step in just 3 μs, over two orders of magnitude faster than any contemporaneous general-purpose computer.

The computation is parallelized across chips using a novel technique, the NT method [28], which requires less communication bandwidth than traditional methods for parallelizing range-limited interactions. Figure 4 shows the spatial volume from which particle data must be imported into each node using the NT method compared with the import volume required by the traditional “half-shell” approach. As the level of parallelism increases, the import volume of the NT method becomes progressively smaller in both absolute and asymptotic terms than that of the traditional method.

Anton, A Special-Purpose Molecular Simulation Machine. Fig. 3 High-throughput interaction subsystem (HTIS) and detail of a single pairwise point interaction module (PPIM). In addition to the 32 PPIMs, the HTIS includes two communication ring interfaces, a buffer area for particle data, and an embedded control core called the *interaction control block*. The U-shaped arrows show the flow of data through the particle distribution and force reduction networks. Each PPIM includes eight matchmaking units (shown stacked), a number of queues, and a force calculation pipeline that computes pairwise interactions

The NT method requires that each chip compute interactions between particles in one spatial region (the *tower*) and particles in another region (the *plate*). The HTIS uses a streaming approach to bring together all pairs of particles from the two sets. Figure 3 depicts the internal structure of the HTIS, which is dominated by the two halves of the PPIM array. The HTIS loads tower particles into the PPIM array and streams the plate particles through the array, past the tower particles. Each plate particle accumulates the force from its interactions with tower particles as it streams through the array. While the plate particles are streaming by, each tower particle also accumulates the force from its interactions with plate particles. After the plate particles have been processed, the accumulated tower forces are streamed out.

Not all plate particles need to interact with all tower particles; some pairs, for example, exceed the cutoff distance. To improve the utilization of the force calculation

pipelines, each PPIM includes eight dedicated *match units* that collectively check each arriving plate particle against the tower particles stored in the PPIM to determine which pairs may need to interact, using a low-precision distance test. Each particle pair that passes this test and satisfies certain other criteria proceeds to the PPIM's force calculation pipeline. As long as at least one-eighth of the pairs checked by the match units proceed, the force calculation pipeline approaches full utilization.

In addition to range-limited interactions, the HTIS performs charge spreading and force interpolation. Anton is able to map these tasks to the HTIS by employing a novel method for efficient electrostatics computation, *k*-space Gaussian Split Ewald (*k*-GSE) [27], which employs radially symmetric spreading and interpolation functions. This radial symmetry allows the hardware that computes pairwise nonbonded interactions between pairs of particles to be reused for

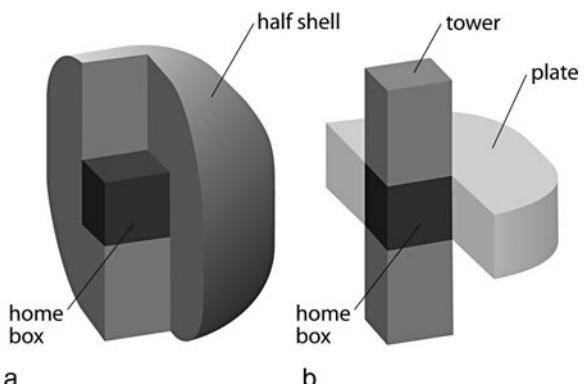

interactions between particles and grid points. Both the *k*-GSE method and the NT method were developed while re-examining fundamental MD algorithms during the design phase of Anton.

The Flexible Subsystem

Although the HTIS handles the most computationally intensive parts of an Anton calculation, the flexible subsystem performs a far wider variety of tasks. It initiates each force computation phase by sending particle positions to multiple ASICs. It handles those parts of force computation not performed in the HTIS, including calculation of bonded force terms and the FFT. It performs all integration tasks, including updating positions and velocities, constraining some particle pairs to be separated by a fixed distance, modulating temperature and pressure, and migrating atoms between nodes as the molecular system evolves. Lastly, it performs all boot, logging, and maintenance activities. The computational details of these tasks vary substantially from one MD simulation to another, making programmability a requirement.

The flexible subsystem contains eight *geometry cores* (GCs) that were designed at D. E. Shaw Research to perform fast numerical computations, four control cores (Tensilica LXs) that coordinate the overall data flow in the Anton system, and four data transfer engines that allow communication to be hidden behind computation. The GCs perform the bulk of the flexible subsystem's computational tasks, and they have been customized in a number of ways to speed up MD. Each GC is a dual-issue, statically scheduled SIMD processor with pipelined multiply accumulate support. The GC's basic data type is a vector of four 32-bit fixed-point values, and two independent SIMD operations on these vectors issue each cycle. The GC's instruction set includes element-wise vector operations (for example, vector addition), more complicated vector operations such as a dot product (which is used extensively in calculating bonded forces and applying distance constraints), and scalar operations that read and write arbitrary scalar components of the vector registers (essentially accessing the SIMD register file as a larger scalar register file).

Each of the four control cores manages a corresponding programmable data transfer engine, used to coordinate communication and synchronization for the

Anton: A Special-Purpose Molecular Simulation Machine.

Fig. 4 Import regions associated with two parallelization methods for range-limited pairwise interactions. (a) In a traditional spatial decomposition method, each node imports particles from the half-shell region so that they can interact with particles in the home box. (b) In the NT method, each node computes interactions between particles in a tower region and particles in a plate region. Both of these regions include the home box, but particles in the remainder of each region must be imported. In both methods, each pair of particles within the cutoff radius of one another will have their interaction computed on some node of the machine

flexible subsystem. In addition to the usual system interface and cache interfaces, each control core also connects to a 32-KB scratchpad memory, which holds MD simulation data for background transfer by the data transfer engine. These engines can be programmed to write data from the scratchpad to network destinations and to monitor incoming writes for synchronization purposes. The background data transfer capability provided by these engines is crucial for performance, as it enables overlapped communication and computation. The control cores also handle maintenance tasks, which tend not to be performance-critical (e.g., checkpointing every million time steps).

Considerable effort went into keeping the flexible subsystem from becoming an Amdahl's law bottleneck. Careful scheduling allows some of the tasks performed by the flexible subsystem to be partially overlapped with or completely hidden behind communication or HTIS computation [19]. Adjusting parameters for the algorithm used to evaluate electrostatic forces (including the

cutoff radius and the FFT grid density) shifts computational load from the flexible subsystem to the HTIS [30]. A number of mechanisms balance load among the cores of the flexible subsystem and across flexible subsystems on different ASICs to minimize Anton's overall execution time. Even with these and other optimizations, the flexible subsystem remains on the critical path for up to one-third of Anton's overall execution time.

Communication Subsystem

The *communication subsystem* provides high-speed, low-latency communication both between ASICs and among the subsystems within an ASIC [5]. Within a chip, two 256-bit, 485-MHz communication rings link all subsystems and the six inter-chip torus ports. Between chips, each torus link provides 50.6-Gbit/s full-duplex communication with a hop latency around 50 ns. The communication subsystem supports efficient multicast, provides flow control, and provides class-based admission control with rate metering.

In addition to achieving high bandwidth and low latency, Anton supports fine-grained inter-node communication, delivering half of peak bandwidth on messages of just 28 bytes. These properties are critical to delivering high performance in the communication-intensive tasks of an MD simulation. A 512-node Anton machine, for example, performs a $32 \times 32 \times 32$, spatially distributed 3D FFT in under 4 μs , an order of magnitude faster than the contemporary implementations in the literature [35].

Software

Although Anton's hardware architecture incorporates substantial flexibility, it was designed to perform variants of a single application: molecular dynamics. Anton's software architecture exploits this fact to maximize application performance by eliminating many of the layers of a traditional software stack. The Anton ASICs, for example, do not run a traditional operating system; instead, the control cores of the flexible subsystem run a loader that installs code and data on the machine, simulates for a time, then unloads the results of the completed simulation segment.

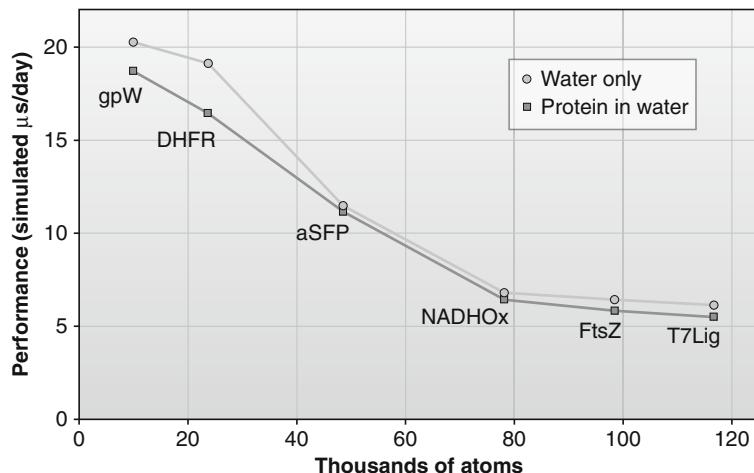

Programming Anton is complicated by the heterogeneous nature of its computational units. The geometry cores of the flexible subsystem are programmed in

assembly language, while the control cores of the flexible subsystem and a control processor in the HTIS are programmed in C augmented with intrinsics. Various fixed-function hardware units, such as the PPIMs, are programmed by configuring state machines and filling tables. Anton's design philosophy emphasized performance over ease of programmability, although increasingly sophisticated compilers and other tools to simplify programming are under development.

Anton Performance

Figure 5 shows the performance of a 512-node Anton machine on several different chemical systems, varying in size and composition. On the widely used Joint AMBER-CHARMM benchmark system, which contains 23,558 atoms and represents the protein dihydrofolate reductase (DHFR) surrounded by water, Anton simulates 16.4 μs per day of wall-clock time [30]. The fastest previously reported simulation of this system was obtained using a software package, called Desmond, which was developed within our group for use on commodity clusters [2]. This Desmond simulation executed at a rate of 471 nanoseconds (ns) per day on a 512-node 2.66-GHz Intel Xeon E5430 cluster connected by a DDR InfiniBand network, using only two of the eight cores on each node in order to maximize network bandwidth per core [3]. (Using more nodes, or more cores per node, leads to a decrease in performance as a result of an increase in communication requirements.) Due to considerations related to the efficient utilization of resources, however, neither Desmond nor other high-performance MD codes for commodity clusters are typically run at such a high level of parallelism, or in a configuration with most cores on each node idle. In practice, the performance realized in such cluster-based simulations is generally limited to speeds on the order of 100 ns/day. The previously published simulations listed in Table 1, for example, ran at 100 ns/day or less – over two orders of magnitude short of the performance we have demonstrated on Anton.

Anton machines with fewer than 512 nodes may prove more cost effective when simulating certain smaller chemical systems. A 512-node Anton machine can be partitioned, for example, into four 128-node machines, each of which achieves 7.5 $\mu\text{s}/\text{day}$ on the DHFR system – well over 25% of the 16.4 $\mu\text{s}/\text{day}$

Anton: A Special-Purpose Molecular Simulation Machine. Fig. 5 Performance of a 512-node Anton machine for chemical systems of different sizes. All simulations used 2.5-femtosecond time steps with long-range interactions evaluated at every other time step; additional simulation parameters can be found in Table 4 of reference [30]

achieved when parallelizing the same simulation across all 512 nodes. Configurations with more than 512 nodes deliver increased performance for larger chemical systems, but do not benefit chemical systems with only a few thousand atoms, for which the increase in communication latency outweighs the increase in parallelism.

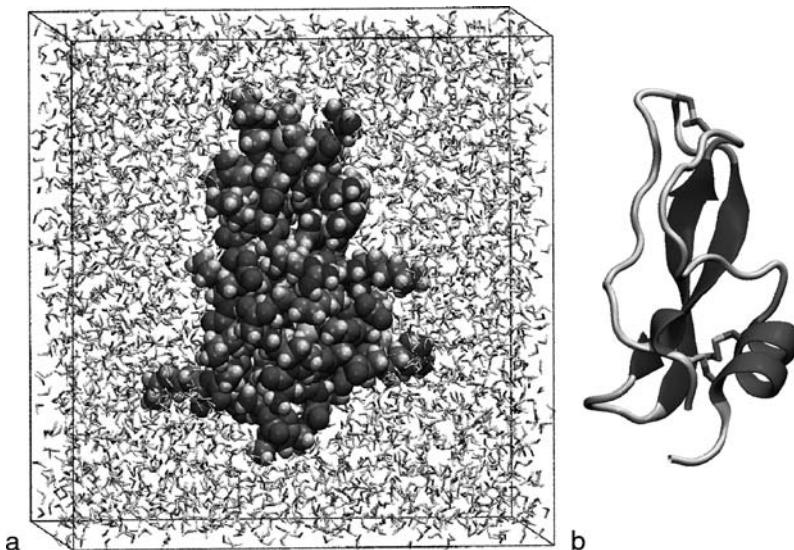

Prior to Anton's completion, few reported all-atom protein simulations had reached 2 μ s, the longest being a 10- μ s simulation that took over 3 months on the NCSA Abe supercomputer [9] (Table 1). On June 1, 2009, Anton completed the first millisecond-long simulation – more than 100 times longer than any reported previously. This 1,031- μ s simulation modeled a protein called bovine pancreatic trypsin inhibitor (BPTI) (Fig. 6), which had been the subject of many previous MD simulations; in fact, the first MD study of a protein, published in 1977 [23], simulated BPTI for 9.2 ps. The Anton simulation, which was over 100 million times longer, revealed unanticipated behavior that was not evident at previously accessible timescales, including transitions among several distinct structural states [30, 31].

Future Directions

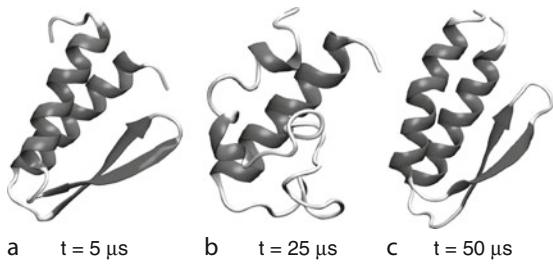

Commodity computing benefits from economies of scale but imposes limitations on the extent to which

an MD simulation, and many other high-performance computing problems, can be accelerated through parallelization. The design of Anton broke with commodity designs, embraced specialized architecture and co-designed algorithms, and achieved a three-order-of-magnitude speedup over a development period of approximately five years. Anton has thus given scientists, for the first time, the ability to perform MD simulations on the order of a millisecond – 100 times longer than any atomically detailed simulation previously reported on either general-purpose or special-purpose hardware. For computer architects, Anton's level of performance raises the questions of which other high-performance computing problems might be similarly accelerated, and whether the economic or scientific benefits of such acceleration would justify building specialized machines for those problems.

In its first two years of operation, Anton has begun to serve as a “computational microscope,” allowing the observation of biomolecular processes that have been inaccessible to laboratory experiments and that were previously well beyond the reach of computer simulation. Anton has revealed, for example, the atomic-level mechanisms by which certain proteins fold (Fig. 7) and the structural dynamics underlying the function of important drug targets [26, 31]. Anton's predictive power has been demonstrated

Anton: A Special-Purpose Molecular Simulation Machine. Fig. 6 Two renderings of a protein (BPTI) taken from a molecular dynamics simulation on Anton. (a) The entire simulated system, with each atom of the protein represented by a sphere and the surrounding water represented by thin lines. For clarity, water molecules in front of the protein are not pictured. (b) A “cartoon” rendering showing important structural elements of the protein (secondary and tertiary structure)

Anton: A Special-Purpose Molecular Simulation Machine. Fig. 7 Unfolding and folding events in a 236- μ s simulation of the protein gpW, at a temperature that equally favors the folded and unfolded states. Panel (a) shows a snapshot of a folded structure early in the simulation, (b) is a snapshot after the protein has partially unfolded, and (c) is a snapshot after it has folded again. Anton has also simulated the folding of several proteins from a completely extended state to the experimentally observed folded state

through comparison with experimental observations [25, 30]. Anton thus provides a powerful complement to laboratory experiments in the investigation of fundamental biological processes, and holds promise as a tool for the design of safe, effective, precisely targeted drugs.

Bibliographic Notes and Further Reading

The first Anton machine was developed at D. E. Shaw Research between 2003 and 2008. The overall architecture was described in [29], with the HTIS, the flexible subsystem, and the communication subsystem described in more detail in [20], [19], and [5], respectively. Initial performance results were presented in [30], and initial scientific results in [31] and [26]. Other aspects of the Anton architecture, software, and design process are described in several additional papers [13, 14, 16, 35].

A number of previous projects built specialized hardware for MD simulation, including MD-GRAPE [33], MD Engine [34], and FASTRUN [7]. Extensive effort has focused on efficient parallelization of MD on general-purpose architectures, including IBM’s Blue

Gene [8] and commodity clusters [1, 2, 15]. More recently, MD has also been ported to the Cell BE processor [21] and to GPUs [32].

Array Languages

CALVIN LIN

University of Texas at Austin, Austin, TX, USA

Definition

An array language is a programming language that supports the manipulation of entire arrays – or portions of arrays – as a basic unit of operation.

Discussion

Array languages provide two primary benefits: (1) They raise the level of abstraction, providing conciseness and programming convenience; (2) they provide a natural source of data parallelism, because the multiple elements of an array can typically be manipulated concurrently. Both benefits derive from the removal of control flow. For example, the following array statement assigns each element of the B array to its corresponding element in the A array:

```
A := B;
```

This same expression could be expressed in a scalar language using an explicit looping construct:

```
for i := 1 to n
  for j := 1 to n
    A[i][j] := B[i][j];
```

The array statement is conceptually simpler because it removes the need to iterate over individual array elements, which includes the need to name individual elements. At the same time, the array expression admits more parallelism because it does not over-specify the order in which the pairs of elements are evaluated; thus,

the elements of the B array can be assigned to the elements of the A array in any order, provided that they obey array language semantics. (Standard array language semantics dictate that the righthand side of an assignment be fully evaluated before its value is assigned to the variable on the lefthand side of the assignment.)

For the above example, the convenience of array operators appears to be minimal, but in the context of a parallel computer, the benefits to programmer productivity can be substantial, because a compiler can translate the above array statement to efficient parallel code, freeing the programmer from having to deal with many low-level details that would be necessary if writing in a lower-level language, such as MPI. In particular, the compiler can partition the work and compute loop bounds, handling the messy cases where values do not divide evenly by the number of processors. Furthermore, if the compiler can statically identify locations where communication must take place, it can allocate extra memory to cache communicated values, and it can insert communication where necessary, including any necessary marshalling of noncontiguous data. Even for shared memory machines, the burden of partitioning work, inserting appropriate synchronization, etc., can be substantial.

Array Indexing

Array languages can be characterized by the mechanisms that they provide for referring to portions of an array. The first array language, APL, provided no method of accessing portions of an array. Instead, in APL, all operators are applied to all elements of their array operands.

Languages such as Fortran 90 use array *slices* to concisely specify indices for each dimension of an array. For example, the following statement assigns the upper left 3×3 corner of array A to the upper left corner of array B.

$$B(1:3, 1:3) = A(1:3, 1:3)$$

The problem with slices is that they introduce considerable redundancy, and they force the programmer to perform index calculations, which can be error prone. For example, consider the Jacobi iteration, which computes for each array element the average of its four nearest neighbors:

$$\begin{aligned} B(2:n, 2:n) &= (A(1:n-1, 2:n) + \\ &\quad A(3:n+1, 2:n) + \\ &\quad A(2:n, 1:n-1) + \\ &\quad A(2:n, 3:n+3) + \end{aligned}$$

The problem becomes much worse, of course, for higher-dimensional arrays.

The C* language [13], which was designed for the Connection machine, simplifies array indexing by defining indices that are relative to each array element. For example, the core of the Jacobi iteration can be expressed in C* as follows, where active is an array that specifies the elements of the array where the computation should take place:

```
where (active)
{
    B = ( [.-1] [.] A + [.+1] [.] A
          + [.] [-1] A + [.] [+1] A) /4;
}
```

C*'s relative indexing is less error prone than slices: Each relative index focuses attention on the differences among the array references, so it is clear that the first two array references refer to the neighbors above and below each element and that the last two array references refer to the neighbors to the left and right of each element.

The ZPL language [4] further raises the level of abstraction by introducing the notion of a *region* to represent index sets. Regions are a first-class language construct, so regions can be named and manipulated. The ability to name regions is important because – for software maintenance and readability reasons – descriptive names are preferable to constant values. The ability to manipulate regions is important because – like C*'s relative indexing – it defines new index sets relative to existing index sets, thereby highlighting the relationship between the new index set and the old index set.

To express the Jacobi iteration in ZPL, programmers would use the At operator (@) to translate an index set by a named vector:

```
[R] B := (A@north + A@south +
           A@west + A@east) /4;
```

The above code assumes that the programmer has defined the region R to represent the index set $[1:n][1:n]$, has defined north to be a vector whose value is $[-1, 0]$, has defined south to be a vector

whose value is $[+1,0]$, and so forth. Given these definitions, the region R provides a base index set $[1:n][1:n]$ for every reference to a two-dimensional array in this statement, so R applies to every occurrence of A in this statement. The direction `north` shifts this base index set by -1 in the first dimension, etc. Thus, the above statement has the same meaning as the Fortran 90 slice notation, but it uses named values instead of hard-coded constants.

ZPL provides other region operators to support other common cases, and it uses regions in other ways, for example, to declare array variables. More significantly, regions are quite general, as they can represent sparse index sets and hierarchical index sets.

More recently, the Chapel language from Cray [5] provides an elegant form of relative indexing that can take multiple forms. For example, the below Chapel code looks almost identical to the ZPL equivalent, except that it includes the base region, R , in each array index expression:

```
T[R] = (A[R+north] + A[R+south] +
        A[R+east] + A[R+west]) / 4.0;
```

Alternatively, the expression could be written from the perspective of a single element in the index set:

```
[ij in R] T(ij) = (A(ij+north) +
                      A(ij+south) +
                      A(ij+east) +
                      A(ij+west)) / 4.0;
```

The above formulation is significant because it allows the variable `ij` to represent an element of an arbitrary tuple, where the tuple (referred to as a *domain* in Chapel) could represent many different types of index sets, including sparse index sets, hierarchical index sets, or even nodes of a graph.

Finally, the following Chapel code fragment shows that the tuple can be decomposed into its constituent parts, which allows arbitrary arithmetic to be performed on each part separately:

```
[(i,j) in R] A(ij) = (A(i-1,j) +
                        A(i+1,j) +
                        A(i,j-1) +
                        A(i,j+1)) / 4.0;
```

The FIDIL language [9] represents an early attempt to raise the level of abstraction, providing support for

irregular grids. In particular, FIDIL supports index sets, known as *domains*, which are first-class objects that can be manipulated through union, intersection, and difference operators.

Array Operators

Array languages can also be characterized by the set of array operators that they provide. All array languages support elementwise operations, which are the natural extension of scalar operators to array operands. The Array Indexing section showed examples of the elementwise `+` and `=` operators.

While element-wise operators are useful, at some point, data parallel computations need to be combined or summarized, so most array languages provide reduction operators, which combine – or reduce – multiple values of an array into a single scalar value. For example, the values of an array can be reduced to a scalar by summing them or by computing their maximum or minimum value.

Some languages provide additional power by allowing reductions to be applied to a subset of an array's dimensions. For example, each row of values in a two-dimensional array can be reduced to produce a single column of values. In general, a partial reduction accepts an n -dimensional array of values and produces an m -dimensional array of values, where $m < n$. This construct can be further generalized by allowing the programmer to specify an arbitrary associative and commutative function as the reduction operator.

Parallel prefix operators – also known as scan operators – are an extension of reductions that produce an array of partial values instead of a single scalar value. For example, the prefix sum accepts as input n values and computes all sums, $x_0 + x_1 + x_2 + \dots + x_k$ for $0 \leq k \leq n$. Other parallel prefix operations are produced by replacing the `+` operator with some other associative operator. (When applied to multi-dimensional arrays, the array indices are linearized in some well-defined manner, e.g., using Row Major Order.)

The parallel prefix operator is quite powerful because it provides a general mechanism for parallelizing computations that might seem to require sequential iteration. In particular, sequential loop iterations that accumulate information as they iterate can typically be solved using a parallel prefix.

Given the ability to index an individual array element, programmers can directly implement their own reduction and scan code, but there are several benefits of language support. First, reduction and scan are common abstractions, so good linguistic support makes these abstractions easier to read and write. Second, language support allows their implementations to be customized to the target machine. Third, compiler support introduces nontrivial opportunities for optimization: When multiple reductions or scans are performed in sequence, their communication components can be combined to reduce communication costs.

Languages such as Fortran 90 and APL also provide additional operators for flattening, re-shaping, and manipulating arrays in other powerful ways. These languages also provide operators such as matrix multiplication and matrix transpose that treat arrays as matrices. The inclusion of matrix operations blurs the distinction between array languages and matrix languages, which are described in the next section.

Matrix Languages

Array languages should not be confused with matrix languages, such as Matlab [7]. An array is a programming language construct that has many uses. By contrast, a matrix is a mathematical concept that carries additional semantic meaning. To understand this distinction, consider the following statement:

```
A = B * C;
```

In an array language, the above statement assigns to A the element-wise product of B and C. In a matrix language, the statement multiples B and C.

The most popular matrix language, Matlab, was originally designed as a convenient interactive interface to numeric libraries, such as EISPACK and LINPACK, that encourages exploration. Thus, for example, there are no variable declarations. These interactive features make Matlab difficult to parallelize, because they inhibit the compiler's ability to carefully communication the computation and communication.

Future Directions

Array language support can be extended in two dimensions. First, the restriction to flat dense arrays is too limiting for many computations, so language support for sparsely populated arrays, hierarchical arrays, and

irregular pointer-based data structures are also needed. In principle, Chapel's domain construct supports all of these extensions of array languages, but further research is required to fully support these data structures and to provide good performance. Second, it is important to integrate task parallelism with data parallelism, as is being explored in languages such as Chapel and X10.

Bibliographic Notes and Further Reading

The first array language, APL [10], was developed in the early 1960s and has often been referred to as the first write-only language because of its terse, complex nature.

Subsequent array languages that extended more conventional languages began to appear in the late 1980s. For example, extensions of imperative languages include C* [13], FIDIL [9], Dataparallel C [8], and Fortran 90 [1]. NESL [3] is a functional language that includes support for nested one dimensional arrays.

In the early 1990s, High Performance Fortran (HPF) was a data parallel language that extended Fortran 90 and Fortran 77 to provide directives about data distribution. At about the same time, the ZPL language [12] showed that a more abstract notion of an array's index set could lead to clear and concise programs.

More recently, the DARPA-funded High-Productivity Computing Systems project led to the development of Chapel [5] and X10 [6], which both integrate array languages with support for task parallelism.

Ladner and Fischer [11] presented key ideas of the parallel prefix algorithm, and Blelloch [2] elegantly demonstrated the power of the scan operator for array languages.

Discussion

Introduction to Array Languages

There are several programming languages providing a rich set of array operations and intrinsic functions along with array constructs to assist data-parallel programming. They include Fortran 90, High Performance Fortran (HPF), APL and MATLAB, etc. Most of them provide programmers array intrinsic functions and array operations to manipulate data elements of multidimensional arrays concurrently without requiring iterative statements. Among these array languages, Fortran 90 is a typical example, which consists of an extensive set of array operations and intrinsic functions as shown in [Table 1](#). In the following paragraphs, several examples will be provided to bring readers basic information about array operations and intrinsic functions supported by Fortran 90. Though in the examples only Fortran 90 array operations are used for illustration, the array programming concepts and compiler techniques are applicable to common array languages.

Fortran 90 extends former Fortran language features to allow a variety of scalar operations and intrinsic functions to be applied to arrays. These array operations and intrinsic functions take array objects as inputs, perform a specific operation on array elements concurrently, and return results in scalars or arrays. The code fragment below is an array accumulation example, which involves two two-dimensional arrays and one array-add operation. In this example, all array elements in the array *S* is going to be updated by accumulating by those of array *A* in corresponding positions. The accumulation result, also a two-dimensional 4×4 array, is at last stored back to array *S*, in which each data element contains element-wise sum of array *A* and array *S*.

```
integer S(4,4), A(4,4)
```

```
S = S + A
```

Besides primitive array operations, Fortran 90 also provides programmers a set of array intrinsic functions to manipulate array objects. These intrinsic functions listed in [Table 1](#) include functions for data movement,

Compiler optimizations for array languages

Definition

Compiler techniques for array languages generally include compiler supports, optimizations and code generation for programs expressed or annotated by all kinds of array languages. These compiler techniques mainly take advantage of data-parallelism explicit in

Array Languages, Compiler Techniques for. Table 1 Array intrinsic functions in Fortran 90

Array intrinsics	Functionality
CSHIFT	Circular-shift elements of the input array along one specified dimension
DOT_PRODUCT	Compute dot-product of two input arrays as two vectors
EOSHIFT	End-off shift elements of the input array along one specified dimension
MATMUL	Matrix multiplication
MERGE	Combine two conforming arrays under the control of an input mask
PACK	Pack an array under the control of an input mask
Reduction	Reduce an array by one specified dimension and operator
RESHAPE	Construct an array of a specified shape from elements of the input array
SPREAD	Replicate an array by adding one dimension
Section move	Perform data movement over a region of the input array
TRANSPOSE	Matrix transposition
UNPACK	Unpack an array under the control of an input mask

matrix multiplication, array reduction, compaction, etc. In the following paragraphs, two examples using array intrinsic functions are provided: the first one with array reduction and the second one with array data movement.

The first example, shown in the code fragment below, presents a way to reduce an array with a specific operator. The SUM intrinsic function, one instance of array reduction functions in Fortran 90, sums up an input array along a specified dimension. In this example, a two-dimension 4×4 array A, composed of total 16 elements, is passed to SUM with its first dimension specified as the target for reduction. After reduction by SUM, it is expected that the SUM will return a one-dimension array consisting of four elements, each of them corresponds to a sum of the array elements in the first dimension.

```
integer A(4,4), S(4)
```

```
S = SUM(A,1)
```

The second example presents a way to reorganize data elements within an input array with array intrinsic functions. The circular-shift (CSHIFT) intrinsic function in Fortran 90 performs data movement over an input array along a given dimension. Given a two-dimensional array, it can be considered to shift data elements of the input array to the left or right, up or down in a circular manner. The first argument of CSHIFT indicates the input array to be shifted while the rest two arguments specify the shift amount and the dimension along which data are shifted. In the code fragment below, one two-dimensional array, A, is going to be shifted by one-element offset along the first dimension. If the initial contents of array A are labeled as the left-hand side of Fig. 1, after the circular-shift its data contents will be moved to new positions as shown in the right-hand side of Fig. 1, where the first row of A sinks to the bottom and the rest move upward by one-element offset.

```
integer A(4,4)
```

```
A = CSHIFT(A,1,1)
```

Compiler Techniques for Array Languages

So far, readers may have experienced the concise representation of array operations and intrinsic functions. The advantages brought by array operations mainly focus on exposing data parallelism to compilers for concurrent data processing. The exposed data parallelism can be used by compilers to generate efficient code to be executed on parallel architectures, such as vector processors, multi-processors and VLIW processors. Array operations provide abundant parallelism to be exploited by compilers for delivering performance on those parallel processors. In the following paragraphs, two compiler techniques on compiling Fortran 90 array operations will be elaborated to readers. Though these techniques are originally developed for Fortran 90, they are also applicable to common array languages, such as Matlab and APL.

The first technique covers array operation synthesis for consecutive array operations, which treats array intrinsic functions as mathematical functions. In the synthesis technique, each array intrinsic function has its data access function that specifies its data access pattern and the mapping relationship between its input and

Array Languages, Compiler Techniques for. Fig. 1 Array contents change after CSHIFT (shift amount = 1, dimension = 1)

output arrays. Through providing data access functions for all array operations, this technique can synthesize multiple array operations into a composite data access function, which expresses data accesses and computation to generate the target arrays from source arrays. In this way, compiling programs directly by the composite data access function can greatly improve performance by reducing redundant data movement and temporary storages required for passing immediate results.

The second compiler technique concerns compiler supports and optimizations for sparse array programs. In contrast with dense arrays, sparse arrays consist of much more zero elements than nonzero elements. Having this characteristic, they are more applicable than dense arrays in many scientific applications. For example, sparse linear systems, such as Boeing–Harwell matrix, are with popular usages. Similar to dense arrays, there are demands for support of array operations and intrinsic functions to elaborate data parallelism in sparse matrices. Later on, we will have several paragraphs illustrating how to support sparse array operations in Fortran 90, and we will also cover some optimizing techniques for sparse programs.

Synthesis for Array Operations

In the next paragraphs, an array operation synthesis technique targeting on compiling Fortran 90 array operations is going to be elaborated. This synthesis technique can be applied to programs that contain consecutive array operations. Array operations here include not only those of Fortran 90 but all array operations that can be formalized into data access functions. With this technique, compilers can generate efficient codes by removing redundant data movement and temporary storages, which are often introduced in compiling array programs.

Consecutive Array Operations

As shown in the previous examples, array operations take one or more arrays as inputs, conduct a specific operation to them, and return results in an array or a scalar value. For more advanced usage, multiple array operations can be cascaded to express compound computation over arrays. An array operation within the consecutive array operations takes inputs either from input arrays or intermediate results from others, processing data elements and passing its results to the next. In this way, they conceptually describe a particular relationship between source arrays and target arrays.

The following code fragment is an example with consecutive array operations, which involves three array operations, TRANSPOSE, RESHAPE, and CSHIFT, and three arrays, A(4, 4), B(4, 4), and C(16). The cascaded array operations at first transpose array A and reshape array C into two 4 × 4 matrices, afterwards sum the two 4 × 4 intermediate results, and finally circular-shift the results along its first dimension. With this example, readers may experience the concise representation and power of compound array operations in the way manipulating arrays without iterative statements.

```
integer A(4, 4), B(4, 4), C(16)
```

```
B = CSHIFT((TRANSPOSE(A)
+ RESHAPE(C, /4, 4/)), 1, 1)
```

To compile programs with consecutive array operations, one straightforward compilation may translate each array operation into a parallel loop and create temporary arrays to pass intermediate results used by rest array operations. Take the previous code fragment as an example, at first, compilers will separate the TRANSPOSE function from the consecutive array operations and create a temporary array T1 to keep the transposed results. Similarly, another array T2 is created for the RESHAPE function, and these two temporary arrays, T1 and T2, are summed into another temporary array, T3. At last, T3 is taken by the CSHIFT and used to produce the final results in the target array B.

```
integer A(4, 4), B(4, 4), C(16)
```

```
integer T1(4, 4), T2(4, 4), T3(4, 4)
```

```
T1 = TRANSPOSE(A)
```

```
T2 = RESHAPE(C, /4, 4/)
```

```
T3 = T1 + T2
B = CSHIFT(T3, 1, 1)
```

This straightforward scheme is inefficient as it introduces unnecessary data movement between temporary arrays and temporary storages for passing intermediate results. To compile array programs in a more efficient way, array operation synthesis can be applied to obtain a function F at compile-time such that $B = F(A, C)$, which is the synthesized data access function of the compound operations and it is functionally identical to the original sequence of array operations. The synthesized data access function specifies a direct mapping from source arrays to target arrays, and can be used by compilers to generate efficient code without introducing temporary arrays.

Data Access Functions

The concept of data access functions needs to be further elaborated here. An array operation has its own data access function that specifies element-wise mapping between its input and output arrays. As array operations in Fortran 90 have various formats, there are different looks of data access functions. In the following paragraphs, total three types of data access functions for different types of array operations will be provided as the basis of array operation synthesis.

The first type of data access functions is for array operations that contain a single source array and comply with continuous data accessing, such as TRANSPOSE and SPREAD in Fortran 90. For an array operation with n -dimensional target array T and m -dimensional source array S , which can be annotated in $T = \text{Array_Operation}(S)$, its data access function can be represented as equation (1). In equation (1), f_i in the right hand side is an index function representing an array subscript of the source array S , where the array subscripts from i_1 to i_n are index variables of the target array T . For example, the data access function for $T = \text{TRANSPOSE}(S)$ is as follows: $T[i, j] = S[j, i]$ where the index functions by definition are $f_1(i, j) = j$ and $f_2(i, j) = i$.

$$T[i_1, i_2, \dots, i_n] = S[f_1(i_1, i_2, \dots, i_n), f_2(i_1, i_2, \dots, i_n), \dots, f_m(i_1, i_2, \dots, i_n)] \quad (1)$$

The second type of data access functions is for array operations that also have a single source array but with

segmented data accessing, which means data in the arrays are accessed in parts or with strides. Due to segmented data access, the data access functions cannot be represented in a single continuous form. Instead, they have to be described by multiple data access patterns, each of which covers an disjointed array index range. To represent an array index range, a notation called, segmentation descriptors, can be used, which are boolean predicates of the form:

$$\phi(/f_i(i_1, i_2, \dots, i_n), \dots, f_m(i_1, i_2, \dots, i_n), /l_1 : u_1 : s_1, l_2 : u_2 : s_2, \dots, l_m : u_m : s_m/)$$

where f_i is an index function and l_i , u_i , and s_i are the lower bound, upper bound, and stride of the index function $f_i(i_1, i_2, \dots, i_n)$. The stride s_i can be omitted if it is equal to one, representing contiguous data access. For example, the segmented descriptor $\phi(/i, j/, /4 : 4, 1 : 4/)$ delimits the range of $(i = 4, j = 1 : 4)$.

After providing a notation for segmented index ranges, let us go back to array operations with single source and segmented data access functions, such as CSHIFT and EOSHIFT in Fortran 90. For an array operation with an n -dimensional target array T and an m -dimensional source array S , annotated in $T = \text{Array_Operation}(S)$, its data access function can be represented as follows:

$$T[i_1, i_2, \dots, i_n] = \begin{cases} S[f_1(i_1, i_2, \dots, i_n), f_2(i_1, i_2, \dots, i_n), \dots, f_m(i_1, i_2, \dots, i_n)] | \gamma_1 \\ S[g_1(i_1, i_2, \dots, i_n), g_2(i_1, i_2, \dots, i_n), \dots, g_m(i_1, i_2, \dots, i_n)] | \gamma_2 \\ \dots \end{cases} \quad (2)$$

where γ_1 and γ_2 are two separate array index ranges for index function f_i and g_i respectively. Take CSHIFT as an example, for an array operation $B = \text{CSHIFT}(A, 1, 1)$ with the input A and output B are both 4×4 arrays, its data access function can be represented as equation (3). In equation (3), the data access function of $\text{CSHIFT}(A, 1, 1)$ is divided into two parts, describing different sections of the target array B will be computed by different formulas: for the index range, $i = 4, j = 1 \sim 4$, $B[i, j]$ is assigned by the value of $A[i-3, j]$; for the index

range, $i = 1 \sim 3$, $j = 1 \sim 4$, $B[i, j]$ is assigned by the value of $A[i + 1, j]$.

$$B[i, j] = \begin{cases} A[i - 3, j] | \phi(/i, j/, /4 : 4, 1 : 4/) \\ A[i + 1, j] | \phi(/i, j/, /1 : 3, 1 : 4/) \end{cases} \quad (3)$$

The third type of data access functions is for array operations with multiple source arrays and continuous data access. For an array operation with k source arrays, annotated as $T = \text{Array_Operation}(S_1, S_2, \dots, S_k)$, its data access function can be represented as equation (4), where F is a k -nary function used to describe how the desired output to be derived by k data elements from the input arrays. Each element from source arrays is associated with an index function of the form f_i^j , where i and j indicates its input array number and dimension, respectively. Take whole-array addition $C(:, :) = A(:, :) + B(:, :)$ as an example, its data access function can be represented in $C[i, j] = F(A[i, j], B[i, j])$, where $F(x, y) = x + y$.

$$\begin{aligned} T[i_1, i_2, \dots, i_n] &= F(S_1 [f_1^1(i_1, i_2, \dots, i_n), \\ &\quad f_1^2(i_1, i_2, \dots, i_n), \dots, f_1^{d1}(i_1, i_2, \dots, i_n)], \dots, \\ &\quad S_k [f_k^1(i_1, i_2, \dots, i_n), f_k^2(i_1, i_2, \dots, i_n), \\ &\quad \dots, f_k^{dk}(i_1, i_2, \dots, i_n)]) \end{aligned} \quad (4)$$

Synthesis of Array Operations

After providing the definition of data access functions, let us begin to elaborate the mechanism of array operation synthesis. For illustration, the synthesis framework can be roughly partitioned into three major steps:

1. Build a parse tree for consecutive array operations
2. Provide a data access function for each array operation
3. Synthesize collected data access functions into a composite one

Throughout the three steps, the consecutive array operations shown in the previous example will again be used as a running example to illustrate the synthesis flow. We replicate the code fragment here for reference.

```
integer A(4,4), B(4,4), C(16)
```

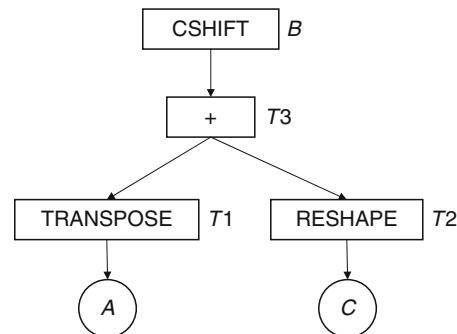

```
B = CSHIFT((TRANSPOSE(A)
+ RESHAPE(C, /4, 4/)), 1, 1)
```

In the first step, a parse tree is constructed for the consecutive array operations. In the parse tree, source arrays are leaf nodes while target arrays are roots, and each internal node corresponds to an array operation. The parse tree for the running example is provided in Fig. 2. All temporary arrays created in the straightforward compilation are arbitrarily given an unique name for identification. In the example, temporary arrays $T1$, $T2$ and $T3$ are attached to nodes of “+,” TRANSPOSE, and RESHAPE as their intermediate results. The root node is labeled with the target array, array B in this example, which will contain the final results of the consecutive array operations.

In the second step, data access functions are provided for all array operations. In the running example, the data access function of $T1 = \text{TRANSPOSE}(A)$ is $T1[i, j] = A[j, i]$; the data access function of $T2 = \text{RESHAPE}(C, /4, 4/)$ is $T2[i, j] = C[i + j * 4]$; the data access function of the $T3 = T1 + T2$ is $T3[i, j] = F_1(T1[i, j], T2[i, j])$, where $F_1(x, y) = x + y$; the data access function of $B = \text{CSHIFT}(T3)$ is as follows:

$$B[i, j] = \begin{cases} T3[i + 1, j] | \phi(/i, j/, /1 : 3, 1 : 4/) \\ T3[i - 3, j] | \phi(/i, j/, /4 : 4, 1 : 4/) \end{cases} \quad (5)$$

In the last step, the collected data access functions are going to be synthesized, starting from the data access

Array Languages, Compiler Techniques for. Fig. 2 The parse tree for consecutive array operations in the running example

function of array operation at the root node. Throughout the synthesis process, every temporary array at right-hand side (RHS) of access function is replaced by the data access function that defines the temporary array. During the substituting process, other temporary arrays will continually appear in the RHS of the updated data access function. This process repeats until all temporary arrays in the RHS are replaced with source arrays.

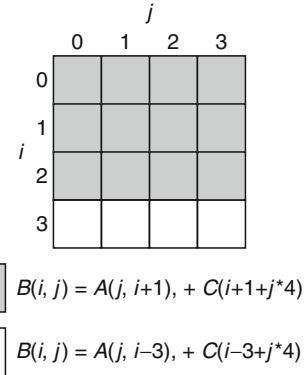

For the running example, the synthesis process begins with the data access function of CSHIFT for it is the root node in the parse tree. The data access function of CSHIFT is listed in Equation (5), in which temporary array $T3$ appears in the right-hand side. To substitute $T3$, the data access function of $T3 = T1 + T2$, which specifies $T3[i, j] = F_1(T1[i, j], T2[i, j])$ is of our interest. After the substitution, it may result in the following data access function:

$$B[i, j] = \begin{cases} F_1(T1[i+1, j], T2[i+1, j]) \mid \phi(/i, j/, /1 : 3, 1 : 4/) \\ F_1(T1[i-3, j], T2[i-3, j]) \mid \phi(/i, j/, /4 : 4, 1 : 4/) \end{cases} \quad (6)$$

In the updated data access function, come out two new temporary arrays $T1$ and $T2$. Therefore, the process continues to substitute $T1$ with $T1[i, j] = A[j, i]$ (the data access function of TRANSPOSE) and $T2$ with $T2[i, j] = C[i + j * 4]$ (the data access function of RESHAPE). At the end of synthesis process, a composite data access function will be derived as follows, containing only the target array B and the source array A and C without any temporary arrays.

$$B[i, j] = \begin{cases} F_1(A[j, i+1], C[i+1+j*4]) \mid \phi(/i, j/, /1 : 3, 1 : 4/) \\ F_1(A[j, i-3], C[i-3+j*4]) \mid \phi(/i, j/, /4 : 4, 1 : 4/) \end{cases} \quad (7)$$

The derived data access function describes a direct and element-wise mapping from data elements in the source arrays to those of the target array. The mapping described by the synthesized data access function can be visualized in Fig. 3. Since the synthesized data access function consists of two formulas with different segmented index ranges, it indicates that two portions of

Array Languages, Compiler Techniques for. Fig. 3
Constituents of the target array are described by the synthesized data access function

the target array B , gray blocks and white blocks in the Fig. 3, will be computed in different manners.

Code Generation with Data Access Functions

After deriving a composite data access function, compilers can generate a parallel loop with FORALL statements for the consecutive array operations. For the running example, compilers may generate the pseudo code below, with no redundant data movement between temporary arrays and therefore no additional storages required.

```
integer A(4,4), B(4,4), C(16)

FORALL i=1 to 4, j=1 to 4
  IF (i,j) ∈ ϕ(/i, j/, /1 : 3, 1 : 4/) THEN
    B[i, j] = A[j, i+1] + C[i+1+j*4]
  IF (i,j) ∈ ϕ(/i, j/, /4 : 4, 1 : 4/) THEN
    B[i, j] = A[j, i-3] + C[i-3+j*4]
END FORALL
```

Optimizations on Index Ranges

The code generated in the previous step consists of only one single nested loop. It is straightforward but inefficient because it includes two if-statements to ensure that different parts of the target array will be computed by different equations. These guarding statements incurred by segmented index ranges will be resolved at runtime and thus lead to performance degradation. To optimize programs with segmented index ranges the loop can be further divided into multiple loops, each of which has a

0	<0,0,0,5,3,0>	0	0	0	0
0	<2,0,1,0,0,0>	<0,0,9,3,0,0>	0	0	0
<9,0,0,0,6,0>	0	0	0	<1,0,6,2,3,5>	0
0	0	0	0	0	<0,2,0,3,4,0>
0	0	<1,0,0,0,7,2>	0	0	0
0	<2,4,2,8,0,0>	0	0	0	<0,0,0,7,3,4>

Array Languages, Compiler Techniques for. Fig. 4 A three-dimensional sparse array $A(6, 6, 6)$

bound to cover its array access range. By the index range optimization, the loop for the running example can be divided into two loops for two disjointed access ranges. At last, we conclude this section by providing efficient code as follows for the running example. It is efficient in array data accessing and promising to deliver performance. For more information about array operation synthesis, readers can refer to [2–4].

```

integer A(4,4), B(4,4), C(16)

FORALL i=1 to 3, j=1 to 4
    B[i,j]= A[j,i+1] + C[i+1+j*4]
END FORALL

FORALL i=4 to 4, j=1 to 4
    B[i,j]=A[j,i-3]+C[i-3+j*4]
END FORALL

```

Support and Optimizations for Sparse Array Operations

In the next section, another compiler technique is going to be introduced, which targets array operation supports and optimizations for sparse arrays. In contrast to dense arrays, sparse arrays consist of more zero elements than nonzero elements. With this characteristic, they are more applicable than dense arrays in many data specific applications, such as network theory and earthquake detection. Besides, they are also extensively used in scientific computation and numerical analysis. To help readers understand sparse arrays, a sparse array

$A(6, 6, 6)$ is depicted in Fig. 4. The sparse array A is a three-dimensional $6 \times 6 \times 6$ matrix with its first two dimensions containing plenty of zero elements, which are zero-vectors in the rows and columns.

Compression and Distribution Schemes for Sparse Arrays

For their sparse property, sparse arrays are usually represented in a compressed format to save computation and memory space. Besides, to process sparse workload on distributed memory environments efficiently sparse computation are often partitioned to be distributed to processors. For these reasons, both compression and distribution schemes have to be considered in supporting parallel sparse computation. Table 2 lists options of compression and distribution schemes for two-dimensional sparse arrays. There will be more detailed descriptions for these compression and distribution in upcoming paragraphs.

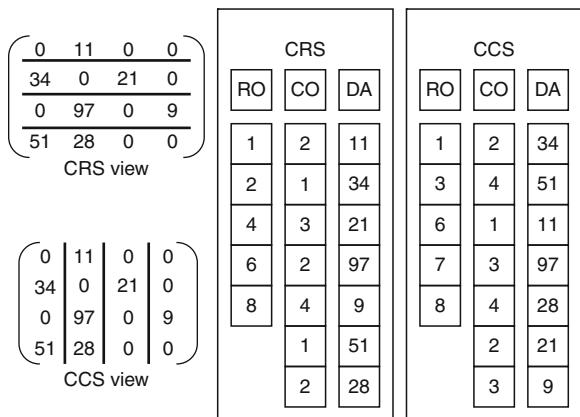

Compression Schemes

For a one-dimensional array, its compression can be either in a dense representation or in a pair-wise sparse representation. In the sparse representation, an array containing index and value pairs are used to record nonzero elements, with no space for keeping zero elements. For example, a one-dimensional array $\{0, 0, 0, 5, 3, 0\}$ can be compressed by the pair $(4, 5)$ and $(5, 3)$, representing two non-zero elements in the array, which are the fourth element equaling to five and the fifth element equaling to three.

Array Languages, Compiler Techniques for. Table 2

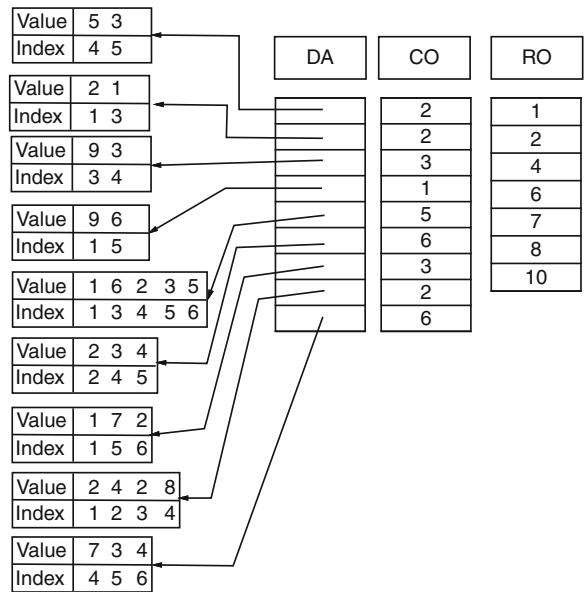

Compression and distribution schemes for two-dimensional arrays

Compression scheme	Distribution scheme
Compressed row storage (CRS)	(Block, *)
Compressed column storage (CCS)	(*, Block)
Dense representation	(Block, Block)

Array Languages, Compiler Techniques for. Fig. 5 CRS and CCS compression schemes for a two-dimensional array

For higher-dimensional arrays, there are two compression schemes for two-dimensional arrays, which are Compressed Row Storage (CRS) and Compressed Column Storage (CCS). They have different ways to compress a two-dimensional array, either by rows or by columns. The CCS scheme regards a two-dimensional array as a one-dimensional array of its rows, whereas the CRS scheme considers it as a one-dimensional array of its columns. Both of them use a CO and DA tuple, an index and data pair, to represent a nonzero element in a one-dimensional array, a row in CRS or a column in CCS. The CO fields correspond to index offsets of nonzero values in a CRS row or in a CCS column. In addition to CO and DA pairs, both CRS and CCS representation contain a RO list that keeps value indexes where each row or column starts. In Fig. 5, we show an example to encode a two-dimensional array with CRS and CCS schemes, where total 7 non-zero values are recorded with their values in the DA fields and CCS column or CRS row indexes in the CO fields.

Array Languages, Compiler Techniques for. Fig. 6 A compression scheme for the three-dimensional array in Fig. 4

Compression schemes for higher-dimensional arrays can be constructed by employing 1-d and 2-d sparse arrays as bases to construct higher-dimensional arrays. Figure 6 shows a compression scheme for the three-dimensional sparse array in Fig. 4. The three-dimensional sparse array is constructed by a two-dimensional CRS structure with each element in the first level is a one-dimensional sparse array. Similarly, one can employ 2-d sparse arrays as bases to build four-dimensional sparse arrays. The representation will be a two-dimensional compressed structure with each DA field in the structure also a two-dimensional compressed structure.

The code fragment below shows an instance to implement three-dimensional sparse arrays for both compression schemes, in which each data field contains a real number. This derived sparse2d_real data type can be used to declare sparse arrays with CRS or CCS compression schemes as the example shown in Fig. 5. All array primitive operations such as +, -, *, etc., and array intrinsic functions applied on the derived type can be overloaded to sparse implementations. In this way, data stored in sparse arrays can be manipulated as

they are in dense arrays. For example, one can conduct a matrix multiplication over two sparse arrays via a sparse matmul, in which only nonzero elements will be computed.

```
type sparse3d_real
  type(descriptor) :: d
  integer, pointer, dimension(:) :: RO
  integer, pointer, dimension(:) :: CO
  type(sparse1d_real), pointer,
    dimension(:) :: DA
end type sparse3d_real
```

Distribution Schemes

In distributed memory environments, data distribution of sparse arrays needs to be considered. The distribution schemes currently considered for sparse arrays are general block partitions based on the number of nonzero elements. For two-dimensional arrays, there are (Block, *), (*, Block) and (Block, Block) distributions. In the (*, Block) scheme a sparse array is distributed by rows, while in the (Block, *) distribution an array is distributed by columns. For the (Block, Block) distribution, an array is distributed both by rows and columns. Similarly, distribution schemes for higher-dimensional arrays can be realized by extending more dimensions in data distribution options.

The following code fragment is used to illustrate how to assign a distribution scheme to a sparse array on a distributed environment. The three-dimensional sparse array in Fig. 4 is again used for explanation. At first, the sparse array is declared as a 3-D sparse array by the derived type, sparse3d_real. Next, the *bound* function is used to specify the shape of the sparse array, specifying its size of each dimension. After shape binding, the sparse array is assigned to a (Block, Block, *) distribution scheme through the *distribution* function, by which the sparse array will be partitioned and distributed along its first two dimensions. Figure 7 shows the partition and distribution situation over a distributed environment with four-processors, where each partition covers data assigned to a target processor.

```
use sparse
type(sparse3d_real):: A

call bound(A, 6,6,6)
call distribution(A, Block, Block, *)
...
```

Programming with Sparse Arrays

With derived data types and operation overloading, sparse matrix computation can also be expressed as

		0 <0,0,0,5,3,0>	0	0	0	0
		0 <2,0,1,0,0,0>	<0,0,9,3,0,0>	0	0	0
	<9,0,0,0,6,0>	0	0	0 <1,0,6,2,3,5>	0	
		0	0	0	0	<0,2,0,3,4,0>
		0	0	<1,0,0,0,7,2>	0	0
		0	<2,4,2,8,0,0>	0	0	<0,0,0,7,3,4>

Array Languages, Compiler Techniques for. Fig. 7 A three-dimensional array is distributed on four processors by (Block, Block, *)

```

integer, parameter :: row = 1000
real, dimension (row,2*row-1) :: A
real, dimension (row) :: x, b
integer, dimension (2*row-1) :: shift

b = sum(A*eoshift (spread (x,dim=2,ncopies=2*row-1),
dim=1,shift=arth(-row+1,1,2*row-1)),dim=2)

```

Array Languages, Compiler Techniques for. Fig. 8
Numerical routines for banded matrix multiplication

concisely as dense computation. The code fragment in Fig. 8 is a part of a Fortran 90 program excerpted from the book, *Numerical Recipes in Fortran 90* [1] with its computation kernel named banded multiplication that calculates $b = Ax$, with the input, A , a matrix and the second input, x , a vector. (For more information about banded vector-matrix multiplication, readers can refer to the book [1].) In Fig. 8, both the input and output are declared as dense arrays, with three Fortran 90 array intrinsic functions, EOSHIFT, SPREAD, and SUM used to produce its results.

When the input and output are sparse matrices with plenty of zero elements, the dense representation and computation will be inefficient. With the support of sparse data types and array operations, the banmul kernel can be rewritten into a sparse version as shown in Fig. 9. Comparing Fig. 8 with Fig. 9, one can find that the sparse implementation is very similar to the dense version, with slight differences in array declaration and extra function calls for array shape binding. By changing inputs and outputs from dense to sparse arrays, a huge amount of space is saved by only recording non-zero elements. Besides, the computation kernel is unchanged thanks to operator overloading, and it tends to have better performance for only processing nonzero elements. One thing to be noted here, the compression and distribution scheme of the sparse implementation are not specified for input and output arrays, and thus the default settings are used. In advanced programming, these schemes can be configured via exposed routines to programmers, which can be used to optimize programs for compressed data organizations. We use following paragraphs to discuss how to select a proper compression and distribution scheme for sparse programs.

```

integer, parameter :: row = 1000
type(sparse2d_real) :: A
type(sparse1d_real) :: x, b
integer, dimension (2*row-1) :: shift

call bound(A, row, 2*row-1)
call bound(x, row)
call bound(b, row)

b = sum(A*eoshift (spread (x,dim=2,ncopies=2*row-1),
dim=1,shift=arth(-row+1,1,2*row-1)),dim=2)

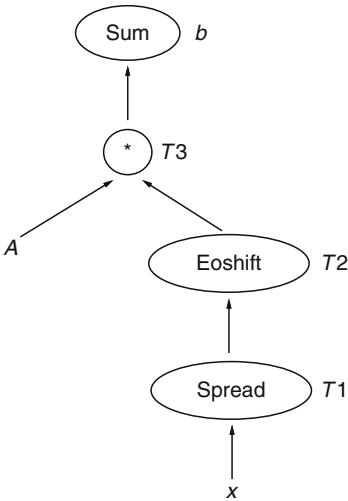

```

Array Languages, Compiler Techniques for. Fig. 9 Sparse implementation for the banmul routine

Selection of Compression and Distribution Schemes

Given a program with sparse arrays, there introduces an optimizing problem, how to select distribution and compression schemes for sparse arrays in the program. In the next paragraphs, two combinations of compression and distribution schemes for the banmul kernel are presented to show how scheme combinations make impact to performance. At first Fig. 10 shows the expression tree of the banmul kernel in Fig. 8, where T_1 , T_2 , and T_3 beside the internal nodes are temporary arrays introduced by compilers for passing intermediate results for array operations. As mentioned before, through exposed routines, programmers can choose compression and distribution schemes for input and output arrays. Nevertheless, it still has the need to figure out proper compression and distribution schemes for temporary arrays since they are introduced by compilers rather than programmers.

The reason why compression schemes for input, output and temporary arrays should be concerned is briefed as follows. When an array operation is conducted on arrays in different compression schemes, it requires data conversion that reorganizes compressed arrays from one compression scheme to another for a conforming format. That is because array operations are designed to process input arrays and return results in one conventional scheme, either in CRS or in CCS. The conversion cost implicit in array operations hurts performance a lot and needs to be avoided.

**Array Languages, Compiler Techniques for. Fig. 10**

Expression tree with intrinsic functions in banmul

Array Languages, Compiler Techniques for. Table 3

Assignments with extra compression conversions needed

Array	Compressed scheme	Distribution scheme
x	$1d$	(Block)
$T1$	CRS	(Block, *)
$T2$	CCS	(Block, *)
$T3$	CRS	(Block, *)
A	CRS	(Block, *)
b	$1d$	(Block)

In [Table 3](#) and [Table 4](#), we present two combinations of compression and distribution schemes for the banmul kernel. To focus on compression schemes, all arrays now have same distribution schemes, (Block) for one-dimensional arrays and (Block, *) for two-dimensional arrays. As shown in [Table 3](#), the input array A and three temporary arrays are in sparse representation, with only $T2$ assigned to CCS scheme and the rest assigned to CRS scheme. When the conversion cost is considered, we can tell that the scheme selection in [Table 4](#) is better than that in [Table 3](#) because it requires less conversions: one for converting the result of Spread to CCS and the other for converting the result of Eoshift to CRS.

Array Languages, Compiler Techniques for. Table 4

Assignments with less compression conversions

Array	Compressed scheme	Distribution scheme
x	$1d$	(Block)
$T1$	CCS	(Block, *)
$T2$	CCS	(Block, *)
$T3$	CCS	(Block, *)
A	CCS	(Block, *)
b	$1d$	(Block)

Sparsity, Cost Models, and the Optimal Selection

To compile sparse programs for distributed environments, in addition to conversion costs, communication costs need to be considered. In order to minimize the total execution time, an overall cost model needs be introduced, which covers three factors that have major impact to performance: computation, communication and compression conversion cost. The costs of computation and communication model time consumed on computing and transferring nonzero elements of sparse arrays, while the conversion cost mentioned before models time consumed on converting data in one compression schemes to another.

All these costs are closely related to the numbers of nonzero elements in arrays, defined as sparsity of arrays, which can be used to infer the best scheme combination for a sparse program. The sparsity informations can be provided by programmers that have knowledge about program behaviors, or they can be obtained through profiling or advanced probabilistic inference schemes discussed in [6]. With sparsity informations, the selection process can be formulated into a cost function that estimates overall execution time to run a sparse program on distributed memory environments. With this paragraph, we conclude the compiler supports and optimizations for sparse arrays. For more information about compiler techniques for sparse arrays, readers can refer to [5, 6].

Bibliographic Notes and Further Reading

For more information about compiler techniques of array operation synthesis, readers can refer to papers [2–4]. Among them, the work in [2, 3] focuses on compiling array operations supported by Fortran 90. Besides this, the synthesis framework, they also provide solutions to performance anomaly incurred by the presence of common subexpressions and one-to-many array operations. In their following work [4], the synthesis framework is extended to synthesize HPF array operations on distributed memory environments, in which communication issues are addressed.

For more information about compiler supports and optimizations for sparse programs, readers can refer to papers [5, 6]. The work in [5] puts lots of efforts to support Fortran 90 array operations for sparse arrays on parallel environments, in which both compression schemes and distribution schemes for multi-dimensional sparse arrays are considered. Besides this, the work also provides a complete complexity analysis for the sparse array implementations and report that the complexity is in proportion to the number of nonzero elements in sparse arrays, which is consistent with the conventional design criteria for sparse algorithms and data structures.

The support of sparse arrays and operations in [5] is divided into a two-level implementation: in the low-level implementation, a sparse array needs to be specified with compression and distribution schemes; in the high-level implementation, all intrinsic functions and operations are overloaded for sparse arrays, and compression and distribution details are hidden in implementations. In the work [6], a compilation scheme is proposed to transform high-level representations to low-level implementations with the three costs, computation, communication and conversion, considered.

Except the compiler techniques mentioned in this entry, there is a huge amount of literature discussing compiler techniques for dense and sparse array programs, which are not limited to Fortran 90. Among them there is a series of work on compiling ZPL [7–9], a language that defines a concise representation for describing data-parallel computations. In [9], another approach similar to array operations synthesis is proposed to achieve the same goal through loop fusion and array contraction. For other sparse program optimizations, there are also several research efforts on Matlab [10–12]. One design and implementation of sparse array support in Matlab is provided in [10], and there are related compiler techniques on Matlab sparse arrays discussed in [11, 12].

Asynchronous Iterative Algorithms

GIORGOS KOLLIAS, ANANTH Y. GRAMA, ZHIYUAN LI
Purdue University, West Lafayette, IN, USA

Synonyms

Asynchronous iterations; Asynchronous iterative computations

Definition

In iterative algorithms, a grid of data points are updated iteratively until some convergence criterion is met. The update of each data point depends on the latest updates of its neighboring points. Asynchronous iterative algorithms refer to a class of parallel iterative algorithms that are capable of relaxing strict data dependencies, hence not requiring the latest updates when they are not ready, while still ensuring convergence. Such relaxation may result in the use of inconsistent data which potentially may lead to an increased iteration count and hence increased computational operations. On the other hand, the time spent on waiting for the latest updates performed on remote processors may be reduced. Where waiting time dominates the computation, a parallel program based on an asynchronous algorithm may outperform its synchronous counterparts.

Discussion

Introduction

Scaling application performance to large number of processors must overcome challenges stemming from

high communication and synchronization costs. While these costs have improved over the years, a corresponding increase in processor speeds has tempered the impact of these improvements. Indeed, the speed gap between the arithmetic and logical operations and the memory access and message passing operations has a significant impact even on parallel programs executing on a tightly coupled shared-memory multiprocessor implemented on a single semiconductor chip.

System techniques such as prefetching and multithreading use concurrency to hide communication and synchronization costs. Application programmers can complement such techniques by reducing the number of communication and synchronization operations when they implement parallel algorithms. By analyzing the dependencies among computational tasks, the programmer can determine a minimal set of communication and synchronization points that are sufficient for maintaining all control and data dependencies embedded in the algorithm. Furthermore, there often exist several different algorithms to solve the same computational problem. Some may perform more arithmetic operations than others but require less communication and synchronization. A good understanding of the available computing system in terms of the tradeoff between arithmetic operations versus the communication and synchronization cost will help the programmer select the most appropriate algorithm.

Going beyond the implementation techniques mentioned above requires the programmer to find ways to relax the communication and synchronization requirement in specific algorithms. For example, an iterative algorithm may perform a convergence test in order to determine whether to start a new iteration. To perform such a test often requires gathering data which are scattered across different processors, incurring the communication overhead. If the programmer is familiar with the algorithm's convergence behavior, such a convergence test may be skipped until a certain number of iterations have been executed. To further reduce the communication between different processors, algorithm designers have also attempted to find ways to relax the data dependencies implied in conventional parallel algorithms such that the frequency of communication can be substantially reduced. The concept of asynchronous iterative algorithms, which dates back over 3 decades, is developed as a result of such attempts.

With the emergence of parallel systems with tens of thousands of processors and the deep memory hierarchy accessible to each processor, asynchronous iterative algorithms have recently generated a new level of interest.

Motivating Applications

Among the most computation-intensive applications currently solved using large-scale parallel platforms are iterative linear and nonlinear solvers, eigenvalue solvers, and particle simulations. Typical time-dependent simulations based on iterative solvers involve multiple levels at which asynchrony can be exploited. At the lowest level, the kernel operation in these solvers are sparse matrix-vector products and vector operations. In a graph-theoretic sense, a sparse matrix-vector product can be thought of as edge-weighted accumulations at nodes in a graph, where nodes correspond to rows and columns and edges correspond to matrix entries. Indeed, this view of a matrix-vector product forms the basis for parallelization using graph partitioners. Repeated matrix-vector products, say, to compute $A^{(n)}y$, while solving $Ax = b$, require synchronization between accumulations. However, it can be shown that within some tolerance, relaxing strict synchronization still maintains convergence guarantees of many solvers. Note that, however, the actual iteration count may be larger. Similarly, vector operations for computing residuals and intermediate norms can also relax synchronization requirements. At the next higher level, if the problem is nonlinear in nature, a quasi-Newton scheme is generally used. As before, convergence can be guaranteed even when the Jacobian solves are not exact. Finally, in time-dependent explicit schemes, some time-skew can be tolerated, provided global invariants are maintained, in typical simulations.

Particle systems exhibit similar behavior to one mentioned above. Spatial hierarchies have been well explored in this context to derive fast methods such as the Fast Multipole Method and Barnes-Hut method. Temporal hierarchies have also been explored, albeit to a lesser extent. Temporal hierarchies represent one form of relaxed synchrony, since the entire system does not evolve in lock steps. Informally, in a synchronous system, the state of a particle is determined by the state of the system in the immediately preceding time step(s) in explicit schemes. Under relaxed models of synchrony,

one can constrain the system state to be determined by the prior state of the system in a prescribed time window. So long as system invariants such as energy are maintained, this approach is valid for many applications. For example, in protein folding and molecular docking, the objective is to find minimum energy states. It is shown to be possible to converge to true minimum energy states under such relaxed models of synchrony.

While these are two representative examples from scientific domains, nonscientific algorithms lend themselves to relaxed synchrony just as well. For example, in information retrieval, PageRank algorithms can tolerate relaxed dependencies on iterative computations [35].

Iterative Algorithms

An iterative algorithm is typically organized as a series of steps essentially of the form

$$x(t+1) \leftarrow f(x(t)) \quad (1)$$

where operator $f(\cdot)$ is applied to some data $x(t)$ to produce new data $x(t+1)$. Here integer t counts the number of steps, assuming starting with $x(0)$, and captures the notion of time. Given certain properties on $f(\cdot)$, that it contracts (or pseudo-contracts) and it has a unique fixed point, and so on, an iterative algorithm is guaranteed to produce at least an approximation within a prescribed tolerance to the solution of the fixed-point equation $x = f(x)$, although the exact number of needed steps cannot be known in advance.

In the simplest computation scenario, data x reside in some Memory Entity (ME) and operator $f(\cdot)$ usually consists of both operations to be performed by some Processing Entity (PE) and parameters (i.e., data) hosted by some ME. For example, if the iteration step is a left matrix-vector multiplication $x \leftarrow Ax$, x is considered to be the “data” and the matrix itself with the set of incurred element-by-element multiplications and subsequent additions to be the “operator”, where the “operator” part also contains the matrix elements as its parameters.

However, in practice this picture can get complicated:

- Ideally x data and $f(\cdot)$ parameters should be readily available to the $f(\cdot)$ operations. This means that one

would like all data to fit in the register file of a typical PE, or even its cache files (data locality). This is not possible except for very small problems which, most of the time, are not of interest to researchers. Data typically reside either in the main memory or for larger problems in a slow secondary memory. Designing data access strategies which feed the PE at the fastest possible rate, in effect optimizing data flow across the memory hierarchy while preserving the semantics of the algorithm, is important in this aspect. Modern multicore architectures, in which many PEs share some levels of the memory hierarchy and compete for the interconnection paths, introduce new dimensions of complexity in the effective mapping of an iterative algorithm.

- There are cases in which data x are assigned to more than one PEs and $f(\cdot)$ is decomposed. This can be the result either of the sheer volume of the data or the parameters of $f(\cdot)$ or even the computational complexity of $f(\cdot)$ application which performs a large number of operations in each iteration on each data unit. In some rarer cases the data itself or the operator remains distributed by nature throughout the computation. Here, the PEs can be the cores of a single processor, the nodes (each consisting of multiple cores and processors) in a shared-memory machine or similar nodes in networked machines. The latter can be viewed as PEs accessing a network of memory hierarchies of multiple machines, i.e., an extra level of ME interconnection paths.

Synchronous Iterations and Their Problems

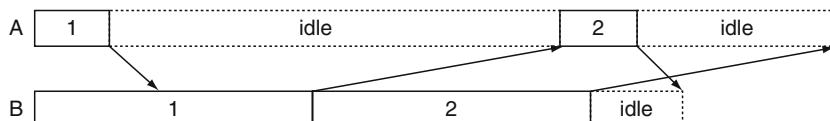

The decomposition of x and $f(\cdot)$, as mentioned above, necessitates the synchronization of all PEs involved at each step. Typically, each fragment $f_i(\cdot)$ of the decomposed operator may need many, if not all, of the

fragments $\{x_j\}$ of the newly computed data x for an iteration step. So, to preserve the exact semantics, it should wait for these data fragments to become available, in effect causing its PE to synchronize with all those PEs executing the operator fragments involved in updating these $\{x_j\}$ in need. Waiting for the availability of data at the end of each iteration make these iterations “synchronous” and this practice preserves the semantics. In networked environments, such synchronous iterations can be coupled with either “synchronous communications” (i.e., synchronous global communication at the end of each step) or “asynchronous communications” for overlapping computation and communication (i.e., asynchronously sending new data fragments as soon as they are locally produced and blocking the receipt of new data fragments at the end of each step) [5].

Synchronization between PEs is crucial to enforcing correctness of the iterative algorithm implementation but it also introduces idle synchronization phases between successive steps. For a moment consider the extreme case of a parallel iterative computation where for some PE the following two conditions happen to hold:

1. It completes its iteration step much faster than the other PEs.
2. Its input communication links from the other PEs are very slow.

It is evident that this PE will suffer a very long idle synchronization phase, i.e., time spent doing nothing (c.f. Fig. 1). Along the same line of thought, one could also devise the most unfavorable instances of computation/communication time assignments for the other PEs which suffer lengthy idle synchronization phases. It is clear that the synchronization penalty for iterative algorithms can be severe.

Asynchronous Iterative Algorithms. Fig. 1 Very long idle periods due to synchronization between A and B executing synchronous iterations. Arrows show exchange messages, the horizontal axis is time, boxes with numbers denote iteration steps, and dotted boxes denote idle time spent in the synchronization. Note that such boxes will be absent in asynchronous iterations

Asynchronous Iterations: Basic Idea and Convergence Issues

The essence of asynchronous iterative algorithms is to reduce synchronization penalty by simply eliminating the synchronization phases in iterative algorithms described above. In other words, each PE is permitted to proceed to its next iteration step without waiting for updating its data from other PEs. Use newly arriving data if available, but otherwise reuse the old data. This approach, however, fails to retain the temporal ordering of the operations in the original algorithm. The established convergence properties are usually altered as a consequence. The convergence behavior of the new asynchronous algorithm is much harder to analyze than the original [20], the main difficulty being the introduction of multiple independent time lines in practice, one for each PE. Even though the convergence analysis uses a global time line, the state space does not involve studying the behavior of the trajectory of only one point (i.e., the shared data at the end of each iteration as in synchronous iterations) but rather of a set of points, one for each PE. An extra complexity is injected by the flexibility of the local operator fragments f_i to be applied to rather arbitrary combinations of data components from the evolution history of their argument lists. Although some assumptions may underly a particular asynchronous algorithm so that certain scenarios of reusing old data components are excluded, a PE is free to use, in a later iteration, data components older than those of the current one. In other words, one can have non-FIFO communication links for local data updates between the PEs.

The most general strategy for establishing convergence of asynchronous iterations for a certain problem is to move along the lines of the Asynchronous Convergence Theorem (ACT) [13]. One tries to construct a sequence of boxes (cartesian products of intervals where data components are known to lie) with the property that the image of each box under $f(\cdot)$ will be contained in the next box in this sequence, given that the original (synchronous) iterative algorithm converges. This nested box structure ensures that as soon as all local states enter such a box, no communication scenario can make any of the states escape to an outer box (deconverge), since updating variables through communication is essentially a coordinate exchange. On the other

hand the synchronous convergence assumption guarantees that local computation also cannot produce any state escaping the current box, its only effect being a possible inclusion of some of the local data components in the respective intervals defining some smaller (nested) box. The argument here is that if communications are nothing but state transitions parallel to box facets and computations just drive some state coordinates in the facet of some smaller (nested) box, then their combination will continuously drive the set of local states to successively smaller boxes and ultimately toward convergence within a tolerance.

It follows that since a synchronous iteration is just a special case in this richer framework, its asynchronous counterpart will typically fail to converge for all asynchronous scenarios of minimal assumptions. Two broad classes of asynchronous scenarios are usually identified:

Totally asynchronous The only constraint here is that, in the local computations, data components are ultimately updated. Thus, no component ever becomes arbitrarily old as the global time line progresses, potentially indefinitely, assuming that any local computation marks a global clock tick. Under such a constraint, ACT can be used to prove, among other things, that the totally asynchronous execution of the classical iteration $x \leftarrow Ax + b$, where x and b are vectors and A a matrix distributed row-wise, converges to the correct solution provided that the spectral radius of the modulus matrix is less than unity ($\rho(|A|) < 1$). This is a very interesting result from a practical standpoint as it directly applies to classical stationary iterative algorithms (e.g., Jacobi) with nonnegative iteration matrix, those commonly used for benchmarking the asynchronous model implementations versus the synchronous ones.

Partially asynchronous The constraint here is stricter: each PE must perform at least one local iteration within the next B global clock ticks (for B a fixed integer) and it must not use components that are computed B ticks prior or older. Moreover, for the locally computed components, the most recent must always be used. Depending on how restricted the value of B may be, partially asynchronous algorithms can be classified in two types, Type I and Type II. The Type I is guaranteed to

converge for arbitrarily chosen B . An interesting case of Type I has the form $x \leftarrow Ax$ where x is a vector and A is a column-stochastic matrix. This case arises in computing stationary distributions of Markov chains [24] like the PageRank computation. Another interesting case is found in gossip-like algorithms for the distributed computation of statistical quantities, where $A = A(t)$ is a time-varying row-stochastic matrix [16]. For Type II partially asynchronous algorithms, B is restricted to be a function of the structure and the parameters of the linear operator itself to ensure convergence. Examples include gradient and gradient projection algorithms, e.g., those used in solving optimization and constrained optimization problems respectively. In these examples, unfortunately, the step parameter in the linearized operator must vary as inversely proportional to B in order to attain convergence. This implies that, although choosing large steps could accelerate the computation, the corresponding B may be too small to enforce in practice.

Implementation Issues

Termination Detection

In a synchronous iterative algorithm, global convergence can be easily decided. It can consist of a local convergence detection (e.g., to make sure a certain norm is below a local threshold in a PE) which triggers global convergence tests in all subsequent steps. The global tests can be performed by some PE acting as the monitor to check, at the end of each step, if the error (determined by substituting the current shared data x in the fixed point equation) gets below a global threshold. At that point, the monitor can signal all PEs to terminate. However, in an asynchronous setting, local convergence detection at some PE does not necessarily mean that the computation is near the global convergence, due to the fact that such a PE may compute too fast and not receive much input from its possibly slow communication in-links. Thus, in effect, there could also be the case in which each PE computes more or less in isolation from the others an approximation to a solution to the less-constrained fixed point problem concerning its respective local operator fragment $f_i(\cdot)$ but not $f(\cdot)$. Hence, local convergence detection may trigger

the global convergence tests too early. Indeed, experiments have shown long phases in which PEs continually enter and exit their “locally converged” status. With the introduction of an extra waiting period for the local convergence status to stabilize, one can avoid the premature trigger of the global convergence detection procedure which may be either centralized or distributed. Taking centralized global detection for example, there is a monitor PE which decides global convergence and notifies all iterating PEs accordingly. A practical strategy is to introduce two integer “persistence parameters” (a `localPersistence` and a `globalPersistence`). If local convergence is preserved for more than `localPersistence` iterations, the PE will notify the monitor. As soon as the monitor finds out that all the PEs remain in locally convergence status for more than `globalPersistence` of their respective checking cycles, it signals global convergence to all the PEs.

Another solution, with a simple proof of correctness, is to embed a conservative iteration number in messages, defined as the smallest iteration number of all those messages used to construct the argument list of the current local computation, incremented by one [9]. This is strongly reminiscent of the ideas in the ACT and practically the iteration number is the box counter in that context, where nested boxes are marked by successively greater numbers of such. In this way, one can precompute some bound for the target iteration number for a given tolerance, with simple local checks and minimal communication overhead. A more elaborate scheme for asynchronous computation termination detection in a distributed setting can be found in literature [1].

Asynchronous Communication

The essence of asynchronous algorithms is not to let local computations be blocked by communications with other PEs. This nonblocking feature is easier to implement on a shared memory system than on a distributed memory system. This is because on a shared memory system, computation is performed either by multiple threads or multiple processes which share the physical address space. In either case, data communication can be implemented by using shared buffers. When a PE sends out a piece of data, it locks the data buffer until the write completes. If another PE tries to receive the latest data but finds the data buffer locked, instead

of blocking itself, the PE can simply continue iterating the computation with its old, local copy of the data. On the other hand, to make sure the receive operation retrieves the data in the buffer in its entirety, the buffer must also be locked until the receive is complete. The sending PE hence may also find itself locked out of the buffer. Conceptually, one can give the send operation the privilege to preempt the receive operation, and the latter may erase the partial data just retrieved and let the send operation deposit the most up to date data. However, it may be easier to just let the send operation wait for the lock, especially because the expected waiting will be much shorter than what is typically experienced in a distributed memory system.

On distributed memory systems, the communication protocols inevitably perform certain blocking operations. For example, on some communication layer, a send operation will be considered incomplete until the receiver acknowledges the safe receipt of the data. Similarly, a receive operation on a certain layer will be considered incomplete until the arriving data become locally available. From this point of view, a communication operation in effect synchronizes the communicating partners, which is not quite compatible with the asynchronous model. For example, the so-called non-blocking send and probe operations assume the existence of a hardware device, namely, the network interface card that is independent of the PE. However, in order to avoid expensive copy operations between the application and the network layers, the send buffer is usually shared by both layers, which means that before the PE can reuse the buffer, e.g., while preparing for the next send in the application layer, it must wait until the buffer is emptied by the network layer. (Note that the application layer cannot force the network layer to undo its ongoing send operation.) This practically destroys the asynchronous semantics. To overcome this difficulty, computation and communication must be decoupled, e.g., implemented as two separate software modules, such that the blocking due to communication does not impede the computation. Mechanisms must be set up to facilitate fast data exchange between these two modules, e.g., by using another data buffer to copy data between them. Now, the computation module will act like a PE sending data in a shared memory system while the communication module acts like a PE receiving data. One

must also note that multiple probes by a receiving PE are necessary since multiple messages with the same “envelope” might have arrived during a local iteration. This again has a negative impact on the performance of an asynchronous algorithm, because the receiving PE must find the most recent of these messages and discard the rest.

The issues listed above have been discussed in the context of the MPI library [10]. Communication libraries such as Jace [7] implemented in Java or its C++ port, CRAC [18], address some of the shortcomings of “general-purpose” message passing libraries. Internally they use separate threads for the communication and computation activities with synchronized queues of buffers for the messages and automatic overwriting on the older ones.

Recent Developments and Potential Future Directions

Two-Stage Iterative Methods and Flexible Communications

There exist cases in which an algorithm can be restructured so as to introduce new opportunities for parallelization and thus yield more places to inject asynchronous semantics. Notable examples are two-stage iterative methods for solving linear systems of equations of the form $Ax = b$. Matrix A is written as $A = M - N$ with M being a block diagonal part. With such splitting, the iteration reads as $Mx(t + 1) \leftarrow (Nx(t) + b)$, and its computation can be decomposed row-wise and distributed to the PEs, i.e., a block Jacobi iteration. However, to get a new data fragment $x_i(t + 1)$ at each iteration step at some PE, a new linear system of equations must be solved, which can be done by a new splitting local M_i part, resulting in a nested iteration. In a synchronous version, new data fragments exchange only at the end of each iteration to coordinate execution. The asynchronous model applied in this context [22] not only relaxes the timing in $x_i(t + 1)$ exchanges in the synchronous model, but it also introduces asynchronous exchanges even during the nested iterations (toward $x_i(t + 1)$) and their immediate use in the computation and not at the end of the respective computational phases. This idea was initially used for solving systems of nonlinear equations [25].

Asynchronous Tiled Iterations (or Parallelizing Data Locality)

As mentioned in Sect. 3, the PEs executing the operator and the MEs hosting its parameters and data must have fast interconnection paths. Restructuring the computation so as to maximize reuse of cached data across iterations have been studied in the past [27]. These are tiling techniques [34] applied to chunks of iterations (during which convergence is not tested) and coupled with strategies for breaking the so induced dependencies. In this way data locality is considerably increased but opportunities for parallelization are confined only within the current tile data and not the whole data set as is the general case, e.g., in iterative stencil computations. Furthermore, additional synchronization barriers, scaling with the number of the tiles in number, are introduced. In a very recent work [23], the asynchronous execution of tiled chunks is proposed for regaining the parallelization degree of nontiled iterations: each PE is assigned a set of tiles (its sub-grid) and performs the corresponding loops without synchronizing with the other PEs. Only the convergence test at the end of such a phase enforces synchronization. So on the one hand, locality is preserved since each PE traverses its current tile data only and on the other hand all available PEs execute concurrently in a similar fashion without synchronizing, resulting in a large degree of parallelization.

When to Use Asynchronous Iterations?

Asynchronism can enter an iteration in both natural and artificial ways. In naturally occurring asynchronous iterations, PEs are either asynchronous by default (or it is unacceptable to synchronize) computation over sensor networks or distributed routing over data networks being such examples.

However, the asynchronous execution of a parallelized algorithm enters artificially, in the sense that most of the times it comes as a variation of the synchronous parallel port of a sequential one. Typically, there is a need to accelerate the sequential algorithm and as a first step it is parallelized, albeit in synchronous mode in order to preserve semantics. Next, in the presence of large synchronization penalties (when PEs are heterogeneous both in terms of computation and communication as in some Grid installations) or extra flexibility needs (such as asynchronous computation starts,

dynamic changes in data or topology, non-FIFO communication channels), asynchronous implementations are evaluated. Note that in all those cases of practical interest, networked PEs are implied. The interesting aspect of [23, 36] is that it broadens the applicability of the asynchronous paradigm in shared memory setups for yet another purpose, which is to preserve locality but without losing parallelism itself as a performance boosting strategy.

Bibliographic Notes and Further Reading

The asynchronous computation model, as an alternative to the synchronous one, has a life span of almost 4 decades. It started with its formal description in the pioneering work of Chazan and Miranker [17] and its first experimental investigations by Baudet [8] back in the 1970s. Perhaps the most extensive and systematic treatment of the subject is contained in a book by Bertsekas and Tsitsiklis in the 1980s [14], particularly in its closing three chapters. During the last 2 decades an extensive literature has been accumulated [4, 11, 12, 15, 19, 21, 26, 29, 30, 32, 33]. Most of these works explore theoretical extensions and variations of the asynchronous model coupled with very specific applications. However in the most recent ones, focus has shifted to more practical, implementation-level aspects [28, 31, 36], since the asynchronous model seems appropriate for the realization of highly heterogeneous, Internet-scale computations [2, 3, 6].

Definition

ATLAS [20–22, 24, 25] is an ongoing research project that uses empirical tuning to optimize dense linear algebra software. The fruits of this research are embodied in an empirical tuning framework available as an open source/free software package (also referred to as “ATLAS”), which can be downloaded from the ATLAS homepage [23]. ATLAS generates optimized libraries which are also often collectively referred to as “ATLAS,” “ATLAS libraries,” or more precisely, “ATLAS-tuned libraries.” In particular, ATLAS provides a full implementation of the BLAS [6, 7, 10, 12] (Basic Linear Algebra Subprograms) API, and a subset of optimized LAPACK [1] (Linear Algebra PACKage) routines. Because dense linear algebra is rich in operand reuse, many routines can run tens or hundreds of times

faster when tuned for the hardware than when written naively. Unfortunately, highly tuned codes are usually not performance portable (i.e., a code transformation that helps performance on architecture A may reduce performance on architecture B).

The BLAS API provides basic building block linear algebra operations, and was designed to help ease the performance portability problem. The idea was to design an API that provides the basic computational needs for most dense linear algebra algorithms, so that when this API has been tuned for the hardware, all higher-level codes that rely on it for computation automatically get the associated speedup. Thus, the job of optimizing a vast library such as LAPACK can be largely handled by optimizing the much smaller code base involved in supporting the BLAS API. The BLAS are split into three “levels” based on how much cache reuse they enjoy, and thus how computationally efficient they can be made to be. In order of efficiency, the BLAS levels are: Level 3 BLAS [6], which involve matrix–matrix operations that can run near machine peak, Level 2 BLAS [7, 8] which involve matrix–vector operations and Level 1 BLAS [10, 12], which involve vector–vector operations. The Level 1 and 2 BLAS have the same order of memory references as floating point operations (FLOPS), and so will run at roughly the speed of memory for out-of-cache operation.

The BLAS were extremely successful as an API, allowing dense linear algebra to run at near-peak rates of execution on many architectures. However, with hardware changing at the frantic pace dictated by Moore’s Law, it was an almost impossible task for hand tuners to keep BLAS libraries up-to-date on even those fortunate families of machines that enjoyed their attentions. Even worse, many architectures did not have anyone willing and able to provide tuned BLAS, which left investigators with codes that literally ran orders of magnitude slower than they should, representing huge missed opportunities for research. Even on systems where a vendor provided BLAS implementations, license issues often prevented their use (e.g., SUN provided an optimized BLAS for the SPARC, but only licensed its use for their own compilers, which left researchers using other languages such as High Performance Fortran without BLAS; this was one of the original motivations to build ATLAS).

Empirical tuning arose as a response to this need for performance portability. The idea is simple enough in principle: Rather than hand-tune operations to the architecture, write a software framework that can vary the implementation being optimized (through techniques such as code generation) so that thousands of inter-related transformation combinations can be empirically evaluated on the actual machine in question. The framework uses actual timings to discover which combinations of transformations lead to high performance on this particular machine, resulting in portably efficient implementations regardless of architecture. Therefore, instead of waiting months (or even years) for a hand tuner to do the same thing, the user need only install the empirical tuning package, which will produce a highly tuned library in a matter of hours.

ATLAS Software Releases and Version Numbering

ATLAS almost always has two current software releases available at any one time. The first is the *stable release*, which is the safest version to use. The stable release has undergone extensive testing, and is known to work on many different platforms. Further, every known bug in the stable release is tracked (along with associated fixes) in the ATLAS errata file [17]. When errors affecting answer accuracy are discovered in the stable release, a message is sent to the ATLAS error list [14], which any user can sign up for. In this way, users get updates anytime the library they are using might have an error, and they can update the software with the supplied patch if the error affects them. Stable releases happen relatively rarely (say once every year or two).

The second available package is the *developer release*, which is meant to be used by ATLAS developers, contributors, and people happy to live on the bleeding edge. Developer releases typically contain a host of features and performance improvements not available in the stable release, but many of these features will have been exposed to minimal testing (a new developer release may have only been crudely tested on a single platform, whereas a new stable release will have been extensively tested on dozens of platforms). Developer releases happen relatively often (it is not uncommon to release two in the same week).

Each ATLAS release comes with a version number, which is comprised of: <major number>.<minor

number>.<update number>. The meaning of these terms is:

Major number: Major release numbers are changed only when fairly large, sweeping changes are made. Changes in the API are the most likely to cause a major release number to increment. For example, when ATLAS went from supporting only matrix multiply to all the Level 3 BLAS, the major number changed; the same happened when ATLAS went from supporting only Level 3 BLAS to all BLAS.

Minor number: Minor release numbers are changed at each official release. Even numbers represent stable releases, while odd minor numbers are reserved for developer releases.

Update number: Update numbers are essentially patches on a particular release. For instance, stable ATLAS releases only occur roughly once per year or two. As errors are discovered, they are errata-ed, so that a user can apply the fixes by hand. When enough errata are built up that it becomes impractical to apply the important ones by hand, an update release is issued. So, stable updates are typically bug fixes, or important system workarounds, while developer updates often involve substantial new code. A typical number of updates to a stable release might be something like 4. A developer release may have any number of updates.

So, 3.8.1 would be a stable release, with one group of fixes already applied. 3.9.12 would be the 12th update (13th release) of the associated developer release.

Essentials of Empirical Tuning

Any package that adapts software based on timings falls into a classification that ATLAS shares, which we call AEOS (Automated Empirical Optimization of Software). These packages can vary strongly on details, but they must have some commonalities:

1. The search must be *automated* in some way, so that an expert hand-tuner is not required.
→ ATLAS has a variety of searches for different operations, all of which can be found in the ATLAS/tune directory.
2. The decision of whether a transformation is useful or not must be *empirical*, in that an actual timing

measurement on the specific architecture in question is performed, as opposed to the traditional application of transformations using static heuristics or profile counts.

- ATLAS has a plethora of timers and testers, which can be found in ATLAS/tune and ATLAS/bin. These timers must be much more accurate and context-sensitive than typical timers, since optimization decisions are based on them. ATLAS uses the methods described in [19] to ensure high-quality timings.
3. These methods must have some way to vary/adapt the software being tuned. ATLAS currently uses *parameterized adaptation*, *multiple implementation*, and *source generation* (see Methods of Software Adaption for details).

Methods of Software Adaptation

Parameterized adaptation: The simplest method is having runtime or compile-time variables that cause different behaviors depending on input values. In linear algebra, the most important of such parameters is probably the blocking factor(s) used in blocked algorithms, which, when varied, varies the data cache utilization. Other parameterized adaptations in ATLAS include a large number of crossover points (empirically found points in some parameter space where a second algorithm becomes superior to a first). Important crossover points in ATLAS include: whether problem size is large enough to withstand a data copy, whether problem is large enough to utilize parallelism, whether a problem dimension is close enough to degenerate that a special-case algorithm should be used, etc.

Not all important tuning variables can be handled by parameterized adaptation (simple examples include instruction cache size, choice of combined or separate multiply and add instructions, length of floating point and fetch pipelines, etc.), since varying them actually requires changing the underlying source code. This then brings in the need for the second method of software adaptation, *source code adaptation*, which involves actually generating differing implementations of the same operation.

ATLAS presently uses two methods of source code adaptation, which are discussed in greater detail below.

1. **Multiple implementation:** Formalized search of multiple hand-written implementations of the kernel in question. ATLAS uses multiple implementation in the tuning of all levels of the BLAS.
2. **Source generation:** Write a program that can generate differing implementations of a given algorithm based on a series of input parameters. ATLAS presently uses source generation in tuning matrix multiply (and hence the entire Level 3 BLAS).

Multiple implementation: Perhaps the simplest approach for source code adaptation is for an empirical tuning package to supply various hand-tuned implementations, and then the search heuristic can be as simple as trying each implementation in turn until the best is found. At first glance, one might suspect that supplying these multiple implementations would make even this approach to source code adaptation much more difficult than the traditional hand-tuning of libraries. However, traditional hand-tuning is not the mere application of known techniques it may appear when examined casually. Knowing the size and properties of your level 1 cache is not sufficient to choose the best blocking factor, for instance, as this depends on a host of interlocking factors which often defy a priori understanding in the real world. Therefore, it is common in hand-tuned optimizations to utilize the known characteristics of the machine to narrow the search, but then the programmer writes various implementations and chooses the best.

For multiple implementation, this process remains the same, but the programmer adds a search and timing layer to accomplish what would otherwise be done by hand. In the simplest cases, the time to write this layer may not be much if any more than the time the implementer would have spent doing the same process in a less formal way by hand, while at the same time capturing at least some of the flexibility inherent in empirical tuning. Due to its obvious simplicity, this method is highly parallelizable, in the sense that multiple authors can meaningfully contribute without having to understand the entire package. In particular, various specialists on given architectures can provide hand-tuned routines without needing to understand other architectures, the higher level codes (e.g., timers, search heuristics, higher-level routines which utilize these basic kernels, etc.). Therefore, writing a multiple

implementation framework can allow for outside contribution of hand-tuned kernels in an open source/free software framework such as ATLAS.

Source generation: In *source generation*, a source generator (i.e., a program that writes other programs) is produced. This source generator takes as parameters the various source code adaptations to be made. As before, simple examples include loop unrolling factors, choice of combined or separate multiply and add instructions, length of floating point and fetch pipelines, and so on. Depending on the parameters, the source generator produces a routine with the requisite characteristics. The great strength of source generators is their ultimate flexibility, which can allow for far greater tunings than could be produced by all but the best hand-coders. However, generator complexity tends to go up along with flexibility, so that these programs rapidly become almost insurmountable barriers to outside contribution.

ATLAS therefore combines these two methods of source adaptation, where the GEMM kernel source generator produces strict ANSI/ISO C for maximal architectural portability. Multiple implementation is utilized to encourage outside contribution, and allows for extreme architectural specialization via assembly implementations. Parameterized adaptation is then combined with these two techniques to fully tune the library.

Both multiple implementation and code generation are specific to the kernel being tuned, and can be either platform independent (if written to use portable languages such as C) or platform dependent (as when assembly is used or generated). Empirically tuned compilers can relax the kernel-specific tuning requirement, and there has been some initial work on utilizing this third method of software adaptation [26, 27] for ATLAS, but this has not yet been incorporated into any ATLAS release.

Search and Software Adaptation for the Level 3 BLAS

ATLAS's Level 3 BLAS are implemented as GEMM-based BLAS, and so ATLAS's empirical tuning is all done for matrix multiply (see [24] and [25] for descriptions of ATLAS's GEMM-based BLAS). As of this writing, the most current stable release is 3.8.3, and the newest developer release is 3.9.16. Some features

discussed below are available only in the later developer releases; this is noted whenever true.

GEMM (GEneral rectangular Matrix Multiply) is empirically tuned using all discussed methods (parameterized adaption, multiple implementation, and source generation). Parameterization is mainly used for crossover points and cache blocking, and ATLAS uses both its methods of source code adaptation in order to optimize GEMM:

1. **Code generation:** ATLAS's main code generator produces ANSI C implementations of ATLAS's matrix multiply kernel [25]. The code generator can be found in `ATLAS/tune/blas/gemm/emit_mm.c`. `ATLAS/tune/blas/gemm/mmsearch.c` is the master GEMM search that not only exercises the options to `emit_mm.c`, but also invokes all subservient searches. With `emit_mm.c` and `mmsearch.c`, ATLAS has a general-purpose code generator that can work on any platform with an ANSI C compiler. However, most compilers are generally unsuccessful in vectorizing these types of code (and vectorization has become critically important, especially on the $\times 86$), and so from version 3.9.15 and later, ATLAS has a code generator written by Chad Zalkin that generates SSE vectorized code using gcc's implementation of the Intel SSE intrinsics. The vectorized source generator is `ATLAS/tune/blas/gemm/mmgen_sse.c`, and the search that exercises its options is `ATLAS/tune/blas/gemm/mmkssearch_sse.c`.
2. **Multiple implementation:** ATLAS also tunes GEMM using multiple implementation, and this search can be found in `ATLAS/tune/blas/gemm/ummsearch.c`, and all the hand-tuned kernel implementations which are searched can be found in `ATLAS/tune/blas/gemm/CASES/`.

Empirical Tuning in the Rest of the Package

Currently, the the Level 1 and 2 BLAS are tuned only via parameterization and multiple implementation searches. ATLAS 3.9.15 and greater has some prototype SSE generators for matrix vector multiply and rank-1 update (most important of the Level 2 BLAS routines) available in `ATLAS/tune/blas/gemv/mvgen_sse.c` & `ATLAS/tune/blas/ger/r1gen_sse.c`, respectively. These generators are currently not

debugged, and lack a search, but may be used in later releases.

ATLAS can also autotune LAPACK's blocking factor, as discussed in [18]. ATLAS currently autotunes the QR factorization for both parallel and serial implementations.

Parallelism in ATLAS

ATLAS is currently used in two main ways in parallel programming. Parallel programmers call ATLAS's serial routines directly in algorithms they themselves have parallelized. The other main avenue of parallel ATLAS use is programmers that write serial algorithms which get implicit parallelism by calling ATLAS's parallelized BLAS implementation. ATLAS currently parallelizes only the Level 3 BLAS (the Level 1 and 2 are typically bus-bound, so parallelization of these operations can sometimes lead to *slowdown* due to increased bus contention). In the current stable (3.8.3), the parallel BLAS use pthreads. However, recent research [3] forced a complete rewrite of the threading system for the developer release which results in as much as a doubling of parallel application performance. The developer release also supports Windows threads and OpenMP in addition to pthreads. Ongoing work involves improving parallelism at the LAPACK level [4], and empirically tuning parallel crossover points, which may lead to the safe parallelization of the Level 1 and 2 BLAS.

Discussion

History of the Project

The research that eventually grew into ATLAS was undertaken by R. Clint Whaley in early 1997, as a direct response to a problem from ongoing research on parallel programming and High Performance Fortran (HPF). The Innovative Computer Laboratory (ICL) of the University of Tennessee at Knoxville (UTK) had two small clusters, one consisting of SPARC chips, and the other PentiumPROs. For the PentiumPROs, no optimized BLAS were available. For the SPARC cluster, SUN provided an optimized BLAS, but licensed them so that they could not be used with non-SUN compilers, such as the HPF compiler. This led to the embarrassment of having a 32-processor parallel algorithm run slower than a serial code on the same chips, due to lack of a portably optimal BLAS.

The PHiPAC effort [2] from Berkeley comprised the first systematic attempt to harness automated empirical tuning in this area. PHiPAC did not deliver the required performance on the platforms being used, but the idea was obviously sound. Whaley began working on this idea on nights and weekends in an attempt to make the HPF results more credible. Eventually, a working prototype was produced, and was demonstrated to the director of ICL (Jack Dongarra), and it became the full-time project for Whaley, who was eventually joined on the project by Antoine Petitet. ATLAS has been under continuous development since that time, and has followed Whaley to a variety of institutions, as shown in the ATLAS timeline below. Please note that ATLAS is an open source project, so many people have substantially contributed to ATLAS that are not mentioned here. Please see `ATLAS/doc/AtlasCredits.txt` for a rough description of developer contribution to ATLAS.

Rough ATLAS Timeline Including Stable Releases

Early 1997: Development of prototype by Whaley in spare time.

Mid 1997: Whaley full time on ATLAS development at ICL/UTK.

Dec 1997: Technical report describing ATLAS published. ATLAS v 0.1 released, provides S/D GEMM only.

Sep 1998: Version 1.0 released, using SuperScalar GEMM-based BLAS [11] to provide entire real Level 3 BLAS in both precisions.

Mid 1998: Antoine Petitet joins ATLAS group at ICL/ UTK.

Feb 1999: Version 2.0 released. Automated install and configure steps, all Level 3 BLAS supported in all four types/precisions, C interface to BLAS added.

Dec 1999: Version 3.0Beta released. ATLAS provides complete BLAS support with C and F77 interfaces. GEMM generator can generate all transpose cases, saving the need to copy small matrices. Addition of LU, Cholesky, and associated LAPACK routines.

Dec 2000: Version 3.2 released. Pthreads support for parallel Level 3 BLAS. Support for user-contribution of kernels, and associated multiple implementation search.

- Mid 2001:** Antoine leaves to take job at SUN/France.
- Jan 2002:** Whaley begins PhD work in iterative compilation at FSU.
- Jun 2002:** Version 3.4 released. Level 1 BLAS optimized. Addition of LAPACK inversion and related routines. Addition of sanity check after install.
- Dec 2003:** Version 3.6 released. Numerous optimizations, but no new API coverage.
- Jul 2005:** Whaley begins as assistant professor at UTSA.
- Mar 2006:** NSF/CRI funding for ATLAS obtained.
- Dec 2007:** Version 3.8 released. Complete rewrite of configure and install, as part of overall modernization of package (brought from 2002 to 2006, where there was no financial support, and so ATLAS work only done on volunteer basis). Numerous fixes and optimizations, but API support unchanged. Addition of ATLAS install guide. Extended LAPACK timing/testing available.

Ongoing Research and Development

There are a host of areas in ATLAS that require significant research in order to improve. Since 2005, there has been continuous ATLAS R&D coming from Whaley's group at the University of Texas at San Antonio. Here, we discuss only those areas that the ATLAS team is actually currently investigating (time of writing: November 2009). Initial work on these ideas is already in the newest developer releases, and at least some of the results will be available in the next stable release (3.10.0).

Kernel Tuning

Improving ATLAS's kernel tuning is an ongoing focus. One area of interest involves exploiting empirical compilation [26, 27] for all kernels, and adding additional vectorized source generators, particularly for the Level 2 and 3 BLAS. Additionally, it is important to add support for tuning the Level 1 and 2 BLAS to different cache states, as discussed in [26]. There is also an ongoing effort to rewrite the ATLAS timing and tuning frameworks so that others can easily plug in their own searches or empirical tuning frameworks for ATLAS to automatically use.

Improvements in Parallel Performance

There is ongoing work aimed at extending [3], both to cover more OSes, to even further improve overheads, and to empirically tune a host of crossover points

between degrees of parallelism, which should improve current performance and enable opportunities to safely parallelize additional operations. Further work along the lines of [4] is being pursued in order to more effectively parallelize LAPACK. Finally, use of massively parallel GPUs is being investigated based on the impressive initial work of [13, 15, 16].

LAPACK

In addition to the parallel work mentioned in the previous section, the ATLAS group is expanding the coverage of routines to include all Householder factorization-related routines, based on the ideas presented in [9] (this will result in ATLAS providing a native implementation, with full C and Fortran interfaces, for all dense factorizations). Another ongoing investigation involves extending the LAPACK tuning discussed in [18] to handle more routines more efficiently. Finally, the ATLAS group is researching error control [5] with an eye to keeping error bounds low while using faster algorithms.

Definition

Automated performance tuning, or *autotuning*, is an automated process, guided by experiments, of selecting one from among a set of candidate program implementations to achieve some performance goal. “Performance goal” may mean, for instance, the minimization of execution time, energy delay, storage, or approximation error. An “experiment” is the execution of a benchmark and observation of its results with respect to the performance goal. A system that implements an autotuning process is referred to as an *autotuner*. An autotuner may be a stand-alone code generation system or may be part of a compiler.

Discussion

Introduction: From Manual to Automated Tuning

When tuning a code by hand, a human programmer typically engages in the following iterative process. Given an implementation, the programmer develops or modifies the program implementation, performs an experiment to measure the implementation’s performance, and then analyzes the results to decide whether the implementation has met the desired performance goal; if not, he or she repeats these steps. The use of an iterative, experiment-driven approach is typically necessary when the program and hardware performance behavior is too complex to model explicitly in another way.

Autotuning attempts to automate this process. More specifically, the modern notion of autotuning is a process consisting of the following components, any or all

of which are automated in a given autotuning approach or system:

- *Identification* of a space of candidate implementations. That is, the computation is associated with some space of possible implementations that may be defined implicitly through parameterization.
- *Generation* of these implementations. That is, an autotuner typically possesses some facility for producing (generating) the actual code that corresponds to any given point in the space of candidates.
- *Search* for the best implementation, where best is defined relative to the performance goal. This search may be guided by an empirically derived model and/or actual experiments, that is, benchmarking candidate implementations.

Bilmes et al. first described this particular notion of autotuning in the context of an autotuner for dense matrix–matrix multiplication [4].

Intellectual Genesis

The modern notion of autotuning can be traced historically to several major movements in program generation.

The first is the work by Rice on *polyalgorithms*. A polyalgorithm is a type of algorithm that, given some a particular input instance, selects from among several candidate algorithms to carry out the desired computation [14]. Rice’s later work included his attempt to formalize algorithm selection mathematically, along with an approximation theory approach to its solution, as well as applications in both numerical algorithms and operating system scheduler selection [15]. The key influence on autotuning is the notion of multiple candidates and the formalization of the selection problem as an approximation and search problem.

A second body of work is in the area of *profile-and feedback-directed compilation*. In this work, the compiler instruments the program to gather and store data about program behavior at runtime, and then uses this data to guide subsequent compilation of the same program. This area began with the introduction of detailed program performance measurement [11] and measurement tools [9]. Soon after, measurement became an integral component in the compilation process itself in several experimental compilers, including Massalin’s *superoptimizer* for

exploring candidate instruction schedules, as well as the peephole optimizers of Chang et al. [6]. Dynamic or just-in-time compilers employ similar ideas; see Smith’s survey of the state-of-the-art in this area as of 2000 [16]. The key influence on modern autotuning is the idea of automated measurement-driven transformation.

The third body of work that has exerted a strong influence on current work in autotuning is that of formalized *domain-driven code generation systems*. The first systems were developed for signal processing and featured high-level transformation/rewrite systems that manipulated symbolic formulas and translated these formulas into code [7, 10]. The key influence on modern autotuning is the notion of high-level mathematical representations of computations and the automated transformations of these representations.

Autotuning as it is largely studied today began with the simultaneous independent development of the PHiPAC autotuner for dense matrix–matrix multiplication [4], FFTW for the fast Fourier transform [8], and the OCEANS iterative compiler for embedded systems [3]. These were soon followed by additional systems for dense linear algebra (ATLAS) [18] and signal transforms (SPIRAL) [13].

Contemporary Issues and Approaches

A developer of an autotuner must, in implementing his or her autotuning system or approach, consider a host of issues for each of the three major autotuning components, that is, identification of candidate implementations, generation, and search. The issues cut across components, though for simplicity the following exposition treats them separately.

Identification of Candidates

The identification of candidates may involve characterization of the target computations and/or anticipation of the likely target hardware platforms. Key design points include what candidates are possible, who specifies the candidates, and how the candidates are represented for subsequent code generation and/or transformation.

For example, for a given computation there may be multiple candidate algorithms and data structures, for example, which linear solver, what type of graph data structure. If the computation is expressed as code, the space may be defined through some parameterization

of the candidate transformations, for example, depth of loop unrolling, cache blocking/tiling sizes. There may be numerous other implementation issues, such as where to place data or how to schedule tasks and communication.

Regarding *who* identifies these candidates, possibilities include the autotuner developer; the autotuner itself, for example, through preprogrammed and possibly extensible rewrite rules; or even the end-user programmer, for example, through a meta-language or directives.

Among target architectures, autotuning researchers have considered all of the different categories of sequential and parallel architectures. These include everything from superscalar cache-based single- and multicore systems, vector-enabled systems, and shared and distributed memory multiprocessor systems.

Code Generation

Autotuners employ a variety of techniques for producing the actual code.

One approach is to build a specialized code generator that can only produce code for a particular computation or family of computations. The generator itself might be as conceptually simple as a script that, given a few parameter settings, produces an output implementation. It could also be as sophisticated as a program that takes an abstract mathematical formula as input, using symbolic algebra and rewriting to transform the formula to an equivalent formula, and translating the formula to an implementation. In a compiler-based autotuner, the input could be code in a general-purpose language, with conventional compiler technology enabling the transformation or rewriting of that input to some implementation output. In other words, there is a large design space for the autotuner code generator component. Prominent examples exist using combinations of these techniques.

Search

Given a space of implementations, selecting the best implementation is, generically, a combinatorial search problem. Key questions are what type of search to use, when to search, and how to evaluate the candidate implementations during search.

Among types of search, the simplest is an exhaustive approach, in which the autotuner enumerates all

possible candidates and experimentally evaluates each one. To reduce the potential infeasibility of exhaustive search, numerous pruning heuristics are possible. These include random search, simulated annealing, statistical experimental design approaches, machine-learning guided search, genetic algorithms, and dynamic programming, among others.

On the question of when to search, the main categories are off-line and at runtime. An off-line search would typically occur once per architecture or architectural families, prior to use by an application. A runtime search, by contrast, occurs when the computation is invoked by the end-user application. Hybrid approaches are of course possible. For example, a series of off-line benchmarks could be incorporated into a runtime model that selects an implementation. Furthermore, tuning could occur across multiple application invocations through historical recording and analysis mechanisms, as is the case in profile and feedback-directed compilation.

The question of evaluation is one of the methodologies for carrying out the experiment. One major issue is whether this evaluation is purely experimental or guided by some predictive model (or both). The model itself may be parameterized and parameter values learned (in the statistical sense) during tuning. A second major issue is under what context evaluation occurs. That is, tuning may depend on features of the input data, so conducting an experiment in the right context could be critical to effective tuning.

Additional Pointers

The literature on work related to autotuning is large and growing. At the time of this writing, the last major comprehensive surveys of autotuning projects had appeared in the Proceedings of the IEEE special issue edited by Moura et al. [12] and the article by Vuduc et al. [17, Section 5], which include many of the methodological aspects autotuning described here.

There are numerous community-driven efforts to assemble autotuning researchers and disseminate their results. These include: the U.S. Department of Energy (DOE) sponsored workshop on autotuning, organized under the auspices of CScADS [5]; the International Workshop on Automatic Performance Tuning [2]; and the Collective Tuning (cTuning) wiki [1], to name a few.

There are numerous debates and issues within this community at present, a few examples of which follow:

- How will we measure the success of autotuners, in terms of performance, productivity, and/or other measures?
- To what extent can entire programs be autotuned, or will large successes be largely limited to relatively small library routines and small kernels extracted from programs?
- For what applications is data-dependent tuning really necessary?
- Is there a common infrastructure (tools, languages, intermediate representations) that could support autotuning broadly, across application domains?
- Where does the line between an autotuner and a “traditional” compiler lie?
- When is search necessary, rather than analytical models? Always? Never? Or only sometimes, perhaps as a “stopgap” measure when porting to new platforms? How does an autotuner know when to stop?

Bandwidth-Latency Models (BSP, LogP)

THILO KIELMANN¹, SERGEI GORLATCH²

¹Vrije Universiteit, Amsterdam, The Netherlands

²Westfälische Wilhelms-Universität Münster, Münster, Germany

Synonyms

Message-passing performance models; Parallel communication models

Definition

Bandwidth-latency models are a group of performance models for parallel programs that focus on modeling the communication between the processes in terms of network bandwidth and latency, allowing quite precise performance estimations. While originally developed for distributed-memory architectures, these models also apply to machines with nonuniform memory access (NUMA), like the modern multi-core architectures.

Discussion

Introduction

The foremost goal of parallel programming is to speed up algorithms that would be too slow when executed sequentially. Achieving this so-called speedup requires a deep understanding of the performance of the inter-process communication and synchronization, together with the algorithm's computation. Both computation and communication/synchronization performance strongly depend on properties of the machine

architecture in use. The strength of the bandwidth-latency models is that they model quite precisely the communication and synchronization operations. When the parameters of a given machine are fed into the performance analysis of a parallel algorithm, bandwidth-latency models lead to rather precise and expressive performance evaluations. The most important models of this class are bulk synchronous parallel (BSP) and LogP, as discussed below.

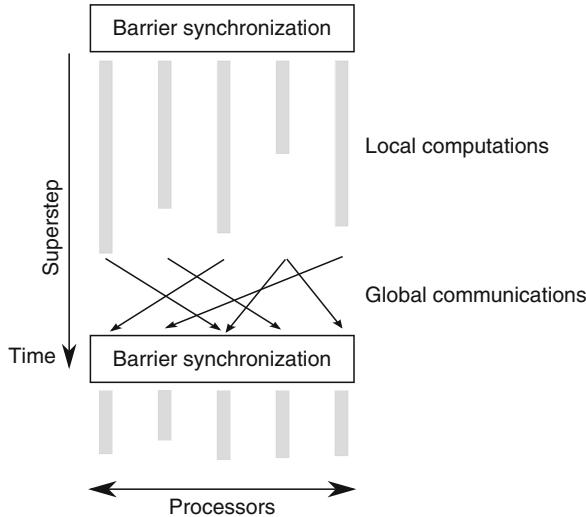

The BSP Model

The *bulk synchronous parallel* (BSP) model was proposed by Valiant [11] to overcome the shortcomings of the traditional PRAM (Parallel Random Access Machine) model, while keeping its simplicity. None of the suggested PRAM models offers a satisfying forecast of the behavior of parallel machines for a wide range of applications. The BSP model was developed as a bridge between software and hardware developers: if the architecture of parallel machines is designed as prescribed by the BSP model, then software developers can rely on the BSP-like behavior of the hardware. Furthermore it should not be necessary to customize perpetually the model of applications to new hardware details in order to benefit from a higher efficiency of emerging architectures.

The BSP model is an abstraction of a machine with physically distributed memory that uses a presentation of communication as a global bundle instead of single point-to-point transfers. A BSP model machine consists of a number of processors equipped with memory, a connection network for point-to-point messages between processors, and a synchronization mechanism, which allows a barrier synchronization of all processors.

Calculations on a BSP machine are organized as a sequence of supersteps as shown in Fig. 1:

- In each superstep, each processor executes local computations and may perform communication operations.

Bandwidth-Latency Models (BSP, LogP). Fig. 1 The BSP model executes calculations in supersteps. Each superstep comprises three phases: (1) simultaneous local computations performed by each process, (2) global communication operations for exchanging data between processes, (3) barrier synchronization for finalizing the communication operation and enabling access to received data by the receiving processes

- A local computation can be executed in every time unit (step).
- The result of a communication operation does not become effective before the next superstep begins, i.e., the receiver cannot use received data until the current superstep is finished.
- At the end of every superstep, a barrier synchronization using the synchronization mechanism of the machine takes place.

The BSP model machine can be viewed as a MIMD (Multiple Instruction Multiple Data) system, because the processes can execute different instructions simultaneously. It is loosely synchronous at the superstep level, compared to the instruction-level tight synchrony in the PRAM model: within a superstep, different processes execute asynchronously at their own pace. There is a single address space, and a processor can access not only its local memory but also any remote memory in another processor, the latter imposing communication.

Within a superstep, each computation operation uses only data in the processor's local memory. These

data are put into the local memory either at the program start-up time or by the communication operations of previous supersteps. Therefore, the computation operations of a process are independent of other processes, while it is not allowed for multiple processes to read or write the same memory location in the same step. Because of the barrier synchronization, all memory and communication operations in a superstep must completely finish before any operation of the next superstep begins. These restrictions imply that a BSP computer has a sequential consistency memory model.

A program execution on a BSP machine is characterized using the following four parameters [6]:

- p : the number of processors.
- s : the computation speed of processors expressed as the number of computation steps that can be executed by a processor per second. In each step, one arithmetic operation on local data can be executed.
- l : the number of steps needed for the barrier synchronization.
- g : the average number of steps needed for transporting a memory word between two processors of the machine.

In a real parallel machine, there are many different patterns of communication between processors. For simplicity, the BSP model abstracts the communication operations using the h relation concept: an h relation is an abstraction of any communication operation, where each node sends at most h words to various nodes and each node receives at most h words. On a BSP computer, the time to realize any h relation is not longer than $g \cdot h$.

The BSP model is more realistic than the PRAM model, because it accounts for several overheads ignored by PRAM:

- To account for load imbalance, the computation time w is defined as the maximum number of steps spent on computation operations by any processor.
- The synchronization overhead is l , which has a lower bound equal to the communication network latency (i.e., the time for a word to propagate through the physical network) and is always greater than zero.
- The communication overhead is $g \cdot h$ steps, i.e., $g \cdot h$ is the time to execute the most time-consuming h relation. The value of g is platform-dependent: it is

smaller on a computer with more efficient communication support.

For a real parallel machine, the value of g depends on the bandwidth of the communication network, the communication protocols, and the communication library. The value of l depends on the diameter of the network, as well as on the communication library. Both parameters are usually estimated using benchmark programs. Since the value s is used for normalizing the values l and g , only p , l and g are independent parameters. The execution time of a BSP-program is a sum of the execution time of all supersteps. The execution time of each superstep comprises three terms: (1) maximum local computation time of all processes, w , (2) costs of global communication realizing a h -relation, and (3) costs for the barrier synchronization finalizing the superstep:

$$T_{\text{superstep}} = w + g \cdot h + l \quad (1)$$

BSP allows for overlapping of the computation, the communication, and the synchronization operations within a superstep. If all three types of operations are fully overlapped, then the time for a superstep becomes $\max(w, g \cdot h, l)$. However, usually the more conservative $w + g \cdot h + l$ is used.

The BSP model was implemented in a so-called BSplib library [5, 6] that provides operations for the initialization of supersteps, execution of communication operations, and barrier synchronizations.

The LogP Model

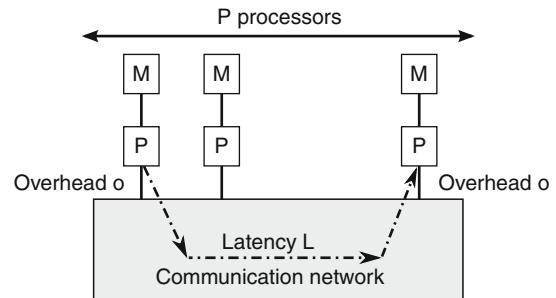

In [4], Culler et al. criticize BSP's assumption that the length of supersteps must allow to realize arbitrary h -relations, which means that the granularity has a lower bound. Also, the messages that have been sent during a superstep are not available for a recipient before the following superstep begins, even if a message is sent and received within the same superstep. Furthermore, the BSP model assumes hardware support for the synchronization mechanism, although most existing parallel machines do not provide such a support. Because of these problems, the LogP model [4] has been devised, which is arguably more closely related to the modern hardware used in parallel machines.

In analogy to BSP, the LogP model assumes that a parallel machine consists of a number of processors

equipped with memory. The processors can communicate using point-to-point messages through a communication network. The behavior of the communication is described using four parameters L , o , g , and P , which give the model the name LogP:

- L (latency) is an upper bound for the network's latency, i.e., the maximum delay between sending and receiving a message.
- o (overhead) describes the period of time in which a processor is busy with sending or receiving a message; during this time, no other work can be performed by that processor.
- g (gap) denotes the minimal timespan between sending or receiving two messages back-to-back.
- P is the number of processors of the parallel machine.

[Figure 2](#) shows a visualization of the LogP parameters [3]. Except P , all parameters are measured in time units or multiple machine cycle units. The model assumes a network with finite capacity. From the definitions of L and g , it follows that, for a given pair of source and destination nodes, the number of messages that can be on their way through the network simultaneously is limited by L/g . A processor trying to send a message that would exceed this limitation will be blocked until the network can accept the next message. This property models the network bandwidth where the parameter g reflects the bottleneck bandwidth, independent of the bottleneck's location, be it the network link, or be it the processing time spent on sending or receiving. g thus denotes an upper bound for o .

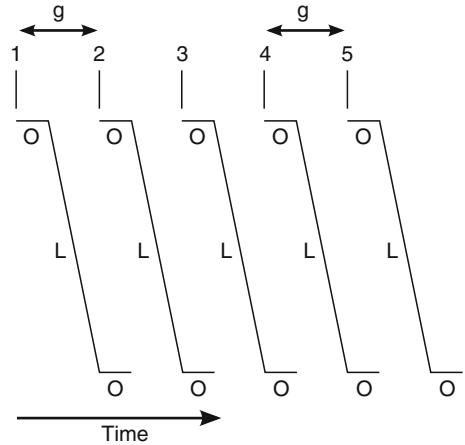

Bandwidth-Latency Models (BSP, LogP). [Fig. 2](#) Parameter visualization of the LogP model

For this capacity constraint, LogP both gets praised and criticized. The advantage of this constraint is a very realistic modeling of communication performance, as the bandwidth capacity of a communication path can get limited by any entity between the sender's memory and the receiver's memory. Due to this focus on point-to-point communication, LogP (variants) have been successfully used for modeling various computer communication problems, like the performance of the Network File System (NFS) [9] or collective communication operations from the Message Passing Interface (MPI) [8]. The disadvantage of the capacity constraint is that LogP exposes the sensitivity of a parallel computation to the communication performance of individual processors. This way, analytic performance modeling is much harder with LogP, as compared to models with a higher abstraction level like BSP [2].

While LogP assumes that the processors are working asynchronously, it requires that no message may exceed a preset size, i.e., larger messages must be fragmented. The latency of a single message is not predictable, but it is limited by L . This means, in particular, that messages can overtake each other such that the recipient may potentially receive the messages out of order. The values of the parameters L , o , and g depend on hardware characteristics, the used communication software, and the underlying communication protocols.

The time to communicate a message from one node to another (i.e., the start-up time t_0) consists of three terms: $t_0 = o + L + o$. The first o is called the *send overhead*, which is the time at the sending node to execute a message send operation in order to inject a message into the network. The second o is called the *receive overhead*, which is the time at the receiving node to execute a message receive operation. For simplicity, the two overheads are assumed equal and called the *overhead* o , i.e., o is the length of a time period that a node is engaged in sending or receiving a message. During this time, the node cannot perform other operations (e.g., overlapping computations).

In the LogP model, the runtime of an algorithm is determined as the maximum runtime across all processors. A consequence of the LogP model is that the access to a data element in memory of another processor costs $T_m = 2L + 4o$ time units (a message round-trip), of

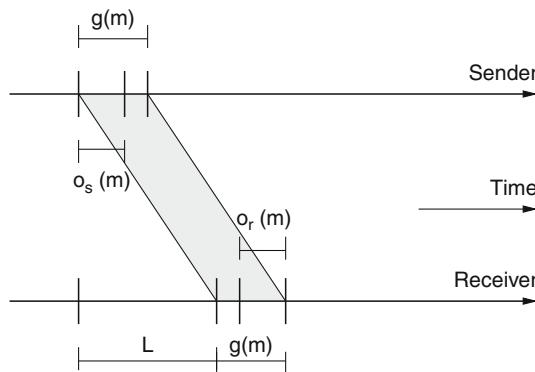

Bandwidth-Latency Models (BSP, LogP). Fig. 3 Modeling the transfer of a large message in n segments using the LogP model. The last message segment is sent at time $T_s = (n - 1) \cdot g$ and will be received at time $T_r = T_s + 2o + L$

which one half is used for reading, and the other half for writing. A sequence of n pipelined messages can be delivered in $T_n = L + 2o + (n - 1)g$ time units, as shown in Fig. 3.

A strong point of LogP is its simplicity. This simplicity, however, can, at times, lead to inaccurate performance modeling. The most obvious limitation is the restriction to small messages only. This was overcome by introducing a LogP variant, called LogGP [1]. It contains an additional parameter G (Gap per Byte) as the time needed to send a byte from a large message. $1/G$ is the bandwidth per processor. The time for sending a message consisting of n Bytes is then $T_n = o + (n - 1)G + L + o$.

A more radical extension is the *parameterized LogP* model [7], PLogP, for short. PLogP has been designed taking observations about communication software, like the Message Passing Interface (MPI), into account. These observations are (1) Overhead and gap strongly depend on the message size; some communication libraries even switch between different transfer implementations, for short, medium, and large messages. (2) Send and receive overhead can strongly differ, as the handling of asynchronously incoming messages needs a fundamentally different implementation than a synchronously invoked send operation. In the PLogP model (see Fig. 4), the original parameters o and g have been replaced by the *send overhead* $o_s(m)$, the *receive*

Bandwidth-Latency Models (BSP, LogP). Fig. 4

Visualization of a message transport with m bytes using the PLogP model. The sender is busy for $o_s(m)$ time. The message has been received at $T = L + g(m)$, out of which the receiver had been busy for $o_r(m)$ time

overhead $o_r(m)$, and the gap $g(m)$, where m is the message size. L and P remain the same as in LogP.

PLogP allows precise performance modeling when parameters for the relevant message sizes of an application are used. In [8], this has been demonstrated for MPI's collective communication operations, even for hierarchical communication networks with different sets of performance parameters. Pješivac-Grbović et al. [10] have shown that PLogP provides flexible and accurate performance modeling.

Concluding Remarks

Historically, the major focus of parallel algorithm development had been the PRAM model, which ignores data access and communication cost and considers only load balance and extra work. PRAM is very useful in understanding the inherent concurrency of an application, which is the first conceptual step in developing a parallel program; however, it does not take into account important realities of particular systems, such as the fact that data access and communication costs are often the dominant components of execution time.

The bandwidth-latency models described in this chapter articulate the performance issues against which software must be designed. Based on a clearer understanding of the importance of communication costs on modern machines, models like BSP and LogP help analyze communication cost and hence improve the structure of communication. These models expose

the important costs associated with a communication event, such as latency, bandwidth, or overhead, allowing algorithm designers to factor them into the comparative analysis of parallel algorithms. Even more, the emphasis on modeling communication cost has shifted to the cost at the nodes that are the endpoints of the communication message, such that the number of messages and contention at the endpoints have become more important than mapping to network technologies. In fact, both the BSP and LogP models ignore network topology, modeling network delay as a constant value.

An in-depth comparison of BSP and LogP has been performed in [2], showing that both models are roughly equivalent in terms of expressiveness, slightly favoring BSP for its higher-level abstraction. But it was exactly this model that was found to be too restrictive by the designers of LogP [4]. Both models have their advantages and disadvantages. LogP is better suited for modeling applications that actually use point-to-point communication, while BSP is better and simpler for data-parallel applications that fit the superstep model. The BSP model also provides an elegant framework that can be used to reason about communication and parallel performance. The major contribution of both models is the explicit acknowledgement of communication costs that are dependent on properties of the underlying machine architecture.

The BSP and LogP models are important steps toward a realistic architectural model for designing and analyzing parallel algorithms. By experimenting with the values of the key parameters in the models, it is possible to determine how an algorithm will perform across a range of architectures and how it should be structured for different architectures or for portable performance.

Bibliographic Notes and Further Reading

The presented models and their extensions were originally introduced in papers [1, 4, 11] and described in

textbooks [12–14] which were partially used for writing this entry. A number of various models similar to BSP and LogP have been proposed: Queuing Shared Memory (QSM) [15], LPRAM [16], Decomposable BSP [17], etc. Further papers in the list of references deal with particular applications of the models and their classification and standardization.

Banerjee's Dependence Test

UTPAL BANERJEE

University of California at Irvine, Irvine, CA, USA

Definition

Banerjee's Test is a simple and effective data dependence test widely used in automatic vectorization and parallelization of loops. It detects dependence between statements caused by subscripted variables by analyzing the subscripts.

Discussion

Introduction

A restructuring compiler transforms a sequential program into a parallel form that can run efficiently on a parallel machine. The task of the compiler is to discover the parallelism that may be hiding in the program and bring it out into the open. The first step in this process is to compute the *dependence structure* imposed on the program operations by the sequential execution order. The parallel version of the sequential program must obey the same dependence constraints, so that it computes the same final values as the original program. (If an operation B depends on an operation A in the sequential program, then A must be executed before B in the parallel program.) To detect possible dependence between two operations, one needs to know if

they access the same memory location during sequential execution and in which order. Banerjee's Test provides a simple mechanism for dependence detection in loops when subscripted variables are involved.

In this essay, Banerjee's test is developed for one-dimensional array variables in assignment statements within a perfect loop nest. Pointers are given for extensions to more complicated situations. The first section below is on mathematical preliminaries, where certain concepts and results are presented that are essential for an understanding of the test. After that the relevant dependence concepts are explained, and then the test itself is discussed.

Mathematical Preliminaries

Linear Diophantine Equations

Let \mathbf{Z} denote the set of all integers. An integer b divides an integer a , if there exists an integer c such that $a = bc$. For a list of integers a_1, a_2, \dots, a_m , not all zero, the *greatest common divisor* or gcd is the largest positive integer that divides each member of the list. It is denoted by $\gcd(a_1, a_2, \dots, a_m)$. The gcd of a list of zeros is defined to be 0.

A *linear diophantine equation* in m variables is an equation of the form

$$a_1x_1 + a_2x_2 + \dots + a_mx_m = c$$

where the coefficients a_1, a_2, \dots, a_m are integers not all zero, c is an integer, and x_1, x_2, \dots, x_m are integer variables. A *solution* to this equation is a sequence of integers (i_1, i_2, \dots, i_m) such that $\sum_{k=1}^m a_k i_k = c$. The following theorem is a well-known result in Number Theory.

Theorem 1 *The linear diophantine equation*

$$a_1x_1 + a_2x_2 + \dots + a_mx_m = c$$

has a solution if and only if $\gcd(a_1, a_2, \dots, a_m)$ divides c .

Proof The “only if” Part is easy to prove. If the equation has a solution, then there are integers i_1, i_2, \dots, i_m such that $\sum_{k=1}^m a_k i_k = c$. Since $\gcd(a_1, a_2, \dots, a_m)$ divides each a_k , it must also divide c . To get the “if” Part (and derive the general solution), see the proof of Theorem 3.5 in [4]. \square

Lexicographic Order

For any positive integer m , the set of all integer m -vectors (i_1, i_2, \dots, i_m) is denoted by \mathbf{Z}^m . The zero vector $(0, 0, \dots, 0)$ is abbreviated as $\mathbf{0}$. Addition and subtraction of members of \mathbf{Z}^m are defined coordinate-wise in the usual way.

For $1 \leq \ell \leq m$, a relation \prec_ℓ in \mathbf{Z}^m is defined as follows: If $\mathbf{i} = (i_1, i_2, \dots, i_m)$ and $\mathbf{j} = (j_1, j_2, \dots, j_m)$ are vectors in \mathbf{Z}^m , then $\mathbf{i} \prec_\ell \mathbf{j}$ if

$$i_1 = j_1, i_2 = j_2, \dots, i_{\ell-1} = j_{\ell-1}, \text{ and } i_\ell < j_\ell.$$

The *lexicographic order* \prec in \mathbf{Z}^m is then defined by requiring that $\mathbf{i} \prec \mathbf{j}$, if $\mathbf{i} \prec_\ell \mathbf{j}$ for some ℓ in $1 \leq \ell \leq m$.

It is often convenient to write $\mathbf{i} \prec_{m+1} \mathbf{j}$ when $i_1 = j_1, i_2 = j_2, \dots, i_m = j_m$, that is, $\mathbf{i} = \mathbf{j}$. The notation $\mathbf{i} \leq \mathbf{j}$ means either $\mathbf{i} \prec \mathbf{j}$ or $\mathbf{i} = \mathbf{j}$, that is, $\mathbf{i} \prec_\ell \mathbf{j}$ for some ℓ in $1 \leq \ell \leq m+1$. Note that \leq is a total order in \mathbf{Z}^m .

The associated relations $>$ and \geq are defined in the usual way: $\mathbf{j} > \mathbf{i}$ means $\mathbf{i} \prec \mathbf{j}$, and $\mathbf{j} \geq \mathbf{i}$ means $\mathbf{i} \leq \mathbf{j}$. (\geq is also a total order in \mathbf{Z}^m .) An integer vector \mathbf{i} is *positive* if $\mathbf{i} > \mathbf{0}$, *nonnegative* if $\mathbf{i} \geq \mathbf{0}$, and *negative* if $\mathbf{i} < \mathbf{0}$.

Let \mathbf{R} denote the field of real numbers. The *sign function* $\operatorname{sgn} : \mathbf{R} \rightarrow \mathbf{Z}$ is defined by

$$\operatorname{sgn}(x) = \begin{cases} 1 & \text{if } x > 0 \\ 0 & \text{if } x = 0 \\ -1 & \text{if } x < 0, \end{cases}$$

for each x in \mathbf{R} . The *direction vector* of any vector (i_1, i_2, \dots, i_m) in \mathbf{Z}^m is $(\operatorname{sgn}(i_1), \operatorname{sgn}(i_2), \dots, \operatorname{sgn}(i_m))$. Note that a vector is positive (negative) if and only if its direction vector is positive (negative).

Extreme Values of Linear Functions

For any positive integer m , let \mathbf{R}^m denote the m -dimensional Euclidean space consisting of all real m -vectors. It is a real vector space where vector addition and scalar multiplication are defined coordinate-wise. The concepts of the previous subsection stated in terms of integer vectors can be trivially extended to the realm of real vectors. For a real number a , we define the *positive part* a^+ and the *negative part* a^- as in [2]:

$$a^+ = \frac{|a| + a}{2} = \max(a, 0) \quad \text{and}$$

$$a^- = \frac{|a| - a}{2} = \max(-a, 0).$$

Thus, $a^+ = a$ and $a^- = 0$ for $a \geq 0$, while $a^+ = 0$ and $a^- = -a$ for $a \leq 0$. For example, $4^+ = 4$, $4^- = 0$, $(-4)^+ = 0$, and $(-4)^- = 4$. The following lemma lists the basic properties of positive and negative parts of a number (Lemma 2.2 in [2], Lemma 3.1 in [4]).

Lemma 2 *For any real number a , the following statements hold:*

1. $a^+ \geq 0$, $a^- \geq 0$,
2. $a = a^+ - a^-$, $|a| = a^+ + a^-$,
3. $(-a)^+ = a^-$, $(-a)^- = a^+$,
4. $(a^+)^+ = a^+$, $(a^+)^- = 0$,
5. $(a^-)^+ = a^-$, $(a^-)^- = 0$,
6. $-a^- \leq a \leq a^+$.

The next lemma gives convenient expressions for the extreme values of a simple function. (This is Lemma 3.2 in [4]; it generalizes Lemma 2.3 in [2].)

Lemma 3 *Let a, p, q denote real constants, where $p < q$. The minimum and maximum values of the function $f(x) = ax$ on the interval $p \leq x \leq q$ are $(a^+p - a^-q)$ and $(a^+q - a^-p)$, respectively.*

Proof For $p \leq x \leq q$, the following hold:

$$a^+p \leq a^+x \leq a^+q$$

$$-a^-q \leq -a^-x \leq -a^-p,$$

since $a^+ \geq 0$ and $-a^- \leq 0$. Adding these two sets of inequalities, one gets

$$a^+p - a^-q \leq ax \leq a^+q - a^-p,$$

since $a = a^+ - a^-$. To complete the proof, note that these bounds for $f(x)$ are actually attained at the end points $x = p$ and $x = q$, and therefore they are the extreme values of f . For example, when $a \geq 0$, it follows that

$$a^+p - a^-q = ap = f(p)$$

$$a^+q - a^-p = aq = f(q).$$

1. If $x = y$, then

$$-(a - b)^-q \leq ax - by \leq (a - b)^+q.$$
2. If $x \leq y - 1$, then

$$-b - (a^- + b)^+(q - 1) \leq ax - by \leq -b + (a^+ - b)^+(q - 1).$$
3. If $x \geq y + 1$, then

$$a - (b^+ - a)^+(q - 1) \leq ax - by \leq a + (b^- + a)^+(q - 1).$$
4. If (x, y) varies freely in A , then

$$-(a^- + b^+)q \leq ax - by \leq (a^+ + b^-)q.$$

Proof By Lemma 3, $0 \leq x \leq q$ implies $-a^-q \leq ax \leq a^+q$. This result and Lemma 2 are used repeatedly in the following proof.

Case 1. Let $x = y$. Then $ax - by = (a - b)x$. Since $0 \leq x \leq q$, one gets

$$-(a - b)^-q \leq ax - by \leq (a - b)^+q.$$

Case 2. Let $0 \leq x \leq y - 1 \leq q - 1$. Then $ax \leq a^+(y - 1)$. Hence,

$$ax - by = -b + [ax - b(y - 1)] \leq -b + (a^+ - b)(y - 1).$$

Since $0 \leq y - 1 \leq q - 1$, an upper bound for $(ax - by)$ is given by:

$$ax - by \leq -b + (a^+ - b)^+(q - 1).$$

To derive a lower bound, replace a with $-a$ and b with $-b$ to get

$$-ax + by \leq b + (a^- + b)^+(q - 1),$$

so that

$$-b - (a^- + b)^+(q - 1) \leq ax - by.$$

Case 3. Let $x \geq y + 1$. Then $0 \leq y \leq x - 1 \leq q - 1$. In Case 2, replace x by y , y by x , a by $-b$, and b by $-a$, to get

$$\begin{aligned} a - ((-b)^- - a)^+(q - 1) &\leq (-b)y - (-a)x \\ &\leq a + ((-b)^+ + a)^+(q - 1), \end{aligned}$$

or

$$a - (b^+ - a)^+(q - 1) \leq ax - by \leq a + (b^- + a)^+(q - 1).$$

Case 4. Since $0 \leq x \leq q$, one gets $-a^-q \leq ax \leq a^+q$. Also, since $0 \leq y \leq q$, it follows that $-b^-q \leq by \leq b^+q$, that is, $-b^+q \leq -by \leq b^-q$. Hence,

$$-a^-q - b^+q \leq ax - by \leq a^+q + b^-q.$$

This gives the bounds for Case 4.

As in the proof of Lemma 3, it can be shown in each case that each bound is actually attained at some point of the corresponding domain. Hence, the bounds represent the extreme values of f in each case. \square

The Euclidean space \mathbf{R}^m is an inner product space, where the inner product of two vectors $\mathbf{x} = (x_1, x_2, \dots, x_m)$ and $\mathbf{y} = (y_1, y_2, \dots, y_m)$ is defined by $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{k=1}^m x_k y_k$. The inner product defines a norm (length), the norm defines a metric (distance), and the metric defines a topology. In this topological vector space, one can talk about bounded sets, open and closed sets, compact sets, and connected sets. The following theorem is easily derived from well-known results in topology. (See the topology book by Kelley [8] for details.)

Theorem 5 *Let $f : \mathbf{R}^m \rightarrow \mathbf{R}$ be a continuous function. If a set $A \subset \mathbf{R}^m$ is closed, bounded, and connected, then $f(A)$ is a finite closed interval of \mathbf{R} .*

Proof Note that R^m and \mathbf{R} are both Euclidean spaces. A subset of a Euclidean space is compact if and only if it is closed and bounded. Thus, the set A is compact and connected. Since f is continuous, it maps a compact set onto a compact set, and a connected set onto a connected set. Hence, the set $f(A)$ is compact and connected, that is, closed, bounded, and connected. Therefore, $f(A)$ must be a finite closed interval of \mathbf{R} . \square

Corollary 1 *Let $f : \mathbf{R}^m \rightarrow \mathbf{R}$ denote a continuous function, and let A be a closed, bounded, and connected subset of \mathbf{R}^m . Then f assumes a minimum and a maximum value on A . And for any real number c satisfying the inequalities*

$$\min_{x \in A} f(x) \leq c \leq \max_{x \in A} f(x),$$

the equation $f(x) = c$ has a solution $x_0 \in A$.

Proof By Theorem 5, the image $f(A)$ of A is a finite closed interval $[\alpha, \beta]$ of \mathbf{R} . Then for each $x \in A$, one has $\alpha \leq f(x) \leq \beta$. So, α is a lower bound and β an upper bound for f on A . Since $\alpha \in f(A)$ and $\beta \in f(A)$, there are points $x_1, x_2 \in A$ such that $f(x_1) = \alpha$ and $f(x_2) = \beta$. Thus, f assumes a minimum and a maximum value on A , and $\alpha = \min_{x \in A} f(x)$ and $\beta = \max_{x \in A} f(x)$. If $\alpha \leq c \leq \beta$, then $c \in f(A)$, that is, $f(x_0) = c$ for some $x_0 \in A$. \square

Dependence Concepts

For more details on the material of this section, see Chapter 4 in [4]. An *assignment statement* has the form

$$S : \quad x = E$$

where S is a label, x a variable, and E an expression. Such a statement reads the memory locations specified in E , and writes the location x . The *output variable* of S is x and its *input variables* are the variables in E . Let $\text{Out}(S) = \{x\}$ and denote by $\text{In}(S)$ the set of all input variables of S .

The basic program model is a perfect nest of loops $\mathbf{L} = (L_1, L_2, \dots, L_m)$ shown in Fig. 1. For $1 \leq k \leq m$, the index variable I_k of L_k runs from 0 to some positive integer N_k in steps of 1. The *index vector* of the loop nest is $\mathbf{I} = (I_1, I_2, \dots, I_m)$. An *index point* or *index value* of the nest is a possible value of the index vector, that is, a vector $\mathbf{i} = (i_1, i_2, \dots, i_m) \in \mathbf{Z}^m$ such that $0 \leq i_k \leq N_k$ for $1 \leq k \leq m$. The subset of \mathbf{Z}^m consisting of all index points is the *index space* of the loop nest. During sequential execution of the nest, the index vector starts at the index point $\mathbf{0} = (0, 0, \dots, 0)$ and ends at the point (N_1, N_2, \dots, N_m) after traversing the entire index space in the lexicographic order.

The *body* of the loop nest \mathbf{L} is denoted by $H(\mathbf{I})$ or H ; it is assumed to be a sequence of assignment statements. A given index value \mathbf{i} defines a particular *instance* $H(\mathbf{i})$ of $H(\mathbf{I})$, which is an *iteration* of \mathbf{L} . An iteration $H(\mathbf{i})$ is executed before an iteration $H(\mathbf{j})$ if and only if $\mathbf{i} < \mathbf{j}$.

A typical statement in the body of the loop nest is denoted by $S(\mathbf{I})$ or S , and its instance for an index value \mathbf{i} is written as $S(\mathbf{i})$. Let S and T denote any two (not necessarily distinct) statements in the body. Statement T depends on statement S , if there exist a memory location M , and two index points \mathbf{i} and \mathbf{j} , such that

```

 $L_1 : \quad \text{do } I_1 = 0, N_1, 1$ 
 $L_2 : \quad \text{do } I_2 = 0, N_2, 1$ 
 $\vdots \quad \vdots$ 
 $L_m : \quad \text{do } I_m = 0, N_m, 1$ 
 $H(I_1, I_2, \dots, I_m)$ 
 $\text{enddo}$ 
 $\vdots$ 
 $\text{enddo}$ 

```

Banerjee's Dependence Test. Fig. 1 A perfect loop nest

1. The instances $S(\mathbf{i})$ of S and $T(\mathbf{j})$ of T both reference (read or write) \mathcal{M}
2. In the sequential execution of the program, $S(\mathbf{i})$ is executed before $T(\mathbf{j})$.

If \mathbf{i} and \mathbf{j} are a pair of index points that satisfy these two conditions, then it is convenient to say that $T(\mathbf{j})$ depends on $S(\mathbf{i})$. Thus, T depends on S if and only if at least one instance of T depends on at least one instance of S . The concept of dependence can have various attributes as described below.

Let $\mathbf{i} = (i_1, i_2, \dots, i_m)$ and $\mathbf{j} = (j_1, j_2, \dots, j_m)$ denote a pair of index points, such that $T(\mathbf{j})$ depends on $S(\mathbf{i})$. If S and T are distinct and S appears lexically before T in H , then $S(\mathbf{i})$ is executed before $T(\mathbf{j})$ if and only if $\mathbf{i} \leq \mathbf{j}$. Otherwise, $S(\mathbf{i})$ is executed before $T(\mathbf{j})$ if and only if $\mathbf{i} < \mathbf{j}$. If $\mathbf{i} \leq \mathbf{j}$, there is a unique integer ℓ in $1 \leq \ell \leq m+1$ such that $\mathbf{i} <_{\ell} \mathbf{j}$. If $\mathbf{i} < \mathbf{j}$, there is a unique integer ℓ in $1 \leq \ell \leq m$ such that $\mathbf{i} <_{\ell} \mathbf{j}$. This integer ℓ is a *dependence level* for the dependence of T on S . The vector $\mathbf{d} \in \mathbb{Z}^m$, defined by $\mathbf{d} = \mathbf{j} - \mathbf{i}$, is a *distance vector* for the same dependence. Also, the direction vector σ of \mathbf{d} , defined by

$$\sigma = (\operatorname{sgn}(j_1 - i_1), \operatorname{sgn}(j_2 - i_2), \dots, \operatorname{sgn}(j_m - i_m)),$$

is a *direction vector* for this dependence. Note that both \mathbf{d} and σ are nonnegative vectors if S precedes T in H , and both are positive vectors otherwise. The dependence of $T(\mathbf{j})$ on $S(\mathbf{i})$ is *carried* by the loop L_{ℓ} if the dependence level ℓ is between 1 and m . Otherwise, the dependence is *loop-independent*.

A statement can reference a memory location only through one of its variables. The definition of dependence is now extended to make explicit the role played by the variables in the statements under consideration. A variable $u(\mathbf{I})$ of the statement S and a variable $v(\mathbf{I})$ of the statement T cause a dependence of T on S , if there are index points \mathbf{i} and \mathbf{j} , such that

1. The instance $u(\mathbf{i})$ of $u(\mathbf{I})$ and the instance $v(\mathbf{j})$ of $v(\mathbf{I})$ both represent the same memory location;
2. In the sequential execution of the program, $S(\mathbf{i})$ is executed before $T(\mathbf{j})$.

If these two conditions hold, then the dependence caused by $u(\mathbf{I})$ and $v(\mathbf{I})$ is characterized as

1. A *flow dependence* if

$$u(\mathbf{I}) \in \operatorname{Out}(S) \text{ and } v(\mathbf{I}) \in \operatorname{In}(T);$$

2. An *anti-dependence* if $u(\mathbf{I}) \in \operatorname{In}(S)$ and $v(\mathbf{I}) \in \operatorname{Out}(T)$;
3. An *output dependence* if $u(\mathbf{I}) \in \operatorname{Out}(S)$ and $v(\mathbf{I}) \in \operatorname{Out}(T)$;
4. An *input dependence* if $u(\mathbf{I}) \in \operatorname{In}(S)$ and $v(\mathbf{I}) \in \operatorname{In}(T)$.

Banerjee's Test

In its simplest form, Banerjee's Test is a necessary condition for the existence of dependence of one statement on another at a given level, caused by a pair of one-dimensional array variables. This form of the test is described in [Theorem 6](#). [Theorem 7](#) gives the version of the test that deals with dependence with a fixed direction vector. Later on, pointers are given for extending the test in different directions.

Theorem 6 Consider any two assignment statements S and T in the body H of the loop nest of [Fig. 1](#). Let $X(f(\mathbf{I}))$ denote a variable of S and $X(g(\mathbf{I}))$ a variable of T , where X is a one-dimensional array, $f(\mathbf{I}) = a_0 + \sum_{k=1}^m a_k I_k$, $g(\mathbf{I}) = b_0 + \sum_{k=1}^m b_k I_k$, and the a 's and the b 's are all integer constants. If $X(f(\mathbf{I}))$ and $X(g(\mathbf{I}))$ cause a dependence of T on S at a level ℓ , then the following two conditions hold:

- (A) $\gcd(a_1 - b_1, \dots, a_{\ell-1} - b_{\ell-1}, a_{\ell}, \dots, a_m, b_{\ell}, \dots, b_m)$ divides $(b_0 - a_0)$;
 - (B) $\alpha \leq b_0 - a_{\ell-1} \leq \beta$, where
- $$\begin{aligned} \alpha &= -b_{\ell} - \sum_{k=1}^{\ell-1} (a_k - b_k)^- N_k - (a_{\ell}^- + b_{\ell})^+ (N_{\ell} - 1) \\ &\quad - \sum_{k=\ell+1}^m (a_k^- + b_k^+) N_k \\ \beta &= -b_{\ell} + \sum_{k=1}^{\ell-1} (a_k - b_k)^+ N_k + (a_{\ell}^+ - b_{\ell})^+ (N_{\ell} - 1) \\ &\quad + \sum_{k=\ell+1}^m (a_k^+ + b_k^-) N_k. \end{aligned}$$

Proof Assume that the variables $X(f(\mathbf{I}))$ and $X(g(\mathbf{I}))$ do cause a dependence of statement T on statement S at a level ℓ . If S precedes T in H , the dependence level ℓ could be any integer in $1 \leq \ell \leq m+1$. Otherwise, ℓ must be in the range $1 \leq \ell \leq m$. By hypothesis, there exist two index points $\mathbf{i} = (i_1, i_2, \dots, i_m)$ and $\mathbf{j} = (j_1, j_2, \dots, j_m)$ such that $\mathbf{i} <_{\ell} \mathbf{j}$, and $X(f(\mathbf{i}))$ and $X(g(\mathbf{j}))$ represent the same memory location.

The restrictions on $i_1, i_2, \dots, i_m, j_1, j_2, \dots, j_m$ are as follows:

$$\left. \begin{array}{l} 0 \leq i_k \leq N_k \\ 0 \leq j_k \leq N_k \end{array} \right\} \quad (1 \leq k \leq m) \quad (1)$$

$$i_k = j_k \quad (1 \leq k \leq \ell - 1) \quad (2)$$

$$i_\ell \leq j_\ell - 1. \quad (3)$$

(As i_ℓ and j_ℓ are integers, $i_\ell < j_\ell$ means $i_\ell \leq j_\ell - 1$.)

Since $f(\mathbf{i})$ and $g(\mathbf{j})$ must be identical, it follows that

$$\begin{aligned} b_0 - a_0 &= \sum_{k=1}^{\ell-1} (a_k i_k - b_k j_k) + (a_\ell i_\ell - b_\ell j_\ell) \\ &\quad + \sum_{k=\ell+1}^m (a_k i_k - b_k j_k). \end{aligned} \quad (4)$$

Because of (2), this equation is equivalent to

$$\begin{aligned} b_0 - a_0 &= \sum_{k=1}^{\ell-1} (a_k - b_k) i_k + (a_\ell i_\ell - b_\ell j_\ell) \\ &\quad + \sum_{k=\ell+1}^m (a_k i_k - b_k j_k). \end{aligned} \quad (5)$$

First, think of $i_1, i_2, \dots, i_m, j_\ell, j_{\ell+1}, \dots, j_m$ as integer variables. Since the linear diophantine equation (5) has a solution, condition (A) of the theorem is implied by [Theorem 1](#).

Next, think of $i_1, i_2, \dots, i_m, j_\ell, j_{\ell+1}, \dots, j_m$ as real variables. Note that for $1 \leq k < t \leq m$, there is no relation between the pair of variables (i_k, j_k) and the pair of variables (i_t, j_t) . Hence, the minimum (maximum) value of the right-hand side of (4) can be computed by summing the minimum (maximum) values of all the individual terms $(a_k i_k - b_k j_k)$. For each k in $1 \leq k \leq m$, one can compute the extreme values of the term $(a_k i_k - b_k j_k)$ by using a suitable case of Theorem 4. It is then clear that α is the minimum value of the right-hand side of (4), and β is its maximum value. Hence, $(b_0 - a_0)$ must lie between α and β . This is condition (B) of the theorem. \square

For the dependence problem of Theorem 6, equation (4) or (5) is the *dependence equation*, condition (A) is the *gcd Test*, and condition (B) is *Banerjee's Test*.

Remarks

1. In general, the two conditions of Theorem 6 are necessary for existence of dependence, but they are not sufficient. Suppose both conditions hold. First, think in terms of real variables. Let P denote the subset of \mathbf{R}^{2m} defined by the inequalities (1)–(3). Then P is a closed, bounded, and connected set. The right-hand side of (5) represents a real-valued continuous function on \mathbf{R}^{2m} . Its extreme values on P are given by α and β . Condition (B) implies that there is a *real* solution to equation (5) with the constraints (1)–(3) (by Corollary 1 to [Theorem 5](#)). On the other hand, condition (A) implies that there is an *integer* solution to equation (5) without any further constraints (by Theorem 1). Theoretically, the two conditions together do not quite imply the existence of an *integer* solution with the constraints needed to guarantee the dependence of $T(\mathbf{j})$ on $S(\mathbf{i})$. However, note that using Theorem 6, one would never falsely conclude that a dependence does not exist when in fact it does.
2. If one of the two conditions of Theorem 6 fails to hold, then there is no dependence. If both of them hold, there may or may not be dependence. In practice, however, it usually turns out that when the conditions hold, there is dependence. This can be explained by the fact that there are certain types of array subscripts for which the conditions are indeed sufficient, and these are the types most commonly encountered in practice. Theorem 4.3 in [2] shows that the conditions are sufficient, if there is an integer $t > 0$ such that $a_k, b_k \in \{-t, 0, t\}$ for $1 \leq k \leq m$. Psarris et al. [11] prove the sufficiency for another large class of subscripts commonly found in real programs.

Example 1 Consider the loop nest of [Fig. 2](#), where X is a one-dimensional array, and the constant terms a_0, b_0 in the subscripts are integers unspecified for the moment. Suppose one needs to check if T is output-dependent on S at level 2. For this problem, $m = 3$, $\ell = 2$, and

$$(N_1, N_2, N_3) = (100, 50, 40),$$

$$(a_1, a_2, a_3) = (1, 2, -1), (b_1, b_2, b_3) = (3, -1, 2).$$

Since $\text{gcd}(a_1 - b_1, a_2, a_3, b_2, b_3) = \text{gcd}(-2, 2, -1, -1, 2) = 1$, condition (A) of Theorem 6 is always satisfied. To test

```

 $L_1 : \text{do } I_1 = 0, 100, 1$ 
 $L_2 : \text{do } I_2 = 0, 50, 1$ 
 $L_3 : \text{do } I_3 = 0, 40, 1$ 
 $S: \quad X(a_0 + I_1 + 2I_2 - I_3) = \dots$ 
 $T: \quad X(b_0 + 3I_1 - I_2 + 2I_3) = \dots$ 
    enddo
  enddo
enddo

```

Banerjee's Dependence Test. Fig. 2 Loop nest of example 1

condition (B), evaluate α and β :

$$\begin{aligned}\alpha &= -b_2 - (a_1 - b_1)^- N_1 - (a_2^- + b_2)^+ (N_2 - 1) \\ &\quad - (a_3^- + b_3^+) N_3 = -319 \\ \beta &= -b_2 + (a_1 - b_1)^+ N_1 + (a_2^+ - b_2)^+ (N_2 - 1) \\ &\quad + (a_3^+ + b_3^-) N_3 = 148.\end{aligned}$$

Condition (B) then becomes

$$-319 \leq b_0 - a_0 \leq 148.$$

First, take $a_0 = -50$ and $b_0 = 100$. Then $(b_0 - a_0)$ is outside this range, and hence Banerjee's Test is not satisfied. By Theorem 6, statement T is not output-dependent on statement S at level 2.

Next, take $a_0 = b_0 = 0$. Then $b_0 - a_0$ is within the range, and Banerjee's Test is satisfied. Theorem 6 cannot guarantee the existence of the dependence under question. However, there exist two index points $\mathbf{i} = (20, 10, 10)$ and $\mathbf{j} = (20, 40, 5)$ of the loop nest, such that $\mathbf{i} <_2 \mathbf{j}$, the instance $S(\mathbf{i})$ of statement S is executed before the instance $T(\mathbf{j})$ of statement T , and both instances write the memory location $X(30)$. Thus, statement T is indeed output-dependent on statement S at level 2.

Theorem 6 dealt with dependence at a level. It is now extended to a result that deals with dependence with a given direction vector. A direction vector here has the general form $\sigma = (\sigma_1, \sigma_2, \dots, \sigma_m)$, where each σ_k is either unspecified, or has one of the values 0, 1, -1. When σ_k is unspecified, one writes $\sigma_k = *$. (As components of a direction vector, many authors use ' $=$ ', ' $<$ ', ' $>$ ' in place of 0, 1, -1, respectively.)

Theorem 7 Consider any two assignment statements S and T in the body H of the loop nest of Fig. 1. Let $X(f(\mathbf{I}))$ denote a variable of S and $X(g(\mathbf{I}))$ a variable of T , where X is a one-dimensional array, $f(\mathbf{I}) = a_0 + \sum_{k=1}^m a_k I_k$, and the a 's and the b 's are all

integer constants. If these variables cause a dependence of T on S with a direction vector $(\sigma_1, \sigma_2, \dots, \sigma_m)$, then the following two conditions hold:

(A) The gcd of all integers in the three lists

$$\{a_k - b_k : \sigma_k = 0\}, \{a_k : \sigma_k \neq 0\}, \{b_k : \sigma_k \neq 0\}$$

divides $(b_0 - a_0)$;

(B) $\alpha \leq b_0 - a_0 \leq \beta$, where

$$\begin{aligned}\alpha &= - \sum_{\sigma_k=0} (a_k - b_k)^- N_k \\ &\quad - \sum_{\sigma_k=1} [b_k + (a_k^- + b_k)^+ (N_k - 1)] \\ &\quad + \sum_{\sigma_k=-1} [a_k - (b_k^+ - a_k)^+ (N_k - 1)] \\ &\quad - \sum_{\sigma_k= *} (a_k^- + b_k^+) N_k \\ \beta &= \sum_{\sigma_k=0} (a_k - b_k)^+ N_k \\ &\quad + \sum_{\sigma_k=1} [-b_k + (a_k^+ - b_k)^+ (N_k - 1)] \\ &\quad + \sum_{\sigma_k=-1} [a_k + (b_k^- + a_k)^+ (N_k - 1)] \\ &\quad + \sum_{\sigma_k= *} (a_k^+ + b_k^-) N_k.\end{aligned}$$

Proof All expressions of the form $(a_k - b_k)$, where $1 \leq k \leq m$ and $\sigma_k = 0$, constitute the list $\{a_k - b_k : \sigma_k = 0\}$. The other two lists have similar meanings. The sum $\sum_{\sigma_k=0}$ is taken over all values of k in $1 \leq k \leq m$ such that $\sigma_k = 0$. The other three sums have similar meanings. As in the case of Theorem 6, the proof of this theorem follows directly from Theorem 1 and Theorem 4. \square

For the dependence problem with a direction vector, condition (A) of Theorem 7 is the gcd Test and condition (B) is Banerjee's Test. Comments similar to those given in Remarks 1 also apply to Theorem 7.

The expressions for α and β in Banerjee's Test may look complicated even though their numerical evaluation is quite straightforward. With the goal of developing the test quickly while avoiding complicated formulas, the perfect loop nest of Fig. 1 was taken as the model program, and the variables were assumed to be one-dimensional array elements. However, Banerjee's Test can be extended to cover multidimensional array elements in a much more general program. Detailed references are given in the section on further reading.

Bibliographic Notes and Further Reading

Banerjee's Test first appeared in Utpal Banerjee's MS thesis [2] at the University of Illinois, Urbana-Champaign, in 1976. In that thesis, the test is developed for checking dependence at any level when the subscript functions $f(\mathbf{I})$ and $g(\mathbf{I})$ are polynomials in I_1, I_2, \dots, I_m . The case where $f(\mathbf{I})$ and $g(\mathbf{I})$ are linear (affine) functions of the index variables is then derived as a special case (Theorem 4.1). Theorem 4.1 of [2] appeared as Theorem 5 in the 1979 paper by Banerjee, Chen, Kuck, and Towle [7]. Theorem 6 presented here is essentially the same theorem, but has a stronger gcd Test. (The stronger gcd Test was pointed out by Kennedy in [9].)

Banerjee's Test for a direction vector of the form $\sigma = (0, \dots, 0, 1, -1, *, \dots, *)$ was given by Kennedy in [9]. It is a special case of Theorem 7 presented here. See also the comprehensive paper by Allen and Kennedy [1]. Wolfe and Banerjee [12] give an extensive treatment of the dependence problem involving direction vectors. (The definition of the negative part of a number used in [12] is slightly different from that used here and in most other publications.)

The first book on dependence analysis [3] was published in 1988; it gave the earliest coverage of Banerjee's Test in a book form. *Dependence Analysis* [6] published in 1997 is a completely new work that subsumes the material in [3].

It is straightforward to extend theorems 6 and 7 to the case where we allow the loop limits to be arbitrary integer constants, as long as the stride of each loop is kept at 1. See theorems 6.2 and 6.3 in [6]. This model can be further extended to test the dependence of a statement T on a statement S when the nest of loops enclosing S is different from the nest enclosing T . See theorems 6.4 and 6.5 in [6].

A loop of the form “**do** $I = p, q, \theta$,” where p, q, θ are integers and $\theta \neq 0$, can be converted into the loop “**do** $\hat{I} = 0, N, 1$,” where $I = p + \hat{I}\theta$ and $N = \lfloor (q - p)/\theta \rfloor$. The new variable \hat{I} is the *iteration variable* of the loop. Using this process of loop normalization, one can convert any nest of loops to a standard form if the loop limits and strides are integer constants. (See [6].)

Consider now the dependence problem posed by variables that come from a multidimensional array, where each subscript is a linear (affine) function of the index variables. The gcd Test can be generalized to handle this case; see Section 5.2 of [4] and Section 5.4 of [6]. Also, Banerjee's Test can be applied separately to the subscripts in each dimension; see Theorem 6.6 in [6]. If the test is not satisfied in one particular dimension, then there is no dependence as a whole. But, if the test is satisfied in each dimension, there is no definite conclusion. Another alternative is array linearization; see Section 6.5 in [3]. Zhiyuan Li et al. [10] did a study of dependence analysis for multidimensional array elements, that did not involve subscript-by-subscript testing, nor array linearization. The general method presented in Chapter 6 of [6] includes Li's λ -test.

The dependence problem is quite complex when one has an arbitrary loop nest with loop limits that are linear functions of index variables, and multidimensional array elements with linear subscripts. To understand the general problem and some methods of solution, see the developments in [4] and [6].

Many researchers have studied Banerjee's Test over the years; the test in various forms can be found in many publications. *Dependence Analysis* [6] covers this test quite extensively. For a systematic development of the dependence problem, descriptions of the needed mathematical tools, and applications of dependence analysis to program transformations, see the books [4–6] in the series on Loop Transformations for Restructuring compilers.

Behavioral Equivalences

ROCCO DE NICOLA
Università degli Studi di Firenze, Firenze, Italy

Synonyms

[Behavioral relations](#); [Extensional equivalences](#)

Definition

Behavioral equivalences serve to establish in which cases two reactive (possible concurrent) systems offer similar interaction capabilities relatively to other systems representing their operating environment. Behavioral equivalences have been mainly developed in the context of *process algebras*, mathematically rigorous languages that have been used for describing and verifying properties of concurrent communicating systems. By relying on the so-called structural operational semantics (SOS), labeled transition systems are associated to each term of a process algebra. Behavioral equivalences are used to abstract from unwanted details and identify those labeled transition systems that react “similarly” to external experiments. Due to the large number of properties which may be relevant in the analysis of concurrent systems, many different theories of equivalences have been proposed in the literature. The main contenders consider those systems equivalent that (1) perform the same sequences of actions, or (2) perform the same sequences of actions and after each sequence are ready to accept the same sets of actions, or (3) perform the same sequences of actions and after each sequence exhibit, recursively, the same behavior. This approach leads to many different equivalences that preserve significantly different properties of systems.

Introduction

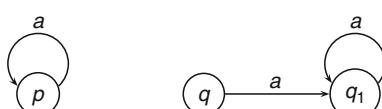

In many cases, it is useful to have theories which can be used to establish whether two systems are equivalent or whether one is a satisfactory “approximation” of another. It can be said that a system S_1 is equivalent to a system S_2 whenever “some” aspects of the externally observable behavior of the two systems are compatible. If the same formalism is used to model what is required of a system (its *specification*) and how it can actually be built (its *implementation*), then it is possible to use theories based on equivalences to prove that a particular concrete description is correct with respect to a given abstract one. If a step-wise development method is used, equivalences may permit substituting large specifications with equivalent concise ones. In general it is useful to be able to interchange subsystems proved behaviorally equivalent, in the sense that one subsystem may replace another as part of a larger system without affecting the behavior of the overall system.

The kind of equivalences, or approximations, involved depends very heavily on how the systems under consideration will be used. In fact, the way a system is used determines the behavioral aspects which must be taken into account and those which can be ignored. It is then important to know, for the considered equivalence, the systems properties it preserves.

In spite of the general agreement on taking an extensional approach for defining the equivalence of concurrent or nondeterministic systems, there is still disagreement on what “reasonable” observations are and how their outcomes can be used to distinguish or identify systems. Many different theories of equivalences have been proposed in the literature for models which are intended to be used to describe and reason about concurrent or nondeterministic systems. This is mainly due to the large number of properties which may be relevant in the analysis of such systems. Almost all the proposed equivalences are based on the idea that two systems are equivalent whenever no external observation can distinguish them. In fact, for any given system it is not its internal structure which is of interest but its behavior with respect to the outside world, i.e., its effect on the environment and its reactions to stimuli from the environment.

One of the most successful approaches for describing the formal, precise, behavior of concurrent systems is the so-called *operational semantics*. Within this approach, concurrent programs or systems are modeled as labeled transition systems (LTSs) that consist of a set of states, a set of transition labels, and a transition relation. The states of the transition systems are programs, while the labels of the transitions between states represent the actions (instructions) or the interactions that are possible in a given state.

When defining behavioral equivalence of concurrent systems described as LTSs, one might think that it is possible to consider systems equivalent if they give rise to the same (isomorphic) LTSs. Unfortunately, this would lead to unwanted distinctions, e.g., it would consider the two LTSs below different

in spite of the fact that their behavior is the same; they can (only) execute infinitely many a -actions, and they should thus be considered equivalent.

The basic principles for any reasonable equivalence can be summarized as follows. It should:

- Abstract from states (consider only the actions)
- Abstract from internal behavior
- Identify processes whose LTSs are isomorphic
- Consider two processes equivalent only if both can execute the same actions sequences
- Allow to replace a subprocess by an equivalent counterpart without changing the overall semantics of the system

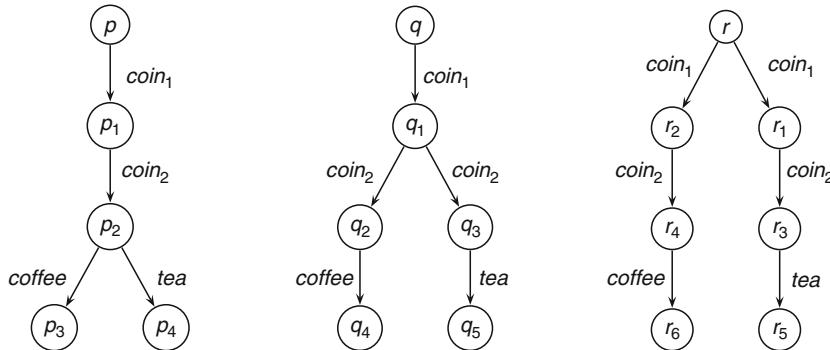

However, these criteria are not sufficiently insightful and discriminative, and the above adequacy requirements turn out to be still too loose. They have given rise to many different kinds of equivalences, even when all actions are considered visible.

The main equivalences over LTSs introduced in the literature consider as equivalent those systems that:

1. Perform the same sequences of actions
2. Perform the same sequences of actions and after each sequence are ready to accept the same sets of actions
3. Perform the same sequences of actions and after each sequence exhibit, recursively, the same behavior

These three different criteria lead to three groups of equivalences that are known as *traces* equivalences, *decorated-traces* equivalences, and *bisimulation-based* equivalences. Equivalences in different classes behave differently relatively to the three-labeled transition systems in Fig. 1. The three systems represent the specifications of three vending machines that accept two coins and deliver coffee or tea. The trace-based equivalences equate all of them, the bisimulation-based equivalences distinguish all of them, and the decorated traces distinguish the leftmost system from the other two, but equate the central and the rightmost one.

Many of these equivalences have been reviewed [11]; here, only the main ones are presented. First, equivalences that consider invisible (τ) actions just normal actions will be presented, then their variants that abstract from internal actions will be introduced.

Behavioral Equivalences. Fig. 1 Three vending machines

The equivalences will be formally defined on states of LTSs of the form $\langle Q, A_\tau, \xrightarrow{\mu} \rangle$, where Q is a set of states, ranging over p, q, p', q_1, \dots , A_τ is the set of labels, ranging over a, b, c, \dots , that also contains the distinct silent action τ , and $\xrightarrow{\mu}$ is the set of transitions. In the following, s will denote a generic element of A_τ^* , the set of all sequences of actions that a process might perform.

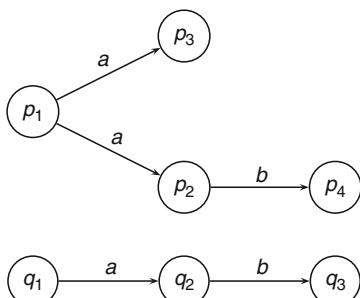

Traces Equivalence

The first equivalence is known as *traces equivalence* and is perhaps the simplest of all; it is imported from automata theory that considers those automata equivalent that generate the same language. Intuitively, two processes are deemed traces equivalent if and only if they can perform exactly the same sequences of actions. In the formal definition, $p \xrightarrow{s} p'$, with $s = \mu_1 \mu_2 \dots \mu_n$, denotes the sequence $p \xrightarrow{\mu_1} p_1 \xrightarrow{\mu_2} p_2 \dots \xrightarrow{\mu_n} p'$ of transitions.

Two states p and q are *traces equivalent* ($p \simeq_T q$) if:

1. $p \xrightarrow{s} p'$ implies $q \xrightarrow{s} q'$ for some q' and
2. $q \xrightarrow{s} q'$ implies $p \xrightarrow{s} p'$ for some p' .

A drawback of \simeq_T is that it is not sensitive to deadlocks. For example, if we consider the two LTSs below:

we have that $P_1 \simeq_T Q_1$, but P_1 , unlike Q_1 , after performing action a , can reach a state in which it cannot perform any action, i.e., a deadlocked state.

Traces equivalence identifies all of the three LTSs of Fig. 1. Indeed, it is not difficult to see that the three vending machines can perform the same sequences of visible actions. Nevertheless, a customer with definite preferences for coffee who is offered to choose between the three machines would definitely select to interact with the leftmost one since the others do not let him choose what to drink.

Bisimulation Equivalence

The classical alternative to traces equivalence is bisimilarity (also known as observational equivalence) that considers equivalent two systems that can simulate each other step after step [8]. Bisimilarity is based on the notion of bisimulation:

A relation $R \subseteq Q \times Q$ is a *bisimulation* if, for any pair of states p and q such that $\langle p, q \rangle \in R$, the following holds:

1. For all $\mu \in A_\tau$ and $p' \in Q$, if $p \xrightarrow{\mu} p'$ then $q \xrightarrow{\mu} q'$ for some $q' \in Q$ s.t. $\langle p', q' \rangle \in R$
2. For all $\mu \in A_\tau$ and $q' \in Q$, if $q \xrightarrow{\mu} q'$ then $p \xrightarrow{\mu} p'$ for some $p' \in Q$ s.t. $\langle p', q' \rangle \in R$

Two states p, q are *bisimilar* ($p \sim q$) if there exists a bisimulation R such that $\langle p, q \rangle \in R$.

This definition corresponds to the circular definition below that more clearly shows that two systems are bisimilar (observationally equivalent) if they can perform the same action and reach bisimilar states. This

recursive definition can be solved with the usual fixed points techniques.

Two states $p, q \in Q$ are *bisimilar*, written $p \sim q$, if and only if for each $\mu \in A_\tau$:

1. if $p \xrightarrow{\mu} p'$ then $q \xrightarrow{\mu} q'$ for some q' such that $p' \sim q'$;
2. if $q \xrightarrow{\mu} q'$ then $p \xrightarrow{\mu} p'$ for some p' such that $p' \sim q'$.

Bisimilarity distinguishes all machines of Fig. 1. This is because the basic idea behind bisimilarity is that two states are considered equivalent if by performing the same sequences of actions from these states it is possible to reach equivalent states. It is not difficult to see that bisimilarity distinguishes the first and the second machine of Fig. 1 because after receiving two coins (*coin*₁ and *coin*₂) the first machine still offers the user the possibility of choosing between having *coffee* or *tea* while the second does not. To see that also the second and the third machine are distinguished, it is sufficient to consider only the states reachable after just inserting *coin*₁ because already after this insertion the user loses his control of the third machine. Indeed, there is no way for this machine to reach a state bisimilar to the one that the second machine reaches after accepting *coin*₁.

Testing Equivalence

The formulation of bisimilarity is mathematically very elegant and has received much attention also in other fields of computer science [10]. However, some researchers do consider it too discriminating: two processes may be deemed unrelated even though there is no practical way of ascertaining it. As an example, consider the two rightmost vending machines of Fig. 1. They are not bisimilar because after inserting the first coin in one case there is still the illusion of having the possibility of choosing what to drink. Nevertheless, a customer would not be able to appreciate their differences since there is no possibility of deciding what to drink with both machines.

Testing equivalence has been proposed [4] (see also [5]) as an alternative to bisimilarity; it takes to the extreme the claim that when defining behavioral equivalences, one does not want to distinguish between systems that cannot be taken apart by external observers and bases the definition of the equivalences

on the notions of *observers*, *observations*, and *successful observations*. Equivalences are defined that consider equivalent those systems that satisfy (lead to successful observations by) the same sets of observers. An *observer* is an LTS with actions in $A_{\tau,w} \triangleq A_\tau \cup \{w\}$, with $w \notin A$. To determine whether a state q satisfies an observer with initial state o , the set $OBS(q, o)$ of all *computations* from $\langle q, o \rangle$ is considered.

Given an LTS $\langle Q, A_\tau, \xrightarrow{\mu} \rangle$ and an observer $\langle O, A_{\tau,w}, \xrightarrow{\mu} \rangle$, and a state $q \in Q$ and the initial state $o \in O$, an *observation* c from $\langle q, o \rangle$ is a maximal sequence of pairs $\langle q_i, o_i \rangle$, such that $\langle q_0, o_0 \rangle = \langle q, o \rangle$. The transition $\langle q_i, o_i \rangle \xrightarrow{\mu} \langle q_{i+1}, o_{i+1} \rangle$ can be proved using the following inference rule:

$$\frac{E \xrightarrow{\mu} E' \quad F \xrightarrow{\mu} F'}{\langle E, F \rangle \xrightarrow{\mu} \langle E', F' \rangle} \mu \in A_\tau$$

An observation from $\langle q, o \rangle$ is *successful* if it contains a configuration $\langle q_n, o_n \rangle \in c$, with $n \geq 0$, such that $o_n \xrightarrow{w} o$ for some o .

When analyzing the outcome of observations, one has to take into account that, due to nondeterminism, a process satisfies an observer **sometimes** or a process satisfies an observer **always**. This leads to the following definitions:

1. q **MAY SATISFY** o if there exists an observation from $\langle q, o \rangle$ that is successful.
2. q **MUST SATISFY** o if all observations from $\langle q, o \rangle$ are successful.

These notions can be used to define *may*, *must* and, *testing* equivalence.

May equivalence: p is *may* equivalent to q ($p \simeq_m q$) if, for all possible observers o :

p **MAY SATISFY** o if and only if q **MAY SATISFY** o ;

Must equivalence: p is *must* equivalent to q ($p \simeq_M q$) if, for all possible observers o :

p **MUST SATISFY** o if and only if q **MUST SATISFY** o .

Testing equivalence: p is *testing* equivalent to q ($p \simeq_{test} q$) if $p \simeq_m q$ and $p \simeq_M q$.

The three vending machines of Fig. 1 are may equivalent, but only the two rightmost ones are must equivalent and testing equivalent. Indeed, in most cases must equivalence implies may equivalence, and thus in most cases must and testing do coincide. The two leftmost

machines are not must equivalent because one after receiving the two coins the machine cannot refuse to (must) deliver the drink chosen by the customer while the other can.

May and must equivalences have nice alternative characterizations. It has been shown that may equivalence coincides with traces equivalence and that must equivalence coincides with *failures equivalence*, another well-studied relation that is inspired by traces equivalence but takes into account the possible interactions (*failures*) after each trace and is thus more discriminative than trace equivalence [7]. Failures equivalence relies on pairs of the form $\langle s, F \rangle$, where s is a trace and F is a set of labels. Intuitively, $\langle s, F \rangle$ is a failure for a process if it can perform the sequence of actions s to evolve into a state from which no action in F is possible. This equivalence can be formulated on LTS as follows:

Failures equivalence: Two states p and q are *failures-equivalent*, written $p \simeq_F q$, if and only if they possess the same failures, i.e., if for any $s \in A_\tau^*$ and for any $F \subseteq A_\tau$:

1. $p \xrightarrow{s} p'$ and $Init(p') \cap F = \emptyset$ implies $q \xrightarrow{s} q'$ for some q' and $Init(q') \cap F = \emptyset$
2. $q \xrightarrow{s} q'$ and $Init(q') \cap F = \emptyset$ implies $p \xrightarrow{s} p'$ for some p' and $Init(p') \cap F = \emptyset$

where $Init(q)$ represents the immediate actions of state q .

Hierarchy of Equivalences

The equivalences considered above can be precisely related (see [3] for a first study). Their relationships over the class of finite transition systems with only visible actions are summarized by the figure below, where the upward arrow indicates containment of the induced relations over states and \equiv indicates coincidence.

$$\begin{array}{c} \simeq_F \equiv \simeq_M \\ \uparrow \\ \simeq_T \equiv \simeq_m \end{array}$$

Overall, the figure states that may testing gives rise to a relation (\simeq_m) that coincides with traces equivalence, while must testing gives rise to a relation \simeq_M

that coincides with failures equivalence. For the considered class of systems, it also holds that must and testing equivalence \simeq_{test} do coincide. Thus, bisimilarity implies testing equivalence that in turn implies traces equivalence.

Weak Variants of the Equivalences

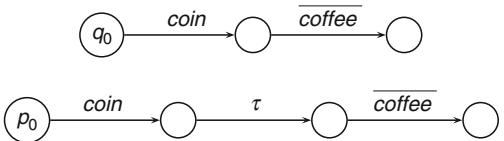

When considering abstract versions of systems making use of invisible actions, it turns out that all equivalences considered above are too discriminating. Indeed, traces, testing/failures, and observation equivalence would distinguish the two machines of Fig. 2 that, nevertheless, exhibit similar observable behaviors: get a coin and deliver a coffee. The second one can be obtained, e.g., from the term

$$coin.grinding.\overline{coffee}.nil$$

by hiding the *grinding* action that is irrelevant for the customer.

Because of this overdiscrimination, *weak variants* of the equivalences have been defined that permit ignoring (to different extents) internal actions when considering the behavior of systems. The key step of their definition is the introduction of a new transition relation that ignores silent actions. Thus, $q \xrightarrow{a} q'$ denotes that q reduces to q' by performing the visible action a possibly preceded and followed by any number (also 0) of invisible actions (τ). The transition $q \xrightarrow{s} q'$, instead, denotes that q reduces to q' by performing the sequence s of visible actions, each of which can be preceded and followed by τ -actions, while $\xrightarrow{\epsilon}$ indicates that only τ -actions, possibly none, are performed.

Weak traces equivalence The weak variant of traces equivalence is obtained by simply replacing the transitions $p \xrightarrow{s} p'$ above with the observable transitions $p \xrightarrow{s} p'$.

Behavioral Equivalences. Fig. 2 Weakly equivalent vending machines

Two states p and q are *weak traces equivalent* ($p \approx_T q$) if for any $s \in A^*$:

1. $p \xrightarrow{s} p'$ implies $q \xrightarrow{s} q'$ for some q'
2. $q \xrightarrow{s} q'$ implies $p \xrightarrow{s} p'$ for some p'

Weak testing equivalence To define the weak variants of may, must, and testing equivalences (denoted by \approx_m , \approx_M , \approx_{test} respectively), it suffices to change experiments so that processes and observers can freely perform silent actions. To this purpose, one only needs to change the inference rule of the observation step: $\langle q_i, o_i \rangle \xrightarrow{\mu} \langle q_{i+1}, o_{i+1} \rangle$ that can now be proved using:

$$\begin{array}{c} E \xrightarrow{\tau} E' \\ \hline \langle E, F \rangle \xrightarrow{\tau} \langle E', F \rangle \end{array} \quad \begin{array}{c} F \xrightarrow{\tau} F' \\ \hline \langle E, F \rangle \xrightarrow{\tau} \langle E, F' \rangle \end{array}$$

$$\frac{E \xrightarrow{a} E' \quad F \xrightarrow{a} F'}{\langle E, F \rangle \xrightarrow{a} \langle E', F' \rangle} \quad a \in A$$

To define, instead, *weak failures equivalence*, it suffices to replace $p \xrightarrow{s} p'$ with $p \overset{s}{\Rightarrow} p'$ in the definition of its strong variant. It holds that weak traces equivalence coincides with weak may equivalence, and that weak failures equivalence \approx_F coincides with weak must equivalence.

Weak bisimulation equivalence For defining weak observational equivalence, a new notion of (weak) bisimulation is defined that again assigns a special role to τ 's. To avoid having four items, the definition below requires that the candidate bisimulation relations be symmetric:

A symmetric relation $R \subseteq Q \times Q$ is a *weak bisimulation* if, for any pair of states p and q such that $\langle p, q \rangle \in R$, the following holds:

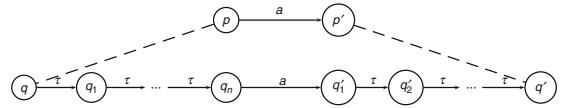

- For all $a \in A$ and $p' \in Q$, if $p \xrightarrow{a} p'$ then $q \xrightarrow{a} q'$ for some $q' \in Q$ s.t. $\langle p', q' \rangle \in R$
- For all $p' \in Q$, if $p \xrightarrow{\tau} p'$ then $q \xrightarrow{\epsilon} q'$ for some $q' \in Q$ s.t. $\langle p', q' \rangle \in R$

Two states p, q are *weakly bisimilar* ($p \approx q$) if there exists a weak bisimulation R such that $\langle p, q \rangle \in R$.

The figure below describes the intuition behind weak bisimilarity. In order to consider two states, say p and q , equivalent, it is necessary that for each visible action performed by one of them the other has to have the possibility of performing the same visible

action possibly preceded and followed by any number of invisible actions.

B

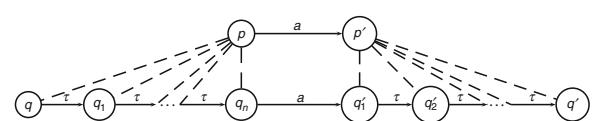

Branching bisimulation equivalence An alternative to weak bisimulation has also been proposed that considers those τ -actions important that appear in branching points of systems descriptions: only silent actions that do not eliminate possible interaction with external observers are ignored.

A symmetric relation $R \subseteq Q \times Q$ is a *branching bisimulation* if, for any pair of states p and q such that $\langle p, q \rangle \in R$, if $p \xrightarrow{\mu} p'$, with $\mu \in A_\tau$ and $p' \in Q$, at least one of the following conditions holds:

- $\mu = \tau$ and $\langle p', q \rangle \in R$
- $q \xrightarrow{\epsilon} q'' \xrightarrow{\mu} q'$ for some $q', q'' \in Q$ such that $\langle p, q'' \rangle \in R$ and $\langle p', q' \rangle \in R$

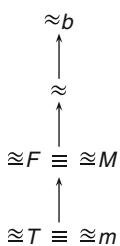

Two states p, q are *branching bisimilar* ($p \approx_b q$) if there exists a branching bisimulation R such that $\langle p, q \rangle \in R$.

The figure below describes the intuition behind branching bisimilarity; it corresponds to the definition above although it might appear, at first glance, more demanding. In order to consider two states, say p and q , equivalent, it is necessary, like for weak bisimilarity, that for each visible action performed by one of them the other has to have the possibility of performing the same visible action possibly preceded and followed by any number of invisible actions. Branching bisimilarity, however, imposes the additional requirement that all performed internal actions are not used to change equivalent class. Thus, all states reached via τ 's before performing the visible action are required to be equivalent to p , while all states reached via τ 's after performing the visible action are required to be equivalent to p' .

Hierarchy of Weak Equivalences

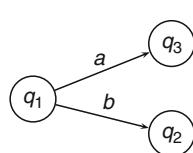

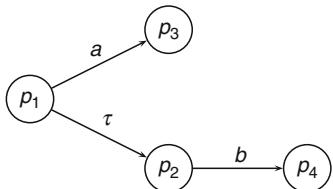

Like for the strong case, also weak equivalences can be clearly related. Their relationships over the class of finite transition systems with invisible actions, but without τ -loops (so-called *non-divergent* or *strongly convergent* LTSs) are summarized by the figure below, where the upward arrow indicates containment of the induced relations over states.

Thus, over *strongly convergent* LTSs with silent actions, branching bisimilarity implies weak bisimilarity, and this implies testing and failures equivalences; and these imply traces equivalence.

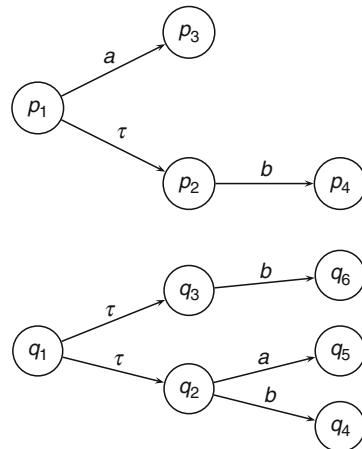

A number of counterexamples can be provided to show that the implications of the figure above are proper and thus that the converse does not hold.

The two LTSs reported below are weak traces equivalent and weakly may equivalent, but are distinguished by all the other equivalences.

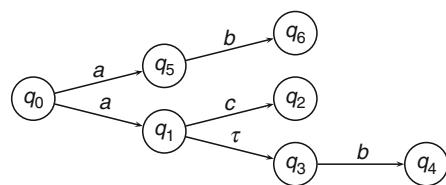

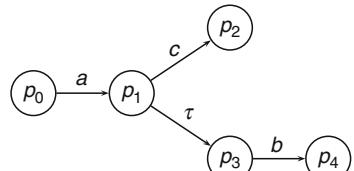

Indeed, they can perform exactly the same weak traces, but while the former can silently reach a state in which an a -action can be refused the second cannot.

The next two LTSs are equated by weak trace and weak must equivalences, but are distinguished by weak bisimulation and branching bisimulation.

Both of them, after zero or more silent actions, can be either in a state where both actions a and b are possible or in a state in which only a b transition is possible. However, via a τ -action, the topmost system can reach a state that has no equivalent one in the bottom one, thus they are not weakly bisimilar.

The next two LTSs are instead equated by weak bisimilarity, and thus by weak trace and weak must equivalences, but are not branching bisimilar.

It is easy to see that from the states p_0 and q_0 , the same visible action is possible and bisimilar states can be reached. The two states p_0 and q_0 are instead not branching bisimilar because p_0 , in order to match the a action of q_0 to q_5 and reach a state equivalent to q_5 , needs to reach p_3 through p_1 , but these two states, connected by a τ -action, are not branching bisimilar.

It is worth concluding that the two LTSs of Fig. 2 are equated by all the considered weak equivalences.

Future Directions

The study on behavioral equivalences of transition systems is still continuing. LTSs are increasingly used as the basis for specifying and proving properties of reactive systems. For example, they are used in *model checking* as the model against which logical properties are checked. It is then important to be able to use minimal systems that are, nevertheless, equivalent to the original larger ones so that preservation of the checked properties is guaranteed. Thus, further research is expected on devising efficient algorithms for equivalence checking and on understanding more precisely the properties of systems that are preserved by the different equivalences.

Bibliographic Notes and Further Reading

The theories of equivalences can be found in a number of books targeted to describing the different process algebras. The theory of bisimulation is introduced in [8], while failure and trace semantics are considered in [7] and [9]. The testing approach is presented in [5].

Moreover, interesting papers relating the different approaches are [3], the first paper to establish precise relationships between the many equivalences proposed in the literature, and the two papers by R. van Glabbeek: [11], considering systems with only visible actions, and [12], considering also systems with invisible actions. In his two companion papers, R. van Glabbeek provides a uniform, model-independent account of many of the equivalences proposed in the literature and proposes several motivating testing scenarios, phrased in terms of “button pushing experiments” on reactive machines to capture them.

Bisimulation and its relationships with modal logics is deeply studied in [6], while a deep study of its origins and its use in other areas of computer science is provided in [10]. Branching bisimulation was first introduced in [1], while the testing based equivalences

were introduced in [4]. Failure semantic was first introduced in [2].

Benchmarks

JACK DONGARRA, PIOTR LUSZCZEK
University of Tennessee, Knoxville, TN, USA

Definition

Computer benchmarks are computer programs that form standard tests of the performance of a computer

and the software through which it is used. They are written to a particular programming model and implemented by specific software, which is the final arbiter as to what the programming model is. A benchmark is therefore testing a software interface to a computer, and not a particular type of computer architecture.

Discussion

The basic goal of performance modeling is to measure, predict, and understand the performance of a computer program or set of programs on a computer system. In other words, it transcends the measurement of basic architectural and system parameters and is meant to enhance the understanding of the performance behavior of full complex applications. However, the programs and codes used in different areas of science differ in a large number of features. Therefore the performance of full application codes cannot be characterized in a general way independent of the application and code used. The understanding of the performance characteristics is tightly bound to the specific computer program code used. Therefore the careful selection of an interesting program for analysis is the crucial first step in any more detailed and elaborate investigation of full application code performance. The applications of performance modeling are numerous, including evaluation of algorithms, optimization of code implementations, parallel library development, and comparison of system architectures, parallel system design, and procurement of new systems.

A number of projects such as Perfect, NPB, Park-Bench, HPC Challenge, and others have laid the groundwork for a new era in benchmarking and evaluating the performance of computers. The complexity of these machines requires a new level of detail in measurement and comprehension of the results. The quotation of a single number for any given advanced architecture is a disservice to manufacturers and users alike, for several reasons. First, there is a great variation in performance from one computation to another on a given machine; typically the variation may be one or two orders of magnitude, depending on the type of machine. Secondly, the ranking of similar machines often changes as one goes from one application to

another, so the best machine for circuit simulation may not be the best machine for computational fluid dynamics. Finally, the performance depends greatly on a combination of compiler characteristics and human efforts were expended on obtaining the results.

The conclusions drawn from a benchmark study of computer performance depend not only on the basic timing results obtained, but also on the way these are interpreted and converted into performance figures. The choice of the performance metric, may itself influence the conclusions. For example, is it desirable to have a computer that generates the most mega op per second (or has the highest Speedup), or the computer that solves the problem in the least time? It is now well known that high values of the first metrics do not necessarily imply the second property. This confusion can be avoided by choosing a more suitable metric that reflects solution time directly, for example, either the Temporal, Simulation, or Benchmark performance, defined below. This issue of the sensible choice of performance metric is becoming increasingly important with the advent of massively parallel computers which have the potential of very high Giga-op rates, but have much more limited potential for reducing solution time.

Given the time of execution T and the floating-point operation-count several different performance measures can be defined. Each metric has its own uses, and gives different information about the computer and algorithm used in the benchmark. It is important therefore to distinguish the metrics with different names, symbols and units, and to understand clearly the difference between them. Much confusion and wasted work can arise from optimizing a benchmark with respect to an inappropriate metric. If the performance of different algorithms for the solution of the same problem needs to be compared, then the correct performance metric to use is the Temporal Performance which is defined as the inverse of the execution time

$$R_T = 1/T.$$

A special case of temporal performance occurs for simulation programs in which the benchmark problem is defined as the simulation of a certain period of physical time, rather than a certain number of timesteps. In this case, the term “simulation performance” is used,

and it is measured in units such as simulated days per day (written sim-d/d or 'd'/d) in weather forecasting, where the apostrophe is used to indicate "simulated" or simulated pico-seconds per second (written sim-ps/s or 'ps'/s) in electronic device simulation. It is important to use simulation performance rather than timestep/s for comparing different simulation algorithms which may require different sizes of timestep for the same accuracy (e.g., an implicit scheme that can use a large timestep, compared with an explicit scheme that requires a much smaller step). In order to compare the performance of a computer on one benchmark with its performance on another, account must be taken of the different amounts of work (measured in op) that the different problems require for their solution. The benchmark performance is defined as the ratio of the floating-point operation-count and the execution time

$$R_B = F_B/T.$$

The units of benchmark performance are Giga-op/s (benchmark name), where the name of the benchmark is included in parentheses to emphasize that the performance may depend strongly on the problem being solved, and to emphasize that the values are based on the nominal benchmark op-count. In other contexts such performance figures would probably be quoted as examples of the so-called sustained performance of a computer. For comparing the observed performance with the theoretical capabilities of the computer hardware, the actual number of floating-point operations performed F_H is computed, and from it the actual hardware performance

$$R_H = F_H/T.$$

Parallel speedup is a popular metric that has been used for many years in the study of parallel computer performance. Speedup is usually defined as the ratio of execution time of one-processor T_1 and execution time on p -processors T_p .

One factor that has hindered the use of full application codes for benchmarking parallel computers in the past is that such codes are difficult to parallelize and to port between target architectures. In addition, full application codes that have been successfully parallelized are

often proprietary, and/or subject to distribution restrictions. To minimize the negative impact of these factors, the use of compact applications was proposed in many benchmarking efforts. Compact applications are typical of those found in research environments (as opposed to production or engineering environments), and usually consist of up to a few thousand lines of source code. Compact applications are distinct from kernel applications since they are capable of producing scientifically useful results. In many cases, compact applications are made up of several kernels, interspersed with data movements and I/O operations between the kernels.

Any of the performance metrics, R , can be described with a two-parameter Amdahl saturation, for a fixed problem size as a function of number of processors p ,

$$R = R_\infty / (1 + p_{1/2}/p)$$

where R_∞ is the saturation performance approached as $p \rightarrow \infty$ and $p_{1/2}$ is the number of processors required to reach half the saturation performance. This universal Amdahl curve [1, 2] could be matched against the actual performance curves by changing values of the two parameters (R_∞ , $p_{1/2}$).

Bernstein's Conditions

PAUL FEAUTRIER

Ecole Normale Supérieure de Lyon, Lyon, France

Definition

Bersntein's conditions [4] are a simple test for deciding if statements or operations can be interchanged without modifying the program results. The test applies to operations which read and write memory at well defined addresses. If u is an operation, let $\mathcal{M}(u)$ be the set of (addresses of) the memory cells it modifies, and $\mathcal{R}(u)$ the set of cells it reads. Operations u and v can be reordered if:

$$\mathcal{M}(u) \cap \mathcal{M}(v) = \mathcal{M}(u) \cap \mathcal{R}(v) = \mathcal{R}(u) \cap \mathcal{M}(v) = \emptyset \quad (1)$$

If these conditions are met, one says that u and v commute or are independent.

Note that in most languages, each operation writes at most one memory cell: $W(u)$ is a singleton. However, there are exceptions: multiple and parallel assignments, vector assignments among others.

The importance of this result stems from the fact that most program optimizations consist – or at least, involve – moving operations around. For instance, to improve cache performance, one must move all uses of a datum as near as possible to its definition. In parallel programming, if u and v are assigned to different threads or processors, their order of execution may be unpredictable, due to arbitrary decisions of a scheduler or to the presence of competing processes. In this case, if Bernstein's conditions are not met, u and v must be kept in the same thread.

Checking Bernstein's conditions is easy for operations accessing scalars (but beware of aliases), is more difficult for array accesses, and is almost impossible for pointer dereferencing. See the ►Dependences entry for an in-depth discussion of this question.

Discussion

Notations and Conventions

In this essay, a program is represented as a sequence of operations, i.e., of instances of high level statements or machine instructions. Such a sequence is called a *trace*. Each operation has a unique name, u , and a text $T(u)$, usually specified as a (high-level language) statement. There are many schemes for naming operations: for polyhedral programs, one may use integer vectors, and operations are executed in lexicographic order. For flowcharts programs, one may use words of a regular language to name operations, and if the program has function calls, words of a context-free language [2]. In the last two cases, u is executed before v iff u is a prefix of v . In what follows, $u < v$ is a shorthand for “ u is executed before v .” For sequential programs, $<$ is a well-founded total order: there is no infinite chain $x_0, x_1, \dots, x_i, \dots$ such that $x_{i+1} < x_i$. This is equivalent to stipulating that a program execution has a beginning, but may not have an end.

All operations will be assumed deterministic: the state of memory after execution of u depends only on $T(u)$ and on the previous state of memory.

For *static control programs*, one can enumerate the unique trace – or at least describe it – once and for all. One can also consider static control program *families*, where the trace depends on a few parameters which are known at program start time. Lastly, one can consider static control parts of programs or SCoPs. Most of this essay will consider only static control programs.

When applying Bernstein's conditions, one usually considers a reference trace, which comes from the original program, and a candidate trace, which is the result of some optimization or parallelization. The problem is to decide whether the two traces are equivalent, in a sense to be discussed later. Since program equivalence is in general undecidable, one has to restrict the set of admissible transformations. Bernstein's conditions are specially useful for dealing with operation reordering.

Commutativity

To prove that Bernstein's conditions are sufficient for commutativity, one needs the following facts:

- When an operation u is executed, the only memory cells which may be modified are those whose addresses are in $\mathcal{M}(u)$

- The values stored in $\mathcal{M}(u)$ depend only on u and on the values read from $\mathcal{R}(u)$.

▶ Consider two operations u and v which satisfy (Eq. 1). Assume that u is executed first. When v is executed later, it finds in $\mathcal{R}(v)$ the same values as if it were executed first, since $\mathcal{M}(u)$ and $\mathcal{R}(v)$ are disjoint. Hence, the values stored in $\mathcal{M}(v)$ are the same, and they do not overwrite the values stored by u , since $\mathcal{M}(u)$ and $\mathcal{M}(v)$ are disjoint. The same reasoning applies if v is executed first.

The fact that u and v do not meet Bernstein's conditions is written $u \perp v$ to indicate that u and v cannot be executed in parallel.

Atomicity

When dealing with parallel programs, commutativity is not enough for correctness. Consider for instance two operations u and v with $\mathcal{T}(u) = [x = x + 1]$ and $\mathcal{T}(v) = [x = x + 2]$. These two operations commute, since their sequential execution in whatever order is equivalent to a unique operation w such that $\mathcal{T}(w) = [x = x + 3]$. However, each one is compiled into a sequence of more elementary machine instructions, which when executed in parallel, may result in x being increased by 1 or 2 or 3 (see Fig. 1, where $r1$ and $r2$ are processor registers).

Observe that these two operations *do not* satisfy Bernstein's conditions. In contrast, operations that satisfy Bernstein's conditions do not need to be protected by critical sections when run in parallel. The reason is that neither operation modifies the input of the other, and that they write in distinct memory cells. Hence, the stored values do not depend on the order in which the writes are interleaved.

$x = 0$	$x = 0$	$x = 0$	$x = 0$
$r1 = x$	$--$	$r1 = x$	$--$
$--$	$r2 = x$	$r1 += 1$	$--$
$r1 += 1$	$--$	$x = r1$	$r2 = x$
$--$	$r2 += 2$	$--$	$r1 += 1$
$x = r1$	$--$	$r2 = x$	$--$
$--$	$x = r2$	$r2 += 2$	$r2 += 2$
$--$	$--$	$x = r2$	$x = r2$
$--$	$--$	$x = r2$	$x = r1$
$x = 2$	$x = 3$	$x = 3$	$x = 1$
P #1	P #2	P #1	P #2

Bernstein's Conditions. Fig. 1 Several possible interleaves of $x = x + 1$ and $x = x + 2$

Legality

Here, the question is to decide whether a candidate trace is equivalent to a reference trace, where the two traces contains exactly the same operations. There are two possibilities for deciding equivalence. Firstly, if the traces are finite, one may examine the state of memory after their termination. There is equivalence if these two states are identical. Another possibility is to construct the *history* of each memory cell. This is a list of values ordered in time. A new value is appended to the history of x each time an operation u such that $x \in \mathcal{M}(u)$ is executed. Two traces are equivalent if all cells have the same history. This is clearly a stronger criterion than equality of the final memory; it has the advantage of being applicable both to terminating programs and to non-terminating systems. The histories are especially simple when a trace has the *single assignment property*: there is only one operation that writes into x . In that case, each history has only one element.

Terminating Programs

A terminating program is specified by a finite list of operations, $[u_1, \dots, u_n]$, in order of sequential execution. There is a dependence relation $u_i \rightarrow u_j$ iff $i < j$ and $u_i \perp u_j$.

All reorderings of the u : $[v_1, \dots, v_n]$ such that the execution order of dependent operations is not modified:

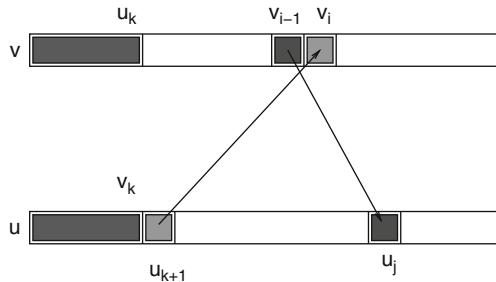

$$u_i \rightarrow u_j, u_i = v_{i'}, u_j = v_{j'} \Rightarrow i' < j'$$

are legal.

- ▶ The proof is by a double induction. Let k be the length of the common prefix of the two programs:

$$u_i = v_i, i = 1, k.$$

Note that k may be null. The element u_{k+1} occurs somewhere among the v , at position $i > k$. The element v_{i-1} occurs among the u at position $j > k+1$ (see Fig. 2). It follows that $u_{k+1} = v_i$ and $u_j = v_{i-1}$ are ordered differently in the two programs, and hence must satisfy Bernstein's condition. v_{i-1} and v_i can therefore be exchanged without modifying the result of the reordered program. Continuing in this way, v_i can be brought in position $k+1$, which means that the common prefix has been extended one position to the right. This process can be continued until the length of the prefix is n . The two programs are now identical, and the final result of the candidate trace has not been modified.

Bernstein's Conditions. Fig. 2 The commutation Lemma

The property which has just been proved is crucial for program optimization, since it gives a simple test for the legality of statement motion, but what is its import for parallel programming?

The point is that when parallelizing a program, its operations are distributed among several processors or among several threads. Most parallel architectures do not try to combine simultaneous writes to the same memory cell, which are arbitrarily ordered by the bus arbiter or a similar device. It follows that if one is only interested in the final result, each parallel execution is equivalent to some interleave of the several threads of the program. Taking care that operations which do not satisfy Bernstein's condition are executed in the order specified by the original sequential program guarantees deterministic execution and equivalence to the sequential program.

Single Assignment Programs

A trace is in single assignment form if, for each memory cell x , there is one and only one operation u such that $x \in \mathcal{M}(u)$. Any trace can be converted to (dynamic) single assignment form – at least in principle – by the following method.

Let A be an (associative) array indexed by the operation names. Assuming that all $\mathcal{M}(u)$ are singletons, operation u now writes into $A[u]$ instead of $\mathcal{M}(u)$. The source of cell x at u , noted $\sigma(x, u)$, is defined as:

- $x \in \mathcal{M}(\sigma(x, u))$
- $\sigma(x, u) < u$
- there is no v such that $\sigma(x, u) < v < u$ and $x \in \mathcal{M}(v)$

In words, $\sigma(x, u)$ is the last write to x that precedes u . Now, in the text of u , replace all occurrences of $y \in \mathcal{R}(u)$

by $A[\sigma(y, u)]$. That the new trace has the single assignment property is clear. It is equivalent to the reference trace in the following sense: for each cell x , construct a history by appending the value of $A[u]$ each time an operation u such that $x \in \mathcal{M}(u)$ is executed. Then the histories of a cell in the reference trace and in the single assignment trace are identical.

- ▶ Let us say that an operation u has a discrepancy for x if the value assigned to x by u in the reference trace is different from the value of $A[u]$ in the single assignment trace. Let u_0 be the earliest such operation. Since all operations are assumed deterministic, this means that there is a cell $y \in \mathcal{R}(u_0)$ whose value is different from $A[\sigma(y, u_0)]$. Hence $\sigma(y, u_0) < u_0$ also has a discrepancy, a contradiction.

Single assignment programs (SAP) where first proposed by Tesler and Enea [9] as a tool for parallel programming. In a SAP, the sets $\mathcal{M}(u) \cap \mathcal{M}(v)$ are always empty, and if there is a non-empty $\mathcal{R}(u) \cap \mathcal{M}(v)$ where $u < v$, it means that some variable is read before being assigned, a programming error. Some authors [3] then noticed that a single assignment program is a collection of algebraic equations, which simplifies the construction of correctness proofs.

Non-Terminating Systems

The reader may have noticed that the above legality proof depends on the finiteness of the program trace. What happens when one wants to build a non-terminating parallel system, as found for instance in signal processing applications or operating systems? For assessing the correctness of a transformation, one cannot observe the final result, which does not exist. Beside, one clearly needs some fairness hypothesis: it would not do to execute all even numbered operations, *ad infinitum*, and then to execute all odd numbered operations, even if Bernstein's conditions would allow it. The needed property is that for all operations u in the reference trace, there is a finite integer n such that u is the n -th operation in the candidate trace.

Consider first the case of two single assignment traces, one of which is the reference trace, the other having been reordered while respecting dependences. Let u be an operation. By the fairness hypothesis, u is present in both traces. Assume that the values written in $A[u]$ by the two traces are distinct. As above, one can find

an operation v such that $A[v]$ is read by u , $A[v]$ has different values in the two traces, and $v < u$ in the two traces. One can iterate this process indefinitely, which contradicts the well-foundedness of $<$.

Consider now two ordinary traces. After conversion to single assignment, one obtain the same values for the $A[u]$. If one extract an history for each cell x as above, one obtain two identical sequence of values, since operations that write to x are in dependence and hence are ordered in the same direction in the two traces.

Observe that this proof applies also to terminating traces. If the cells of two terminating traces have identical histories, it obviously follows that the final memory states are identical. On the other hand, the proof for terminating traces applies also, in a sequential context, to operations which commutes without satisfying Bernstein's conditions.

Dynamic Control Programs

The presence of tests whose outcome cannot be predicted at compile time greatly complicates program analysis. The simplest case is that of well structured programs, which uses only the **if then else** construct. For such programs, a simple syntactical analysis allows the compiler to identify all tests which have an influence on the execution of each operation. One has to take into account three new phenomena:

- A test is an operation in itself, which has a set of read cells, and perhaps a set of modified cells if the source language allows side effects
- An operation cannot be executed before the outcomes of all controlling tests are known
- No dependence exists for two operations which belong to opposite branches of a test

A simple solution, known as *if-conversion* [1], can be used to solve all three problems at once. Each test: **if(e) then ... else ...** is replaced by a new operation $\mathbf{b} = \mathbf{e}$; where b is a fresh boolean variable. Each operation in the range of the test is guarded by b or $\neg b$, depending on whether the operation is on the **then** or **else** branch of the test. In the case of nested tests, this transformation is applied recursively; the result is that each operation is guarded by a conjunction of the b 's or their complements. Bernstein's conditions are then applied to the resulting trace, the b variables being included in the read and modified sets as necessary. This insures that the test

is not executed too early, and since there is a dependence from a test to each enclosed operation, that no operation is executed before the tests results are known. One must take care not to compute dependences between operations u and v which have incompatible guards g_u and g_v such that $g_u \wedge g_v = \text{false}$.

The case of **while** loops is more complex. Firstly, the construction **while(true)** is the simplest way of writing a non terminating program, whose analysis has been discussed above. Anything that follows an infinite loop is dead code, and no analysis is needed for it. Consider now a terminating loop:

```
while (p) do S;
```

The several executions of the continuation predicate, p , must be considered as operations. Strictly speaking, one cannot execute an instance of S before the corresponding instance of p , since if the result of p is false, S is not executed. On the other hand, there must be a dependence from S to p , since otherwise the loop would not terminate. Hence, a **while** loop must be executed sequentially. The only way out is to run the loop *speculatively*, i.e., to execute instances of the loop body before knowing the outcome of the continuation predicate, but this method is beyond the scope of this essay.

is punctuated by the occasional development of new technologies in the field which generally created new types of data acquisition (such as microarrays to capture gene expression developed in the mid-1990s) or more rapid acquisition of data (such as the development of next-generation sequencing technologies in the mid-2000s). Generally, these developments have ushered in new avenues of bioinformatics research due to new applications enabled by novel data sources, or increases in the scale of data that need to be archived and analyzed, or new applications that come within reach due to improved scales and efficiencies. For example, the rapid adoption of microarray technologies for measuring gene expressions ushered in the era of systems biology; the relentless increases in cost efficiencies in sequencing enabled genome sequencing for many species, which then formed the foundation for the field of comparative genomics.

Thanks to the aforementioned advances and our continually improving knowledge of how biological systems are designed and operate, bioinformatics developed into a broad field with several well-defined sub-fields of specialization – computational genomics, comparative genomics, metagenomics, phylogenetics, systems biology, structural biology, etc. Several entries in this encyclopedia are designed along the lines of such subfields whenever a sufficient body of work exists in development of parallel methods in the area. This entry contains general remarks about the field of parallel computational biology; the readers are referred to the related entries for an in-depth discussion and appropriate references for specific topics. An alternative view to classifying bioinformatics research relies on the organisms of study – (1) microbial organisms, (2) plants, and (3) humans/animals. Even though the underlying bioinformatics techniques are generally applicable across organisms, the key target applications tend to vary based on this organismal classification. In studying microbial organisms, a key goal is the ability to engineer them for increased production of certain products or to meet certain environmental objectives. In agricultural biotechnology, key challenges being pursued include increasing yields, increasing nutritional content, developing robust crops and biofuel production. On the other hand, much of the research on humans is driven by medical concerns and understanding and treating complex diseases.

Definition

Bioinformatics and/or computational biology is broadly defined as the development and application of informatics techniques for solving problems arising in biological sciences.

Discussion

The terms “Bioinformatics” and “Computational Biology” are broadly used to represent research in computational models, methods, databases, software, and analysis tools aimed at solving applications in the biological sciences. Although the origins of the field can be traced as far back as 1970, the field exploded in prominence during the 1990s with the conception and execution of the human genome project, and such explosive growth continues to this date. This long time line

Perhaps the oldest studied problem in computational biology is that of molecular dynamics, originally studied in computational chemistry but increasingly being applied to the study of protein structures in biology. Outside of this classical area, research in parallel computational biology can be traced back to the development of parallel sequence alignment algorithms in the late 1980s. One of the early applications where parallel bioinformatics methods proved crucial is that of genome assembly. At the human genome scale, this requires inferring a sequence by assembling tens of millions of randomly sampled fragments of it, which would take weeks to months if done serially. Albeit the initial use of parallelism only in phases where such parallelism is obvious, the resulting improvements in time-to-solution proved adequate, and subsequently motivated the development of more sophisticated parallel bioinformatics methods for genome assembly. Spurred by the enormous data sizes, problem complexities, and multiple scales of biological systems, interest in parallel computational biology continues to grow. However, the development of parallel methods in bioinformatics represents a mere fraction of the problems for which sequential solutions have been developed. In addition, progress in parallel computational biology has not been uniform across all subfields of computational biology. For example, there has been little parallel work in the field of comparative genomics, not counting trivial uses of parallelism such as in all-pairs alignments. In other fields such as systems biology, work in parallel methods is in its nascent stages with certain problem areas (such as network inference) targeted more than others. The encyclopedia entries reflect this development and cover the topical areas that reflect strides in parallel computational biology.

Going forward, there are compelling developments that favor growing prominence of parallel computing in the field of bioinformatics and computational biology. One such development is the creation of high-throughput second- and third-generation sequencing technologies. After more than three decades of sequencing DNA one fragment at a time, next-generation sequencing technologies permit the simultaneous sequencing of a large number of DNA fragments. With throughputs increasing at the rate of a factor of 10 per year, sequencers that were generating a few million DNA reads per experiment in 2008 are delivering

upward of 2 billion reads per experiment by early 2011. The high throughput sequencing data generated by these systems is impacting many subfields of computational biology, and the data deluge is severely straining the limits of what can be achieved by sequential methods. Next-generation sequencing is shifting individual investigators into terascale and bigger organizations into petascale, necessitating the development of parallel methods. Many other types of high-throughput instrumentation are becoming commonplace in biology, raising further complexities in massive scale, heterogenous data integration and multiscale modeling of biological systems. Emerging high performance computing paradigms such as Clouds and manycore GPU platforms are also providing impetus to the development of parallel bioinformatics methods.

Definition

Bisimulation equivalence is a semantic equivalence relation on labeled transition systems, which are used to represent distributed systems. It identifies systems with the same branching structure.

Discussion

Labeled Transition Systems

A labeled transition system consists of a collection of states and a collection of transitions between them. The transitions are labeled by actions from a given set A that happen when the transition is taken, and the states may

be labeled by predicates from a given set P that hold in that state.

Definition 1 Let A and P be sets (of *actions* and *predicates*, respectively).

A *labeled transition system* (LTS) over A and P is a triple $(S, \rightarrow, \models)$ with:

- S a class (of *states*).
- \rightarrow a collection of binary relations $\xrightarrow{a} \subseteq S \times S$ – one for every $a \in A$ – (the *transitions*), such that for all $s \in S$ the class $\{t \in S \mid s \xrightarrow{a} t\}$ is a set.
- $\models \subseteq S \times P$. $s \models p$ says that predicate $p \in P$ holds in state $s \in S$.

LTSs with A a singleton (i.e., with \rightarrow a single binary relation on S) are known as *Kripke structures*, the models of modal logic. General LTSs (with A arbitrary) are the Kripke models for polymodal logic. The name “labeled transition system” is employed in concurrency theory. There, the elements of S represent the systems one is interested in, and $s \xrightarrow{a} t$ means that system s can evolve into system t while performing the action a . This approach identifies states and systems: The states of a system s are the systems reachable from s by following the transitions. In this realm P is often taken to be empty, or it contains a single predicate \checkmark indicating successful termination.

Definition 2 A *process graph* over A and P is a tuple $g = (S, I, \rightarrow, \models)$ with $(S, \rightarrow, \models)$ an LTS over A and P in which S is a set, and $I \in S$.

Process graphs are used in concurrency theory to disambiguate between states and systems. A process graph $(S, I, \rightarrow, \models)$ represents a single system, with S the set of its states and I its initial state. In the context of an LTS $(S, \rightarrow, \models)$ two concurrent systems are modeled by two members of S ; in the context of process graphs, they are two different graphs. The *nondeterministic finite automata* used in *automata theory* are process graphs with a finite set of states over a finite alphabet A and a set P consisting of a single predicate denoting *acceptance*.

Bisimulation Equivalence

Bisimulation equivalence is defined on the states of a given LTS, or between different process graphs.

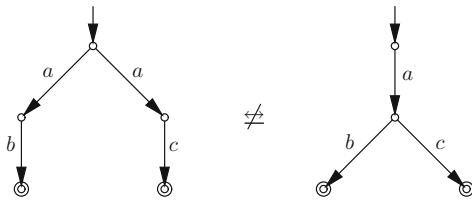

Definition 3 Let $(S, \rightarrow, \models)$ be an LTS over A and P . A *bisimulation* is a binary relation $R \subseteq S \times S$, satisfying:

- Λ if sRt then $s \models p \Leftrightarrow t \models p$ for all $p \in P$.
- Λ if sRt and $s \xrightarrow{a} s'$ with $a \in A$, then there exists a t' with $t \xrightarrow{a} t'$ and $s'Rt'$.
- Λ if sRt and $t \xrightarrow{a} t'$ with $a \in A$, then there exists an s' with $s \xrightarrow{a} s'$ and $s'Rt'$.

Two states $s, t \in S$ are *bisimilar*, denoted $s \leftrightarrow t$, if there exists a bisimulation R with sRt .

Bisimilarity turns out to be an equivalence relation on S , and is also called *bisimulation equivalence*.

Definition 4 Let $g = (S, I, \rightarrow, \models)$ and $h = (S', I', \rightarrow', \models')$ be process graphs over A and P . A *bisimulation* between g and h is a binary relation $R \subseteq S \times S'$, satisfying IRI' and the same three clauses as above. g and h are *bisimilar*, denoted $g \leftrightarrow h$, if there exists a bisimulation between them.

Example The two process graphs above (over $A = \{a, b, c\}$ and $P = \{\checkmark\}$), in which the initial states are indicated by short incoming arrows and the final states (the ones labeled with \checkmark) by double circles, are not bisimulation equivalent, even though in automata theory they accept the same language. The choice between b and c is made at a different moment (namely, before vs. after the a -action); that is, the two systems have a different *branching structure*. Bisimulation semantics distinguishes systems that differ in this manner.

Modal Logic

(Poly)modal logic is an extension of propositional logic with formulas $\langle a \rangle \varphi$, saying that it is possible to follow an a -transition after which the formula φ holds. Modal formulas are interpreted on the states of labeled transition systems. Two systems are bisimilar iff they satisfy the same infinitary modal formulas.

Definition 5 The language \mathcal{L} of *polymodal logic* over A and P is given by:

- $\top \in \mathcal{L}$
- $p \in \mathcal{L}$ for all $p \in P$
- if $\varphi, \psi \in \mathcal{L}$ for then $\varphi \wedge \psi \in \mathcal{L}$
- if $\varphi \in \mathcal{L}$ then $\neg\varphi \in \mathcal{L}$
- if $\varphi \in \mathcal{L}$ and $a \in A$ then $\langle a \rangle \varphi \in \mathcal{L}$

Basic (as opposed to *poly-*) modal logic is the special case where $|A| = 1$; there $\langle a \rangle \varphi$ is simply denoted $\diamond\varphi$. The *Hennessy–Milner logic* is polymodal logic with $P = \emptyset$. The language \mathcal{L}^∞ of *infinitary polymodal logic* over A and P is obtained from \mathcal{L} by additionally allowing $\bigwedge_{i \in I} \varphi_i$ to be in \mathcal{L}^∞ for arbitrary index sets I and $\varphi_i \in \mathcal{L}^\infty$ for $i \in I$. The connectives \top and \wedge are then the special cases $I = \emptyset$ and $|I| = 2$.

Definition 6 Let $(S, \rightarrow, \models)$ be an LTS over A and P . The relation $\models \subseteq S \times P$ can be extended to the *satisfaction relation* $\models \subseteq S \times \mathcal{L}^\infty$, by defining

- $s \models \bigwedge_{i \in I} \varphi_i$ if $s \models \varphi_i$ for all $i \in I$ – in particular, $s \models \top$ for any state $s \in S$
- $s \models \neg\varphi$ if $s \not\models \varphi$
- $s \models \langle a \rangle \varphi$ if there is a state t with $s \xrightarrow{a} t$ and $t \models \varphi$

Write $\mathcal{L}(s)$ for $\{\varphi \in \mathcal{L} \mid s \models \varphi\}$.

Theorem 1 [5] Let $(S, \rightarrow, \models)$ be an LTS and $s, t \in S$. Then $s \leftrightarrow t \Leftrightarrow \mathcal{L}^\infty(s) = \mathcal{L}^\infty(t)$.

In case the systems s and t are image finite, it suffices to consider finitary polymodal formulas only [3]. In fact, for this purpose it is enough to require that one of s and t is image finite.

Definition 7 Let $(S, \rightarrow, \models)$ be an LTS. A state $t \in S$ is *reachable* from $s \in S$ if there are $s_i \in S$ and $a_i \in A$ for $i = 0, \dots, n$ with $s = s_0, s_{i-1} \xrightarrow{a_i} s_i$ for $i = 1, \dots, n$, and $s_n = t$. A state $s \in S$ is *image finite* if for every state $t \in S$ reachable from s and for every $a \in A$, the set $\{u \in S \mid t \xrightarrow{a} u\}$ is finite.

Theorem 2 [4] Let $(S, \rightarrow, \models)$ be an LTS and $s, t \in S$ with s image finite. Then $s \leftrightarrow t \Leftrightarrow \mathcal{L}(s) = \mathcal{L}(t)$.

Non-well-Founded Sets

Another characterization of bisimulation semantics can be given by means of Aczel's universe \mathcal{V} of

non-well-founded sets [1]. This universe is an extension of the Von Neumann universe of well-founded sets, where the axiom of foundation (every chain $x_0 \ni x_1 \ni \dots$ terminates) is replaced by an *anti-foundation axiom*.

Definition 8 Let $(S, \rightarrow, \models)$ be an LTS, and let \mathcal{B} denote the unique function $\mathcal{M} : S \rightarrow \mathcal{V}$ satisfying, for all $s \in S$,

$$\mathcal{M}(s) = \{\langle a, \mathcal{M}(t) \rangle \mid s \xrightarrow{a} t\}.$$

It follows from Aczel's anti-foundation axiom that such a function exists. In fact, the axiom amounts to saying that systems of equations like the one above have unique solutions. $\mathcal{B}(s)$ could be taken to be the *branching structure* of s . The following theorem then says that two systems are bisimilar iff they have the same branching structure.

Theorem 3 [2] Let $(S, \rightarrow, \models)$ be an LTS and $s, t \in S$. Then $s \sqsubseteq t \Leftrightarrow \mathcal{B}(s) = \mathcal{B}(t)$.

Abstraction

In concurrency theory it is often useful to distinguish between *internal actions*, which do not admit interactions with the outside world, and *external ones*. As normally there is no need to distinguish the internal actions from each other, they all have the same name, namely, τ . If A is the set of external actions a certain class of systems may perform, then $A_\tau := A \dot{\cup} \{\tau\}$. Systems in that class are then represented by labeled transition systems over A_τ and a set of predicates P . The variant of bisimulation equivalence that treats τ just like any action of A is called *strong bisimulation equivalence*. Often, however, one wants to abstract from internal actions to various degrees. A system doing two τ actions in succession is then considered equivalent to a system doing just one. However, a system that can do either a or b is considered different from a system that can do either a or first τ and then b , because if the former system is placed in an environment where b cannot happen, it can still do a instead, whereas the latter system may reach a state (by executing the τ action) in which a is no longer possible.

Several versions of bisimulation equivalence that formalize these desiderata occur in the literature. *Branching bisimulation equivalence* [2], like strong bisimulation, faithfully preserves the branching structure

of related systems. The notions of *weak* and *delay* bisimulation equivalence, which were both introduced by Milner under the name *observational equivalence*, make more identifications, motivated by observable machine-behaviour according to certain testing scenarios.

Write $s \xrightarrow{\tau} t$ for $\exists n \geq 0 : \exists s_0, \dots, s_n : s = s_0 \xrightarrow{\tau} s_1 \xrightarrow{\tau} \dots \xrightarrow{\tau} s_n = t$, that is, a (possibly empty) path of τ -steps from s to t . Furthermore, for $a \in A_\tau$, write $s \xrightarrow{(a)} t$ for $s \xrightarrow{a} t \vee (a = \tau \wedge s = t)$. Thus $\xrightarrow{(a)}$ is the same as $\xrightarrow{\tau}$ for $a \in A$, and $\xrightarrow{\tau}$ denotes zero or one τ -step.

Definition 9 Let $(S, \rightarrow, \models)$ be an LTS over A_τ and P . Two states $s, t \in S$ are *branching bisimulation equivalent*, denoted $s \sqsubseteq_b t$, if they are related by a binary relation $R \subseteq S \times S$ (a *branching bisimulation*), satisfying:

- ^ if sRt and $s \models p$ with $p \in P$, then there is a t_1 with $t \xrightarrow{\tau} t_1 \models p$ and sRt_1 .
- ^ if sRt and $t \models p$ with $p \in P$, then there is a s_1 with $s \xrightarrow{\tau} s_1 \models p$ and s_1Rt .
- ^ if sRt and $s \xrightarrow{a} s'$ with $a \in A_\tau$, then there are t_1, t_2, t' with $t \xrightarrow{\tau} t_1 \xrightarrow{(a)} t_2 = t'$, sRt_1 , and $s'Rt'$.
- ^ if sRt and $t \xrightarrow{a} t'$ with $a \in A_\tau$, then there are s_1, s_2, s' with $s \xrightarrow{\tau} s_1 \xrightarrow{a} s_2 = s'$, s_1Rt , and $s'Rt'$.

Delay bisimulation equivalence, \sqsubseteq_d , is obtained by dropping the requirements sRt_1 and s_1Rt . *Weak bisimulation equivalence* [5], \sqsubseteq_w , is obtained by furthermore relaxing the requirements $t_2 = t'$ and $s_2 = s'$ to $t_2 \xrightarrow{\tau} t'$ and $s_2 \xrightarrow{\tau} s'$.

These definitions stem from concurrency theory. On Kripke structures, when studying modal or temporal logics, normally a stronger version of the first two conditions is imposed:

- ^ if sRt and $p \in P$, then $s \models p \Leftrightarrow t \models p$.

For systems without τ 's all these notions coincide with strong bisimulation equivalence.

Concurrency

When applied to *parallel systems*, capable of performing different actions at the same time, the versions of bisimulation discussed here employ *interleaving semantics*: no distinction is made between true parallelism and its nondeterministic sequential simulation. Versions of bisimulation that do make such a distinction have been developed as well, most notably the *ST-bisimulation* [2],

which takes temporal overlap of actions into account, and the *history preserving bisimulation* [2], which even keeps track of causal relations between actions. For this purpose, system representations such as *Petri nets* or *event structures* are often used instead of labeled transition systems.

Bitonic sorting network; Bitonic sorting

Definition

Bitonic Sort is a sorting algorithm that uses comparison-swap operations to arrange into nondecreasing order an input sequence of elements on which a linear order is defined (for example, numbers, words, and so on).

Discussion

Introduction

Henceforth, all inputs are assumed to be numbers, without loss of generality. For ease of presentation, it is also assumed that the length of the sequence to be sorted is an integer power of 2. The *Bitonic Sort* algorithm has the following properties:

1. *Oblivious*: The indices of all pairs of elements involved in comparison-swaps throughout the execution of the algorithm are predetermined, and do not depend in any way on the values of the input elements. It is important to note here that the elements to be sorted are assumed to be kept into an array and swapped in place. The indices that are referred to here are those in the array.
2. *Recursive*: The algorithm can be expressed as a procedure that calls itself to operate on smaller versions of the input sequence.
3. *Parallel*: It is possible to implement the algorithm using a set of special processors called “comparators” that operate simultaneously, each implementing a comparison-swap. A comparator receives a distinct pair of elements as input and produces that pair in sorted order as output in one time unit.

Bitonic sequence. A sequence $(a_1, a_2, \dots, a_{2m})$ is said to be *bitonic* if and only if:

(a) Either there is an integer j , $1 \leq j \leq 2m$, such that

$$a_1 \leq a_2 \leq \dots \leq a_j \geq a_{j+1} \geq a_{j+2} \geq \dots \geq a_{2m}$$

(b) Or the sequence does not initially satisfy the condition in (a), but can be shifted cyclically until the condition is satisfied.

For example, the sequence (8, 9, 10, 12, 7, 5, 4, 3, 1) is bitonic, as it satisfies condition (a). Similarly, the sequence (3, 2, 1, 5, 8, 9, 4), which does not satisfy condition (a), is also bitonic, as it can be shifted cyclically to obtain (1, 5, 8, 9, 4, 3, 2).

Let $(a_1, a_2, \dots, a_{2m})$ be a bitonic sequence, and let $d_i = \min(a_i, a_{m+i})$ and $e_i = \max(a_i, a_{m+i})$, for $i = 1, 2, \dots, m$. The following properties hold:

- (a) The sequences (d_1, d_2, \dots, d_m) and (e_1, e_2, \dots, e_m) are both bitonic.
- (b) $\max(d_1, d_2, \dots, d_m) \leq \min(e_1, e_2, \dots, e_m)$.

In order to prove the validity of these two properties, it suffices to consider sequences of the form:

$$a_1 \leq a_2 \leq \dots \leq a_{j-1} \leq a_j \geq a_{j+1} \geq \dots \geq a_{2m},$$

for some $1 \leq j \leq 2m$, since a cyclic shift of $\{a_1, a_2, \dots, a_{2m}\}$ affects $\{d_1, d_2, \dots, d_m\}$ and $\{e_1, e_2, \dots, e_m\}$ similarly, while affecting neither of the two properties to be established. In addition, there is no loss in generality to assume that $m < j \leq 2m$, since $\{a_{2m}, a_{2m-1}, \dots, a_1\}$ is also bitonic and neither property is affected by such reversal.

There are two cases:

1. If $a_m \leq a_{2m}$, then $a_i \leq a_{m+i}$. As a result, $d_i = a_i$, and $e_i = a_{m+i}$, for $1 \leq i \leq m$, and both properties hold.
2. If $a_m > a_{2m}$, then since $a_{j-m} \leq a_j$, an index k exists, where $j \leq k < 2m$, such that $a_{k-m} \leq a_k$ and $a_{k-m+1} > a_{k+1}$. Consequently:

$$d_i = a_i \text{ and } e_i = a_{m+i} \text{ for } 1 \leq i \leq k-m,$$

and

$$d_i = a_{m+i} \text{ and } e_i = a_i \text{ for } k-m < i \leq m.$$

Hence:

$$d_i \leq d_{i+1} \text{ for } 1 \leq i < k-m,$$

and

$$d_i \geq d_{i+1} \text{ for } k-m \leq i < m,$$

implying that $\{d_1, d_2, \dots, d_m\}$ is bitonic. Similarly, $e_i \leq e_{i+1}$, for $k-m \leq i < m$, $e_m \leq e_1$, $e_i \leq e_{i+1}$, for $1 \leq i < j-m$, and $e_i \geq e_{i+1}$, for $j-m \leq i < k-m$, implying that $\{e_1, e_2, \dots, e_m\}$ is also bitonic. Also,

$$\begin{aligned} \max(d_1, d_2, \dots, d_m) &= \max(d_{k-m}, d_{k-m+1}) \\ &= \max(a_{k-m}, a_{k+1}), \end{aligned}$$

and

$$\begin{aligned} \min(e_1, e_2, \dots, e_m) &= \min(e_{k-m}, e_{k-m+1}) \\ &= \min(a_k, a_{k-m+1}). \end{aligned}$$

Finally, since $a_k \geq a_{k+1}$, $a_k \geq a_{k-m}$, $a_{k-m+1} \geq a_{k-m}$, and $a_{k-m+1} \geq a_{k+1}$, it follows that:

$$\max(a_{k-m}, a_{k+1}) \leq \min(a_k, a_{k-m+1}).$$

Sorting a Bitonic Sequence

Given a bitonic sequence $(a_1, a_2, \dots, a_{2m})$, it can be sorted into a sequence $(c_1, c_2, \dots, c_{2m})$, arranged in nondecreasing order, by the following algorithm $MERGE_{2m}$:

Step 1. The two sequences (d_1, d_2, \dots, d_m) and (e_1, e_2, \dots, e_m) are produced.

Step 2. These two bitonic sequences are sorted independently and recursively, each by a call to $MERGE_m$.

It should be noted that in Step 2 the two sequences can be sorted independently (and simultaneously if enough comparators are available), since no element of (d_1, d_2, \dots, d_m) is larger than any element of (e_1, e_2, \dots, e_m) . The m smallest elements of the final sorted sequence are produced by sorting (d_1, d_2, \dots, d_m) , and the m largest by sorting (e_1, e_2, \dots, e_m) . The recursion terminates when $m = 2$, since $MERGE_2$ is implemented directly by one comparison-swap (or one comparator).

Sorting an Arbitrary Sequence

Algorithm $MERGE_{2m}$ assumes that the input sequence to be sorted is bitonic. However, it is easy to modify an arbitrary input sequence into a sequence of bitonic sequences as follows. Let the input sequence be (a_1, a_2, \dots, a_n) , and recall that, for simplicity, it is assumed that n is a power of 2. Now the following $n/2$ comparisons-swaps are performed: For all odd i , a_i is compared with a_{i+1} and a swap is applied if necessary. These comparison-swaps are numbered from 1 to $n/2$. Odd-numbered comparison-swaps place the smaller of (a_i, a_{i+1}) first and the larger of the pair second. Even-numbered comparison-swaps place the larger of (a_i, a_{i+1}) first and the smaller of the pair second.

At the end of this first stage, $n/4$ bitonic sequences are obtained. Each of these sequences is of length 4 and can be sorted using $MERGE_4$. These instances of $MERGE_4$ are numbered from 1 to $n/4$. Odd-numbered instances sort their inputs in nondecreasing order while

even-numbered instances sort their inputs in nonincreasing order. This yields $n/8$ bitonic sequences each of length 8.

The process continues until a single bitonic sequence of length n is produced and is sorted by giving it as input to $MERGE_n$. If a comparator is used to implement each comparison-swap, and all independent comparison-swaps are allowed to be executed in parallel, then the sequence is sorted in $((1 + \log n) \log n)/2$ time units (all logarithms are to the base 2). This is now illustrated.

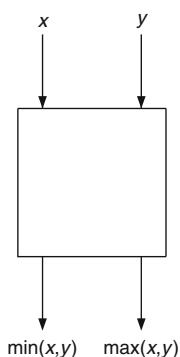

Implementation as a Combinational Circuit

[Figure 1](#) shows a schematic diagram of a comparator. The comparator receives two numbers x and y as input, and produces the smaller of the two on its left output line, and the larger of the two on its right output line.

A combinational circuit for sorting is a device, built entirely of comparators that takes an arbitrary sequence at one end and produces that sequence in sorted order at the other end. The comparators are arranged in rows. Each comparator receives its two inputs from the input sequence, or from comparators in the previous row, and delivers its two outputs to the comparators in the following row, or to the output sequence. A combinational circuit has no feedback: Data traverse the circuit in the same way as water flows from high to low terrain.

[Figure 2](#) shows a schematic diagram of a combinational circuit implementation of algorithm $MERGE_{2m}$, which sorts the bitonic sequence $(a_1, a_2, \dots, a_{2m})$ into nondecreasing order from smallest, on the leftmost line, to largest, on the rightmost.

Clearly, a bitonic sequence of length 2 is sorted by a single comparator. Combinational circuits for sorting

Bitonic Sort. Fig. 1 A comparator

bitonic sequences of length 4 and 8 are shown in [Figs. 3](#) and [4](#), respectively.

Finally, a combinational circuit for sorting an arbitrary sequence of numbers, namely, the sequence (5, 3, 2, 6, 1, 4, 7, 5) is shown in [Fig. 5](#). Comparators that reverse their outputs (i.e., those that produce the larger of their two inputs on the left output line, and the smaller on the right output line) are indicated with the letter R.

Analysis

The *depth* of a sorting circuit is the number of rows it contains – that is, the maximum number of comparators on a path from input to output. Depth, in other words, represents the time it takes the circuit to complete the sort. The *size* of a sorting circuit is defined as the number of comparators it uses.

Taking $2m = 2^i$, the depth of the circuit in [Fig. 2](#), which implements algorithm $MERGE_{2m}$ for sorting a bitonic sequence of length $2m$, is given by the recurrence:

$$\begin{aligned} d(2) &= 1 \\ d(2^i) &= 1 + d(2^{i-1}), \end{aligned}$$

whose solution is $d(2^i) = i$. The size of the circuit is given by the recurrence:

$$\begin{aligned} s(2) &= 1 \\ s(2^i) &= 2^{i-1} + 2s(2^{i-1}), \end{aligned}$$

whose solution is $s(2^i) = i2^{i-1}$.

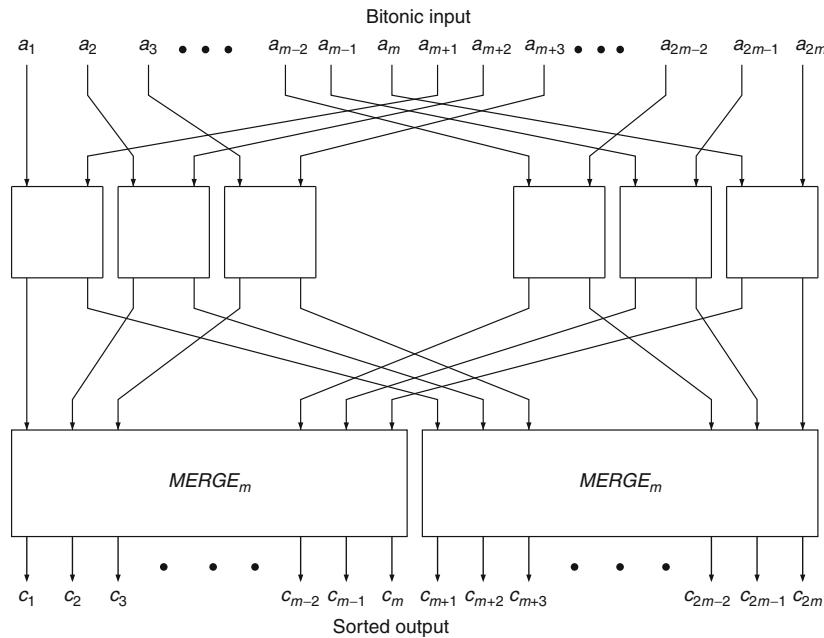

A circuit for sorting an arbitrary sequence of length n , such as the circuit in [Fig. 5](#) where $n = 8$, consists of $\log n$ phases: In the i th phase, $n/2^i$ circuits are required, each implementing $MERGE_{2^i}$, and having a size of $s(2^i)$ and a depth of $d(2^i)$, for $i = 1, 2, \dots, \log n$. The depth and size of this circuit are

$$\sum_{i=1}^{\log n} d(2^i) = \sum_{i=1}^{\log n} i = \frac{(1 + \log n) \log n}{2},$$

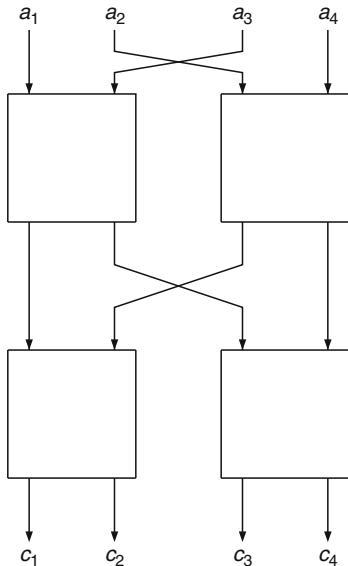

and

$$\begin{aligned} \sum_{i=1}^{\log n} 2^{(\log n)-i} s(2^i) &= \sum_{i=1}^{\log n} 2^{(\log n)-i} i 2^{i-1} \\ &= \frac{n(1 + \log n) \log n}{4}, \end{aligned}$$

respectively.

Lower Bounds

In order to evaluate the quality of the *Bitonic Sort* circuit, its depth and size are compared to two types of lower bounds.

A lower bound on the number of comparisons. A lower bound on the number of comparisons required in the worst case by a comparison-based sorting algorithm to sort a sequence of n numbers is derived as follows. All comparison-based sorting algorithms are modeled by a binary tree, each of whose nodes represents a comparison between two input elements. The leaves of the tree represent the $n!$ possible outcomes of the sort. A path from the root of the tree to a leaf is a complete execution of an algorithm on a given input. The length of the longest such path is $\log n!$, which is a quantity on the order of $n \log n$.

Several sequential comparison-based algorithms, such as *Heapsort* and *Mergesort*, for example, achieve this bound, to within a constant multiplicative factor, and are therefore said to be *optimal*. The *Bitonic Sort* circuit always runs in time on the order of $\log^2 n$ and is therefore significantly faster than any sequential algorithm. However, the number of comparators it uses, and therefore the number of comparisons it performs, is on the order of $n \log^2 n$, and consequently, it is not optimal in that sense.

Lower bounds on the depth and size. These lower bounds are specific to circuits. A lower bound on the depth of a sorting circuit for an input sequence of n elements is obtained as follows. Each comparator has

Bitonic Sort. Fig. 4 A circuit for sorting a bitonic sequence of length 8

two outputs, implying that an input element can reach at most 2^r locations after r rows. Since each element should be able to reach all n output positions, a lower bound on the depth of the circuit is on the order of $\log n$.

A lower bound on the size of a sorting circuit is obtained by observing that the circuit must be able to produce any of the $n!$ possible output sequences for each input sequence. Since each comparator can be in one of two states (swapping or not swapping its two inputs), the total number of configurations in which a circuit with c comparators can be is 2^c , and this needs to be at least equal to $n!$. Thus, a lower bound on the size of a sorting circuit is on the order of $n \log n$.

The *Bitonic Sort* circuit exceeds each of the lower bounds on depth and size by a factor of $\log n$, and is therefore not optimal in that sense as well.

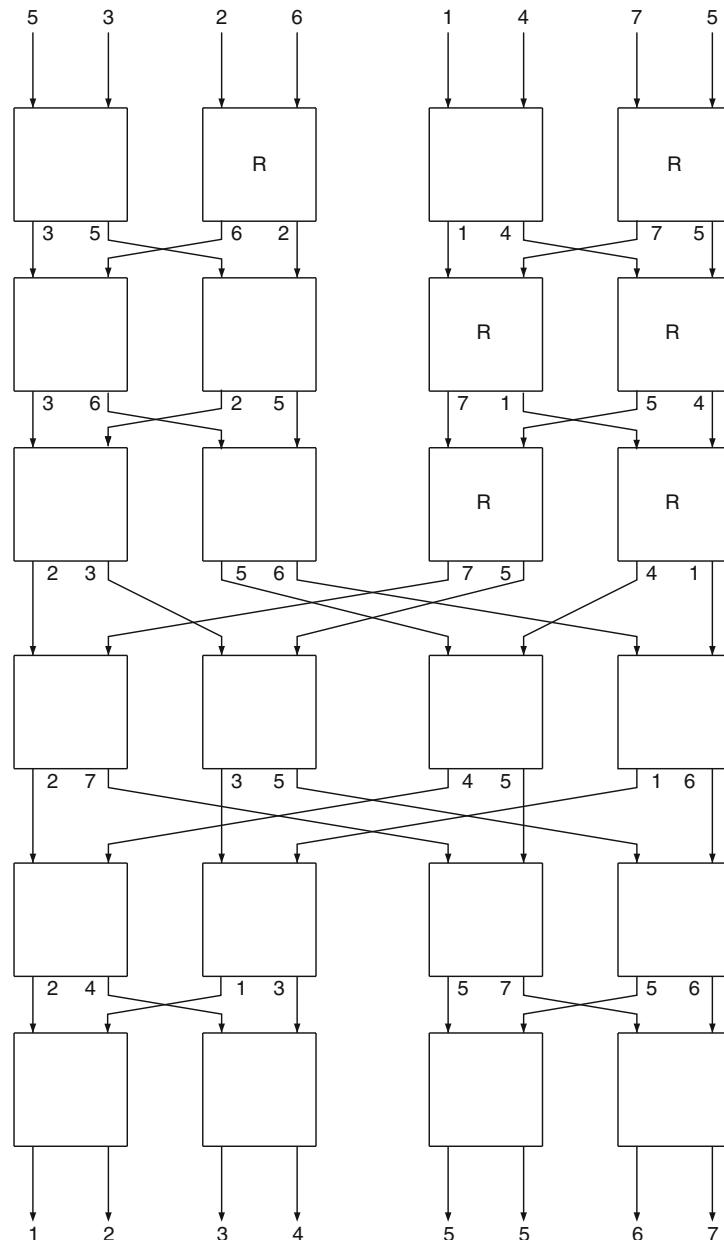

There exists a sorting circuit, known as the AKS circuit, which has a depth on the order of $\log n$ and a size on the order of $n \log n$. This circuit meets the lower

bound on the number of comparisons required to sort, in addition to the lower bounds on depth and size specific to circuits. It is, therefore, theoretically optimal on all counts.

In practice, however, the AKS circuit may not be very useful. In addition to its high conceptual complexity, its depth and size expressions are preceded by constants on the order of 10^3 . Even if the depth of the AKS circuit were as small as $200 \log n$, in order for the latter to be smaller than the depth of the *Bitonic Sort* circuit, namely, $((1 + \log n) \log n)/2$, the input sequence will need to have the astronomical length of $n > 2^{399}$, which is greater than the number of atoms that the observable universe is estimated to contain.

Future Directions

An interesting open problem in this area of research is to design a sorting circuit with the elegance, regularity, and simplicity of the *Bitonic Sort* circuit, while at the same

Bitonic Sort. Fig. 5 A circuit for sorting an arbitrary sequence of length 8

time matching the theoretical lower bounds on depth and size as closely as possible.

Bibliographic Notes and Further Reading

In 1968, Ken Batcher presented a paper at the AFIPS conference, in which he described two circuits for

sorting, namely, the *Odd-Even Sort* and the *Bitonic Sort* circuits [6]. This paper pioneered the study of parallel sorting algorithms and effectively launched the field of parallel algorithm design and analysis. Proofs of correctness of the *Bitonic Sort* algorithm are provided in [3, 6, 8]. Implementations of *Bitonic Sort* on other architectures beside combinational circuits have been proposed, including implementations on a perfect shuffle computer [20], a mesh of processors [16, 21], and on a shared-memory parallel machine [7].

In its simplest form, *Bitonic Sort* assumes that n , the length of the input sequence, is a power of 2. When n is not a power of 2, the sequence can be padded with z zeros such that $n + z$ is the smallest power of 2 larger than n . Alternatively, several variants of *Bitonic Sort* were proposed in the literature that are capable of sorting input sequences of arbitrary length [14, 15, 22].

Combinational circuits for sorting (also known as *sorting networks*) are discussed in [3–5, 8, 11–13, 17]. A lower bound for oblivious merging is derived in [9] and generalized in [23], which demonstrates that the bitonic merger is optimal to within a small constant factor. The AKS sorting circuit (whose name derives from the initials of its three inventors) was first described in [1] and then in [2]. Unlike the *Bitonic Sort* circuit that is based on the idea of repeatedly merging increasingly longer subsequences, the AKS circuit sorts by repeatedly splitting the original input sequence into increasingly shorter and disjoint subsequences. While theoretically optimal, the circuit suffers from large multiplicative constants in the expressions for its depth and size, making it of little use in practice, as mentioned earlier. A formulation in [18] manages to reduce the constants to a few thousands, still a prohibitive number. Descriptions of the AKS circuit appear in [5, 10, 17, 19]. Sequential sorting algorithms, including *Heapsort* and *Mergesort*, are covered in [8, 12].

One property of combinational circuits, not shared by many other parallel models of computation, is their ability to allow several input sequences to be processed simultaneously, in a *pipeline fashion*. This is certainly true of sorting circuits: Once the elements of the first input sequence have traversed the first row and moved on to the second, a new sequence can enter the first row,

and so on. If the circuit has depth D , then M sequences can be sorted in $D + M - 1$ time units [5].

- It can be implemented in a highly parallel manner on modern architectures, such as a streaming architecture (GPUs), even without any scatter operations, that is, without random access writes.

One of the main differences between “regular” bitonic sorting and adaptive bitonic sorting is that regular bitonic sorting is data-independent, while adaptive bitonic sorting is data-dependent (hence the name).

As a consequence, adaptive bitonic sorting cannot be implemented as a sorting network, but only on architectures that offer some kind of flow control. Nonetheless, it is convenient to derive the method of adaptive bitonic sorting from bitonic sorting.

Sorting networks have a long history in computer science research (see the comprehensive survey [2]). One reason is that sorting networks are a convenient way to describe parallel sorting algorithms on CREW-PRAMs or even EREW-PRAMs (which is also called PRAC for “parallel random access computer”).

In the following, let n denote the number of keys to be sorted, and p the number of processors. For the sake of clarity, n will always be assumed to be a power of 2. (In their original paper [5], Bilardi and Nicolau have described how to modify the algorithms such that they can handle arbitrary numbers of keys, but these technical details will be omitted in this article.)

The first to present a sorting network with optimal asymptotic complexity were Ajtai, Komlós, and Szemeredi [1]. Also, Cole [6] presented an optimal parallel merge sort approach for the CREW-PRAM as well as for the EREW-PRAM. However, it has been shown that neither is fast in practice for reasonable numbers of keys [8, 15].

In contrast, adaptive bitonic sorting requires less than $2n \log n$ comparisons in total, independent of the number of processors. On p processors, it can be implemented in $O\left(\frac{n \log n}{p}\right)$ time, for $p \leq \frac{n}{\log n}$.

Even with a small number of processors it is efficient in practice: in its original implementation, the sequential version of the algorithm was at most by a factor 2.5 slower than quicksort (for sequence lengths up to 2^{19}) [5].

Fundamental Properties

One of the fundamental concepts in this context is the notion of a *bitonic sequence*.

Bitonic Sorting Network

► Bitonic Sort

Bitonic Sorting, Adaptive

GABRIEL ZACHMANN

Clausthal University, Clausthal-Zellerfeld, Germany

Definition

Adaptive bitonic sorting is a sorting algorithm suitable for implementation on EREW parallel architectures. Similar to bitonic sorting, it is based on merging, which is recursively applied to obtain a sorted sequence. In contrast to bitonic sorting, it is data-dependent. Adaptive bitonic merging can be performed in $O\left(\frac{n}{p}\right)$ parallel time, p being the number of processors, and executes only $O(n)$ operations in total. Consequently, adaptive bitonic sorting can be performed in $O\left(\frac{n \log n}{p}\right)$ time, which is optimal. So, one of its advantages is that it executes a factor of $O(\log n)$ less operations than bitonic sorting. Another advantage is that it can be implemented efficiently on modern GPUs.

Discussion

Introduction

This chapter describes a parallel sorting algorithm, *adaptive bitonic sorting* [5], that offers the following benefits:

- It needs only the optimal total number of comparison/exchange operations, $O(n \log n)$.
- The hidden constant in the asymptotic number of operations is less than in other optimal parallel sorting methods.

Definition 1 (Bitonic sequence) Let $\mathbf{a} = (a_0, \dots, a_{n-1})$ be a sequence of numbers. Then, \mathbf{a} is *bitonic*, iff it monotonically increases and then monotonically decreases, or if it can be cyclically shifted (i.e., rotated) to become monotonically increasing and then monotonically decreasing.

Figure 1 shows some examples of bitonic sequences.

In the following, it will be easier to understand any reasoning about bitonic sequences, if one considers them as being arranged in a circle or on a cylinder: then, there are only two inflection points around the circle. This is justified by **Definition 1**. **Figure 2** depicts an example in this manner.

As a consequence, all index arithmetic is understood *modulo n*, that is, index $i + k \equiv i + k \bmod n$, unless otherwise noted, so indices range from 0 through $n - 1$.

As mentioned above, adaptive bitonic sorting can be regarded as a variant of bitonic sorting, which is in order to capture the notion of “rotational invariance” (in some

sense) of bitonic sequences; it is convenient to define the following *rotation operator*.

Definition 2 (Rotation) Let $\mathbf{a} = (a_0, \dots, a_{n-1})$ and $j \in \mathbb{N}$. We define a rotation as an operator R_j on the sequence \mathbf{a} :

$$R_j \mathbf{a} = (a_j, a_{j+1}, \dots, a_{j+n-1})$$

This operation is performed by the network shown in **Fig. 4**. Such networks are comprised of elementary comparators (see **Fig. 3**).

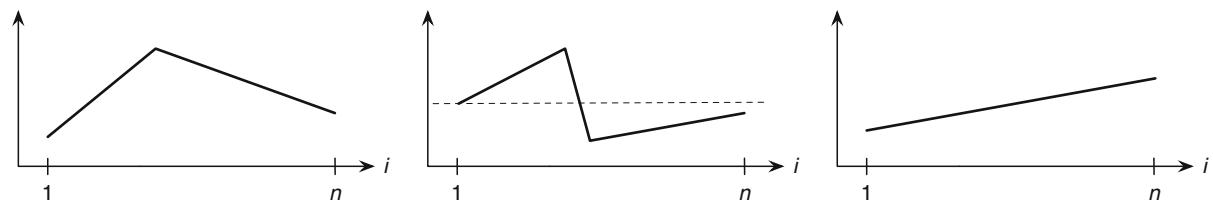

Two other operators are convenient to describe sorting.

Definition 3 (Half-cleaner) Let $\mathbf{a} = (a_0, \dots, a_{n-1})$.

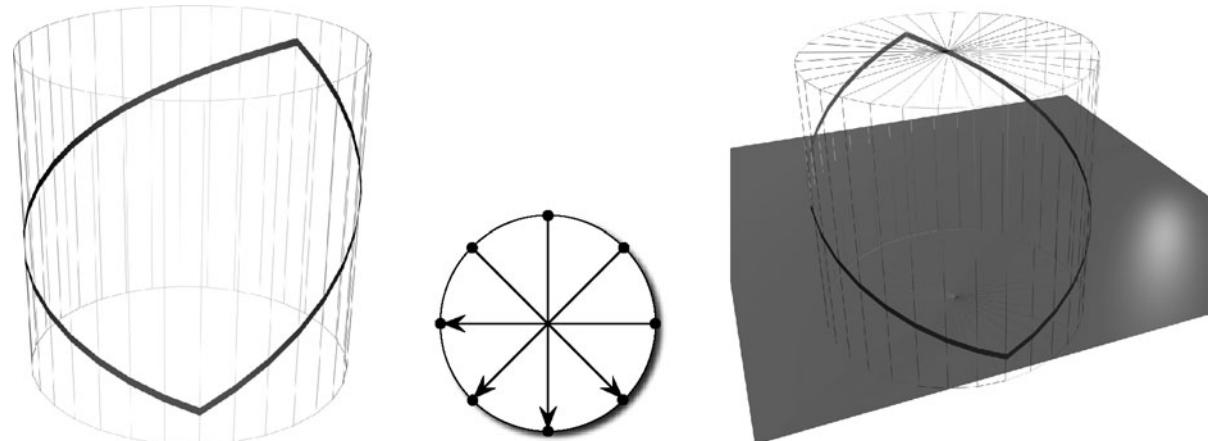

$$L\mathbf{a} = (\min(a_0, a_{\frac{n}{2}}), \dots, \min(a_{\frac{n}{2}-1}, a_{n-1})),$$

$$U\mathbf{a} = (\max(a_0, a_{\frac{n}{2}}), \dots, \max(a_{\frac{n}{2}-1}, a_{n-1})).$$

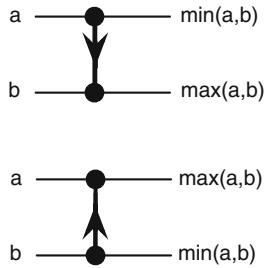

In [7], a network that performs these operations together is called a *half-cleaner* (see **Fig. 5**).

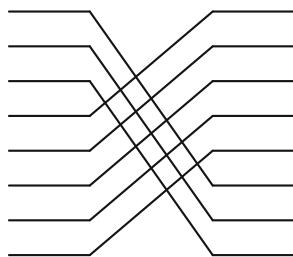

Bitonic Sorting, Adaptive. Fig. 1 Three examples of sequences that are bitonic. Obviously, the mirrored sequences (either way) are bitonic, too

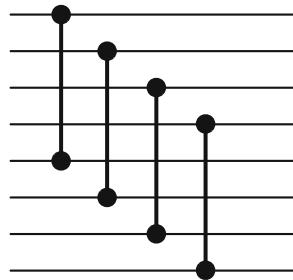

Bitonic Sorting, Adaptive. Fig. 2 Left: according to their definition, bitonic sequences can be regarded as lying on a cylinder or as being arranged in a circle. As such, they consist of one monotonically increasing and one decreasing part. Middle: in this point of view, the network that performs the L and U operators (see **Fig. 5**) can be visualized as a wheel of “spokes.” Right: visualization of the effect of the L and U operators; the blue plane represents the median

Bitonic Sorting, Adaptive. Fig. 3 Comparator/exchange elements

Bitonic Sorting, Adaptive. Fig. 4 A network that performs the rotation operator

Bitonic Sorting, Adaptive. Fig. 5 A network that performs the L and U operators

It is easy to see that, for any j and \mathbf{a} ,

$$L\mathbf{a} = R_{-j \bmod \frac{n}{2}} LR_j \mathbf{a}, \quad (1)$$

and

$$U\mathbf{a} = R_{-j \bmod \frac{n}{2}} UR_j \mathbf{a}. \quad (2)$$

This is the reason why the cylinder metaphor is valid.

The proof needs to consider only two cases: $j = \frac{n}{2}$ and $1 \leq j < \frac{n}{2}$. In the former case, Eq. 1 becomes $L\mathbf{a} =$

$LR_{\frac{n}{2}} \mathbf{a}$, which can be verified trivially. In the latter case, Eq. 1 becomes

$$\begin{aligned} LR_j \mathbf{a} &= (\min(a_j, a_{j+\frac{n}{2}}), \dots, \min(a_{\frac{n}{2}-1}, a_{n-1}), \dots, \\ &\quad \min(a_{j-1}, a_{j-1+\frac{n}{2}})) \\ &= R_j L\mathbf{a}. \end{aligned}$$

Thus, with the cylinder metaphor, the L and U operators basically do the following: cut the cylinder with circumference n at any point, roll it around a cylinder with circumference $\frac{n}{2}$, and perform position-wise the max and min operator, respectively. Some examples are shown in Fig. 6.

The following theorem states some important properties of the L and U operators.

Theorem 1 Given a bitonic sequence \mathbf{a} ,

$$\max\{L\mathbf{a}\} \leq \min\{U\mathbf{a}\}.$$

Moreover, $L\mathbf{a}$ and $U\mathbf{a}$ are bitonic too.

In other words, each element of $L\mathbf{a}$ is less than or equal to each element of $U\mathbf{a}$.

This theorem is the basis for the construction of the bitonic sorter [4]. The first step is to devise a *bitonic merger* (BM). We denote a BM that takes as input bitonic sequences of length n with BM_n . A BM is recursively defined as follows:

$$BM_n(\mathbf{a}) = (BM_{\frac{n}{2}}(L\mathbf{a}), BM_{\frac{n}{2}}(U\mathbf{a})).$$

The base case is, of course, a two-key sequence, which is handled by a single comparator. A BM can be easily represented in a network as shown in Fig. 7.

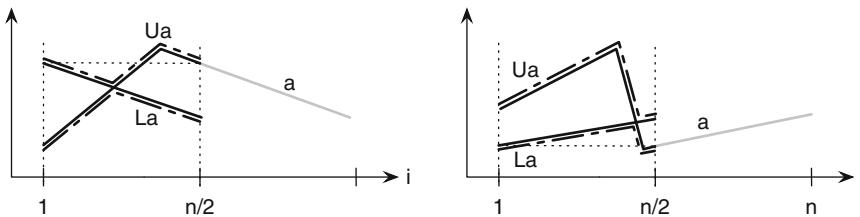

Given a bitonic sequence \mathbf{a} of length n , one can show that

$$BM_n(\mathbf{a}) = Sorted(\mathbf{a}). \quad (3)$$

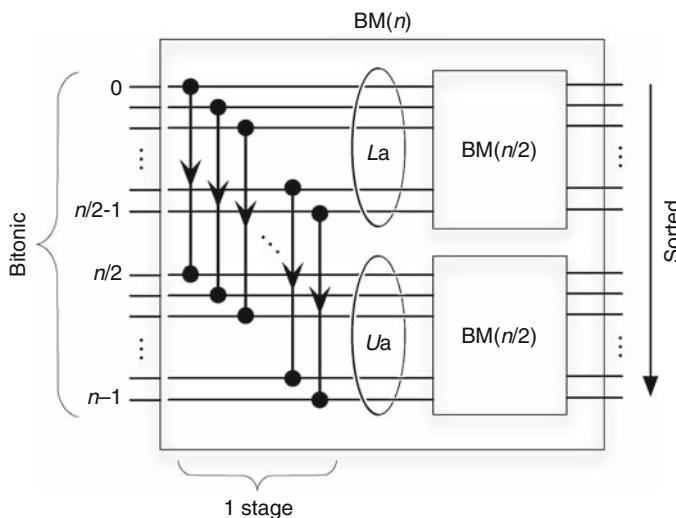

It should be obvious that the sorting direction can be changed simply by swapping the direction of the elementary comparators.

Coming back to the metaphor of the cylinder, the first stage of the bitonic merger in Fig. 7 can be visualized as $\frac{n}{2}$ comparators, each one connecting an element of the cylinder with the opposite one, somewhat like spokes in a wheel. Note that here, while the cylinder can rotate freely, the “spokes” must remain fixed.

From a bitonic merger, it is straightforward to derive a bitonic sorter, BS_n , that takes an unsorted sequence, and produces a sorted sequence either up or down. Like the BM, it is defined recursively, consisting of two

Bitonic Sorting, Adaptive. Fig. 6 Examples of the result of the L and U operators. Conceptually, these operators fold the bitonic sequence (black), such that the part from indices $\frac{n}{2} + 1$ through n (light gray) is shifted into the range 1 through $\frac{n}{2}$ (black); then, L and U yield the upper (medium gray) and lower (dark gray) hull, respectively

Bitonic Sorting, Adaptive. Fig. 7 Schematic, recursive diagram of a network that performs bitonic merging

smaller bitonic sorters and a bitonic merger (see Fig. 8). Again, the base case is the two-key sequence.

Analysis of the Number of Operations of Bitonic Sorting

Since a bitonic sorter basically consists of a number of bitonic mergers, it suffices to look at the total number of comparisons of the latter.

The total number of comparators, $C(n)$, in the bitonic merger BM_n is given by:

$$C(n) = 2C\left(\frac{n}{2}\right) + \frac{n}{2}, \quad \text{with } C(2) = 1,$$

which amounts to

$$C(n) = \frac{1}{2}n \log n.$$

As a consequence, the bitonic sorter consists of $O(n \log^2 n)$ comparators.

Clearly, there is some redundancy in such a network, since n comparisons are sufficient to merge two sorted sequences. The reason is that the comparisons performed by the bitonic merger are *data-independent*.

Derivation of Adaptive Bitonic Merging

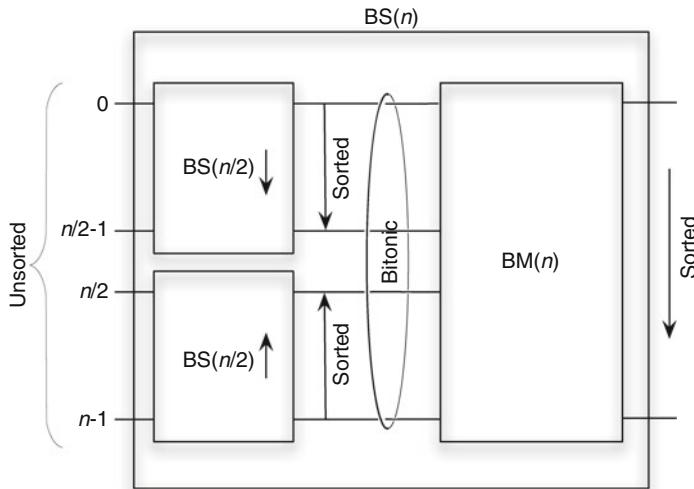

The algorithm for adaptive bitonic sorting is based on the following theorem.

Theorem 2 Let \mathbf{a} be a bitonic sequence. Then, there is an index q such that

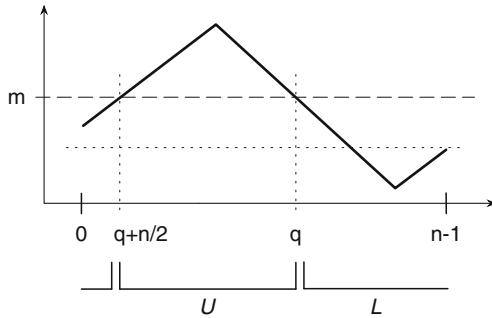

$$L\mathbf{a} = (a_q, \dots, a_{q+\frac{n}{2}-1}) \quad (4)$$

$$U\mathbf{a} = (a_{q+\frac{n}{2}}, \dots, a_{q-1}) \quad (5)$$

(Remember that index arithmetic is always modulo n .)

Bitonic Sorting, Adaptive. Fig. 8 Schematic, recursive diagram of a bitonic sorting network

Bitonic Sorting, Adaptive. Fig. 9 Visualization for the proof of Theorem 2

The following outline of the proof assumes, for the sake of simplicity, that all elements in \mathbf{a} are distinct. Let m be the median of all a_i , that is, $\frac{n}{2}$ elements of \mathbf{a} are less than or equal to m , and $\frac{n}{2}$ elements are larger. Because of Theorem 1,

$$\max\{L\mathbf{a}\} \leq m < \min\{U\mathbf{a}\}.$$

Employing the cylinder metaphor again, the median m can be visualized as a horizontal plane $z = m$ that cuts the cylinder. Since \mathbf{a} is bitonic, this plane cuts the sequence in exactly two places, that is, it partitions the sequence into two contiguous halves (actually, any horizontal plane, i.e., any percentile partitions a bitonic sequence in two contiguous halves), and since it is

the median, each half must have length $\frac{n}{2}$. The indices where the cut happens are q and $q + \frac{n}{2}$. Figure 9 shows an example (in one dimension).

The following theorem is the final keystone for the adaptive bitonic sorting algorithm.

Theorem 3 Any bitonic sequence \mathbf{a} can be partitioned into four subsequences $(\mathbf{a}^1, \mathbf{a}^2, \mathbf{a}^3, \mathbf{a}^4)$ such that either

$$(L\mathbf{a}, U\mathbf{a}) = (\mathbf{a}^1, \mathbf{a}^4, \mathbf{a}^3, \mathbf{a}^2) \quad (6)$$

or

$$(L\mathbf{a}, U\mathbf{a}) = (\mathbf{a}^3, \mathbf{a}^2, \mathbf{a}^1, \mathbf{a}^4). \quad (7)$$

Furthermore,

$$|\mathbf{a}^1| + |\mathbf{a}^2| = |\mathbf{a}^3| + |\mathbf{a}^4| = \frac{n}{2}, \quad (8)$$

$$|\mathbf{a}^1| = |\mathbf{a}^3|, \quad (9)$$

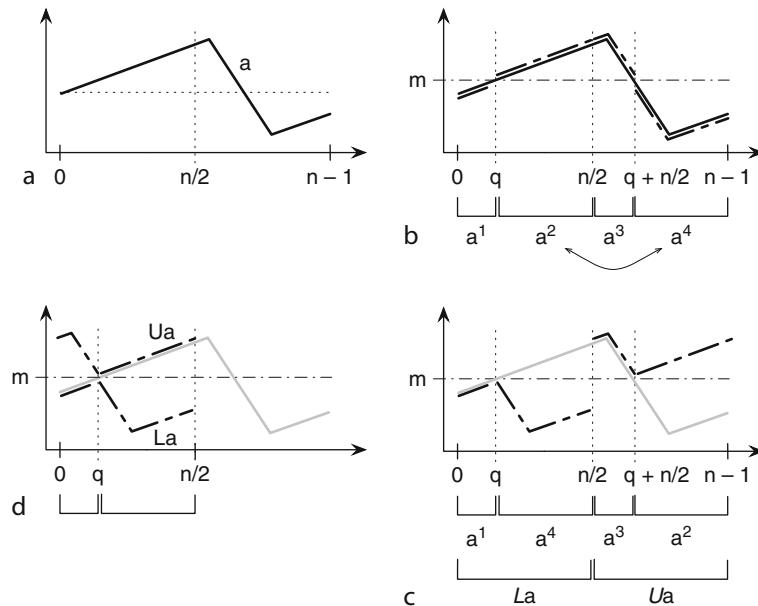

and

$$|\mathbf{a}^2| = |\mathbf{a}^4|, \quad (10)$$

where $|\mathbf{a}|$ denotes the length of sequence \mathbf{a} .

Figure 10 illustrates this theorem by an example.

This theorem can be proven fairly easily too: the length of the subsequences is just q and $\frac{n}{2} - q$, where q is the same as in Theorem 2. Assuming that $\max\{\mathbf{a}^1\} < m < \min\{\mathbf{a}^3\}$, nothing will change between those two subsequences (see Fig. 10). However, in that case $\min\{\mathbf{a}^2\} > m > \max\{\mathbf{a}^4\}$; therefore, by swapping

Bitonic Sorting, Adaptive. Fig. 10 Example illustrating Theorem 3

a^2 and a^4 (which have equal length), the bounds $\max\{a^1, a^4\} < m < \min\{a^3, a^3\}$ are obtained. The other case can be handled analogously.

Remember that there are $\frac{n}{2}$ comparator-and-exchange elements, each of which compares a_i and $a_{i+\frac{n}{2}}$. They will perform exactly this exchange of subsequences, without ever looking at the data.

Now, the idea of adaptive bitonic sorting is to find the subsequences, that is, to find the index q that marks the border between the subsequences. Once q is found, one can (conceptually) swap the subsequences, instead of performing $\frac{n}{2}$ comparisons unconditionally.

Finding q can be done simply by binary search driven by comparisons of the form $(a_i, a_{i+\frac{n}{2}})$.

Overall, instead of performing $\frac{n}{2}$ comparisons in the first stage of the bitonic merger (see Fig. 7), the adaptive bitonic merger performs $\log(\frac{n}{2})$ comparisons in its first stage (although this stage is no longer representable by a network).

Let $C(n)$ be the total number of comparisons performed by adaptive bitonic merging, in the worst case. Then

$$C(n) = 2C\left(\frac{n}{2}\right) + \log(n) = \sum_{i=0}^{k-1} 2^i \log\left(\frac{n}{2^i}\right),$$

with $C(2) = 1, C(1) = 0$ and $n = 2^k$. This amounts to

$$C(n) = 2n - \log n - 2.$$

The only question that remains is how to achieve the data rearrangement, that is, the swapping of the subsequences a^1 and a^3 or a^2 and a^4 , respectively, without sacrificing the worst-case performance of $O(n)$. This can be done by storing the keys in a perfectly balanced tree (assuming $n = 2^k$), the so-called bitonic tree. (The tree can, of course, store only $2^k - 1$ keys, so the n -th key is simply stored separately.) This tree is very similar to a search tree, which stores a monotonically increasing sequence: when traversed in-order, the bitonic tree produces a sequence that lists the keys such that there are exactly two inflection points (when regarded as a circular list).

Instead of actually copying elements of the sequence in order to achieve the exchange of subsequences, the adaptive bitonic merging algorithm swaps $O(\log n)$ pointers in the bitonic tree. The recursion then works on the two subtrees. With this technique, the overall number of operations of adaptive bitonic merging is $O(n)$. Details can be found in [5].

Clearly, the adaptive bitonic sorting algorithm needs $O(n \log n)$ operations in total, because it consists of $\log(n)$ many complete merge stages (see Fig. 8).

It should also be fairly obvious that the adaptive bitonic sorter performs an (adaptive) subset of the comparisons that are executed by the (nonadaptive) bitonic sorter.

The Parallel Algorithm

So far, the discussion assumed a sequential implementation. Obviously, the algorithm for adaptive bitonic merging can be implemented on a parallel architecture, just like the bitonic merger, by executing recursive calls on the same level in parallel.

Unfortunately, a naïve implementation would require $O(\log^2 n)$ steps in the worst case, since there are $\log(n)$ levels. The bitonic merger achieves $O(\log n)$ parallel time, because all pairwise comparisons within one stage can be performed in parallel. But this is not straightforward to achieve for the $\log(n)$ comparisons of the binary-search method in adaptive bitonic merging, which are inherently sequential.

However, a careful analysis of the data dependencies between comparisons of successive stages reveals that the execution of different stages can be partially overlapped [5]. As La , Ua are being constructed in one stage by moving down the tree in parallel layer by layer (occasionally swapping pointers); this process can be started for the next stage, which begins one layer beneath the one where the previous stage began, before the first stage has finished, provided the first stage has progressed “far enough” in the tree. Here, “far enough” means exactly two layers ahead.

This leads to a parallel version of the adaptive bitonic merge algorithm that executes in time $O\left(\frac{n}{p}\right)$ for $p \in O\left(\frac{n}{\log n}\right)$, that is, it can be executed in $(\log n)$ parallel time.

Furthermore, the data that needs to be communicated between processors (either via memory, or via communication channels) is in $O(p)$.

It is straightforward to apply the classical sorting-by-merging approach here (see Fig. 8), which yields the *adaptive bitonic sorting* algorithm. This can be implemented on an EREW machine with p processors in $O\left(\frac{n \log n}{p}\right)$ time, for $p \in O\left(\frac{n}{\log n}\right)$.

A GPU Implementation

Because adaptive bitonic sorting has excellent scalability (the number of processors, p , can go up to $n/\log(n)$) and the amount of inter-process communication is fairly low (only $O(p)$), it is perfectly suitable for implementation on stream processing architectures. In addition, although it was designed for a random access architecture, adaptive bitonic sorting can be adapted to a stream processor, which (in general) does not have the ability of random-access writes. Finally, it can be implemented on a GPU such that there are only $O(\log^2(n))$ passes (by utilizing $O(n/\log(n))$ (conceptual) processors), which is very important, since the

Algorithm 1: Adaptive construction of La and Ua (one stage of adaptive bitonic merging)

call merging recursively with $\text{right}(r)$ as root and e as extra node

number of passes is one of the main limiting factors on GPUs.

This section provides more details on the implementation on a GPU, called “GPU-ABiSort” [11, 12]. For the sake of simplicity, the following always assumes increasing sorting direction, and it is thus not explicitly specified. As noted above, the sorting direction must be reversed in the right branch of the recursion in the bitonic sorter, which basically amounts to reversing the comparison direction of the values of the keys, that is, compare for $<$ instead of $>$ in Algorithm 3.

As noted above, the bitonic tree stores the sequence (a_0, \dots, a_{n-2}) in in-order, and the key a_{n-1} is stored in the *extra node*. As mentioned above, an algorithm that constructs (La, Ua) from a can traverse this bitonic tree and swap pointers as necessary. The index q , which is mentioned in the proof for Theorem 3, is only determined implicitly. The two different cases that are mentioned in Theorem 3 and Eqs. 6 and 7 can be distinguished simply by comparing elements $a_{\frac{n}{2}-1}$ and a_{n-1} .

This leads to Algorithm 1. Note that the root of the bitonic tree stores element $a_{\frac{n}{2}-1}$ and the extra node stores a_{n-1} . Applying this recursively yields Algorithm 2. Note that the bitonic tree needs to be constructed only once at the beginning during setup time.

Because branches are very costly on GPUs, one should avoid as many conditionals in the inner loops as possible. Here, one can exploit the fact that $R_{n/2}a = (a_{\frac{n}{2}}, \dots, a_{n-1}, a_0, \dots, a_{\frac{n}{2}-1})$ is bitonic, provided a is bitonic too. This operation basically amounts to swapping the two pointers $\text{left}(\text{root})$ and $\text{right}(\text{root})$. The

Algorithm 3: Simplified adaptive construction of La and Ua

input : Bitonic tree, with root node r and extra node e , representing bitonic sequence a

output: La in the left subtree of r plus root r , and Ua in the right subtree of r plus extra node e

// phase 0

if $\text{value}(r) > \text{value}(e)$ **then**
 swap $\text{value}(r)$ and $\text{value}(e)$
 swap pointers $\text{left}(r)$ and $\text{right}(r)$
 $(p, q) = (\text{left}(r), \text{right}(r))$

for $i = 1, \dots, \log n - 1$ **do**

// phase i

if $\text{value}(p) > \text{value}(q)$ **then**
 swap $\text{value}(p)$ and $\text{value}(q)$
 swap pointers $\text{left}(p)$ and $\text{left}(q)$
 $(p, q) = (\text{right}(p), \text{right}(q))$

else
 $(p, q) = (\text{left}(p), \text{left}(q))$

simplified construction of La and Ua is presented in Algorithm 3. (Obviously, the simplified algorithm now really needs trees with pointers, whereas Bilardi’s original bitonic tree could be implemented pointer-less (since it is a complete tree). However, in a real-world implementation, the keys to be sorted must carry pointers to some “payload” data anyway, so the additional memory overhead incurred by the child pointers is at most a factor 1.5.)

Outline of the Implementation

As explained above, on each recursion level $j = 1, \dots, \log(n)$ of the adaptive bitonic sorting algorithm, $2^{\log n - j + 1}$ bitonic trees, each consisting of 2^{j-1} nodes, have to be merged into $2^{\log n - j}$ bitonic trees of 2^j nodes. The merge is performed in j stages. In each stage $k = 0, \dots, j-1$, the construction of La and Ua is executed on 2^k subtrees. Therefore, $2^{\log n - j} \cdot 2^k$ instances of the La / Ua construction algorithm can be executed in parallel during that stage. On a stream architecture, this potential parallelism can be exposed by allocating a stream consisting of $2^{\log n - j + k}$ elements and executing a so-called kernel on each element.

The *La / Ua* construction algorithm consists of $j - k$ phases, where each phase reads and modifies a pair of nodes, (p, q) , of a bitonic tree. Assume that a kernel implementation performs the operation of a single phase of this algorithm. (How such a kernel implementation is realized without random-access writes will be described below.) The temporary data that have to be preserved from one phase of the algorithm to the next one are just two node pointers (p and q) per kernel instance. Thus, each of the $2^{\log n-j+k}$ elements of the allocated stream consist of exactly these two node pointers. When the kernel is invoked on that stream, each kernel instance reads a pair of node pointers, (p, q) , from the stream, performs one phase of the *La/Ua* construction algorithm, and finally writes the updated pair of node pointers (p, q) back to the stream.

Eliminating Random-Access Writes

Since GPUs do not support random-access writes (at least, for almost all practical purposes, random-access writes would kill any performance gained by the parallelism) the kernel has to be implemented so that it modifies node pairs (p, q) of the bitonic tree without random-access writes. This means that it can output node pairs from the kernel only via linear stream write. But this way it cannot write a modified node pair to its original location from where it was read. In addition, it cannot simply take an input stream (containing a bitonic tree) and produce another output stream (containing the modified bitonic tree), because then it would have to process the nodes in the same order as they are stored in memory, but the adaptive bitonic merge processes them in a random, data-dependent order.

Fortunately, the bitonic tree is a linked data structure where all nodes are directly or indirectly linked to the root (except for the extra node). This allows us to change the location of nodes in memory during the merge algorithm as long as the child pointers of their respective parent nodes are updated (and the root and extra node of the bitonic tree are kept at well-defined memory locations). This means that for each node that is modified its parent node has to be modified also, in order to update its child pointers.

Notice that Algorithm 3 basically traverses the bitonic tree down along a path, changing some of the

nodes as necessary. The strategy is simple: simply output every node visited along this path to a stream. Since the data layout is fixed and predetermined, the kernel can store the index of the children with the node as it is being written to the output stream. One child address remains the same anyway, while the other is determined when the kernel is still executing for the current node. Figure 11 demonstrates the operation of the stream program using the described stream output technique.

Complexity

A simple implementation on the GPU would need $O(\log^2 n)$ phases (or “passes” in GPU parlance) in total for adaptive bitonic sorting, which amounts to $O(\log^3 n)$ operations in total.

This is already very fast in practice. However, the optimal complexity of $O(\log n)$ passes can be achieved exactly as described in the original work [5], that is, phase i of a stage k can be executed immediately after phase $i + 1$ of stage $k - 1$ has finished. Therefore, the execution of a new stage can start at every other step of the algorithm.

The only difference from the simple implementation is that kernels now must write to parts of the output stream, because other parts are still in use.

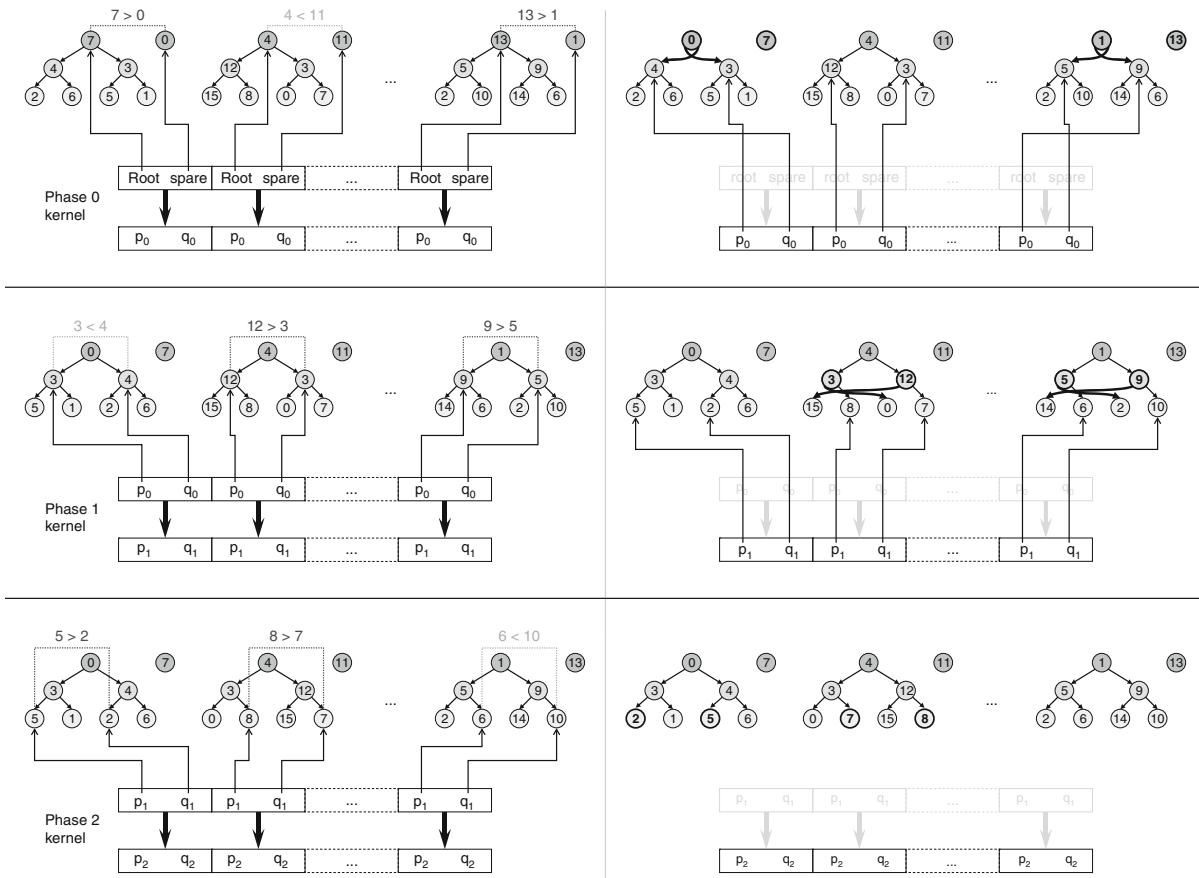

GPU-Specific Details

For the input and output streams, it is best to apply the *ping-pong* technique commonly used in GPU programming: allocate two such streams and alternately use one of them as input and the other one as output stream.

Preconditioning the Input

For merge-based sorting on a PRAM architecture (and assuming $p < n$), it is a common technique to sort *locally*, in a first step, p blocks of n/p values, that is, each processor sorts n/p values using a standard sequential algorithm.

The same technique can be applied here by implementing such a *local sort* as a kernel program. However, since there is no random write access to non-temporary memory from a kernel, the number of values that can be sorted locally by a kernel is restricted by the number of temporary registers.

Bitonic Sorting, Adaptive. Fig. 11 To execute several instances of the adaptive La/Ua construction algorithm in parallel, where each instance operates on a bitonic tree of 2^3 nodes, three phases are required. This figure illustrates the operation of these three phases. On the left, the node pointers contained in the input stream are shown as well as the comparisons performed by the kernel program. On the right, the node pointers written to the output stream are shown as well as the modifications of the child pointers and node values performed by the kernel program according to Algorithm 3

On recent GPUs, the maximum output data size of a kernel is 16×4 bytes. Since usually the input consists of key/pointer pairs, the method starts with a local sort of 8-key/pointer pairs per kernel. For such small numbers of keys, an algorithm with asymptotic complexity of $O(n)$ performs faster than asymptotically optimal algorithms.

After the local sort, a further stream operation converts the resulting sorted subsequences of length 8 pairwise to bitonic trees, each containing 16 nodes. Thereafter, the GPU-ABiSort approach can be applied as described above, starting with $j = 4$.

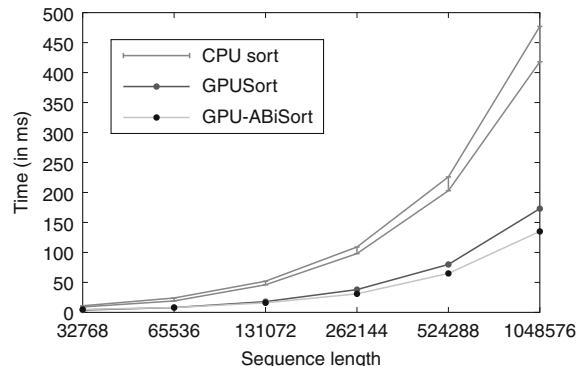

The Last Stage of Each Merge

Adaptive bitonic merging, being a recursive procedure, eventually merges small subsequences, for instance of length 16. For such small subsequences it is better to use a (nonadaptive) bitonic merge implementation that can be executed in a single pass of the whole stream.

Timings

The following experiments were done on arrays consisting of key/pointer pairs, where the key is a uniformly distributed random 32-bit floating point value and the pointer a 4-byte address. Since one can assume (without

n	CPU sort	GPUSort	GPU-ABiSort
32,768	9–11 ms	4 ms	5 ms
65,536	19–24 ms	8 ms	8 ms

262,144	98–109 ms	38 ms	31 ms
524,288	203–226 ms	80 ms	65 ms
1,048,576	418–477 ms	173 ms	135 ms

Bitonic Sorting, Adaptive. Fig. 12 Timings on a GeForce 7800 system. (There are two curves for the CPU sort, so as to visualize that its running time is somewhat data-dependent)

loss of generality) that all pointers in the given array are unique, these can be used as secondary sort keys for the adaptive bitonic merge.

The experiments described in the following compare the implementation of GPU-ABiSort of [11, 12] with sorting on the CPU using the C++ STL sort function (an optimized quicksort implementation) as well as with the (nonadaptive) bitonic sorting network implementation on the GPU by Govindaraju et al., called GPUSort [10].

Contrary to the CPU STL sort, the timings of GPU-ABiSort do not depend very much on the data to be sorted, because the total number of comparisons performed by the adaptive bitonic sorting is not data-dependent.

Figure 12 shows the results of timings performed on a PCI Express bus PC system with an AMD Athlon-64 4200+ CPU and an NVIDIA GeForce 7800 GTX GPU with 256 MB memory. Obviously, the speedup of GPU-ABiSort compared to CPU sorting is 3.1–3.5 for $n \geq 2^{17}$. Furthermore, up to the maximum tested sequence length $n = 2^{20}$ (= 1,048,576), GPU-ABiSort is up to 1.3 times faster than GPUSort, and this speedup is increasing with the sequence length n , as expected.

The timings of the GPU approaches assume that the input data is already stored in GPU memory. When embedding the GPU-based sorting into an otherwise purely CPU-based application, the input data has to be transferred from CPU to GPU memory, and afterwards the output data has to be transferred back to CPU memory. However, the overhead of this transfer is usually negligible compared to the achieved sorting speedup:

according to measurements by [11], the transfer of one million key/pointer pairs from CPU to GPU and back takes in total roughly 20 ms on a PCI Express bus PC.

Conclusion

Adaptive bitonic sorting is not only appealing from a theoretical point of view, but also from a practical one. Unlike other parallel sorting algorithms that exhibit optimal asymptotic complexity too, adaptive bitonic sorting offers low hidden constants in its asymptotic complexity and can be implemented on parallel architectures by a reasonably experienced programmer. The practical implementation of it on a GPU outperforms the implementation of simple bitonic sorting on the same GPU by a factor 1.3, and it is a factor 3 faster than a standard CPU sorting implementation (STL).

Bibliographic Notes and Further Reading

As mentioned in the introduction, this line of research began with the seminal work of Batcher [4] in the late 1960s, who described parallel sorting as a network.

Research of parallel sorting algorithms was reinvigorated in the 1980s, where a number of theoretical questions have been settled [1, 3, 5, 6, 14, 18].

Another wave of research on parallel sorting ensued from the advent of affordable, massively parallel architectures, namely, GPUs, which are, more precisely, streaming architectures. This spurred the development of a number of practical implementations [9, 11–13, 16, 17, 19].

BLAS (Basic Linear Algebra Subprograms)

ROBERT VAN DE GEIJN, KAZUSHIGE GOTO
The University of Texas at Austin, Austin, TX, USA

Definition

The Basic Linear Algebra Subprograms (BLAS) are an interface to commonly used fundamental linear algebra operations.

Discussion

Introduction

The BLAS interface supports portable high-performance implementation of applications that are matrix and vector computation intensive. The library or application developer focuses on casting computation in terms of the operations supported by the BLAS, leaving the architecture-specific optimization of that software layer to an expert.

A Motivating Example

The use of the BLAS interface will be illustrated by considering the Cholesky factorization of an $n \times n$ matrix A . When A is Symmetric Positive Definite (a property that guarantees that the algorithm completes), its Cholesky factorization is given by the lower triangular matrix L such that $A = LL^T$.

An algorithm for this operation can be derived as follows: Partition

$$A \rightarrow \left(\begin{array}{c|c} \alpha_{11} & * \\ \hline a_{21} & A_{22} \end{array} \right) \quad \text{and} \quad L \rightarrow \left(\begin{array}{c|c} \lambda_{11} & 0 \\ \hline l_{21} & L_{22} \end{array} \right),$$

where α_{11} and λ_{11} are scalars, a_{21} and l_{21} are vectors, A_{22} is symmetric, L_{22} is lower triangular, and the $*$ indicates the symmetric part of A that is not used. Then

$$\begin{aligned} \left(\begin{array}{c|c} \alpha_{11} & * \\ \hline a_{21} & A_{22} \end{array} \right) &= \left(\begin{array}{c|c} \lambda_{11} & 0 \\ \hline l_{21} & L_{22} \end{array} \right) \left(\begin{array}{c|c} \lambda_{11} & 0 \\ \hline l_{21} & L_{22} \end{array} \right)^T \\ &= \left(\begin{array}{c|c} \lambda_{11}^2 & * \\ \hline \lambda_{11}l_{21} & l_{21}l_{21}^T + L_{22}L_{22}^T \end{array} \right) \end{aligned}$$

This yields the following algorithm for overwriting A with L :

- $\alpha_{11} \leftarrow \sqrt{\alpha_{11}}$.
- $a_{21} \leftarrow a_{21}/\alpha_{11}$.
- $A_{22} \leftarrow -a_{21}a_{21}^T + A_{22}$, updating only the lower triangular part of A_{22} . (This is called a symmetric rank-1 update.)
- Continue by overwriting A_{22} with L_{22} where $A_{22} = L_{22}L_{22}^T$.

A simple code in Fortran is given by

```
do j=1, n
  A( j,j ) = sqrt( A( j,j ) )
  do i=j+1,n
    A( i,j ) = A( i,j ) / A( j,j )
  enddo
  do k=j+1,n
    do i=k,n
      A( i,k ) = A( i,k )
      - A( i,j ) * A( k,j )
    enddo
  enddo
enddo
```

Vector–Vector Operations (Level-1 BLAS)

The first BLAS interface was proposed in the 1970s when vector supercomputers were widely used for computational science. Such computers could achieve near-peak performance as long as the bulk of computation was cast in terms of vector operations and memory was accessed mostly contiguously. This interface is now referred to as the Level-1 BLAS.

Let x and y be vectors of appropriate length and α be scalar. Commonly encountered vector operations are multiplication of a vector by a scalar ($x \leftarrow \alpha x$), inner (dot) product ($\alpha \leftarrow x^T y$), and scaled vector addition ($y \leftarrow \alpha x + y$). This last operation is known as an `axpy`: alpha times x plus y .

The Cholesky factorization, coded in terms of such operations, is given by

```
do j=1, n
  A( j,j ) = sqrt( A( j,j ) )
  call dscal( n-j, 1.0d00/A( j,j ), 
  A( j+1, j ), 1 )
  do k=j+1,n
    call daxpy( n-k+1, -A( k,j ), 
    A(k,j), 1, A( k, k ), 1 );
  enddo
enddo
```

Here

- The first letter in `dscal` and `daxpy` indicates that the computation is with `double` precision numbers.
- The call to `dscal` performs the computation $a_{21} \leftarrow a_{21}/\alpha_{11}$.
- The loop

```
do i=k,n
  A( i,k ) = A( i,k ) - A( i,j )
  * A( k,j )
enddo
```

is replaced by the call

```
call daxpy( n-k+1, -A( k,j ), 
A(k,j), 1, A( k, k ), 1 )
```

If the operations supported by `dscal` and `daxpy` achieve high performance on a target architecture *then* so will the implementation of the Cholesky factorization, since it casts most computation in terms of those operations.

A representative calling sequence for a Level-1 BLAS routine is given by

```
_axpy( n, alpha, x, incx, y, incy )
```

which implements the operation $y = \alpha x + y$. Here

- The “_” indicates the data type. The choices for this first letter are

s	<u>s</u> ingle precision
d	<u>d</u> ouble precision
c	<u>s</u> ingle precision <u>c</u> omplex
z	<u>d</u> ouble precision <u>c</u> omplex

- The operation is identified as axpy: alpha times x plus y.
- n indicates the number of elements in the vectors x and y.
- alpha is the scalar α .
- x and y indicate the memory locations where the first elements of x and y are stored, respectively.
- incx and incy equal the increment by which one has to stride through memory to locate the elements of vectors x and y, respectively.

The following are the most frequently used Level-1 BLAS:

Routine/ Function	Operation
<u>_swap</u>	$x \leftrightarrow y$
<u>_scal</u>	$x \leftarrow \alpha x$
<u>_copy</u>	$y \leftarrow x$
<u>_axpy</u>	$y \leftarrow \alpha x + y$
<u>_dot</u>	$x^T y$
<u>_nrm2</u>	$\ x\ _2$
<u>_asum</u>	$\ \text{re}(x)\ _1 + \ \text{im}(x)\ _1$
<u>i_max</u>	$\min(k) : \text{re}(x_k) + \text{im}(x_k) = \max(\text{re}(x_i) + \text{im}(x_i))$

Matrix–Vector Operations (Level-2 BLAS)

The next level of BLAS supports operations with matrices and vectors. The simplest example of such an operation is the matrix–vector product: $y \leftarrow Ax$ where x and y are vectors and A is a matrix. Another example is the computation $A_{22} = -a_{21}a_{21}^T + A_{22}$ (symmetric rank-1 update) in the Cholesky factorization. This operation can be recoded as

```
do j=1, n
```

```

A( j,j ) = sqrt( A( j,j ) )
call dscal( n-j, 1.0d00 /
A( j,j ), A( j+1, j ), 1 )
call dsyr( 'Lower triangular',
n-j, -1.0d00,
A( j+1,j ), 1, A( j+1,j+1 ), lda )
enddo
```

Here, dsyr is the routine that implements a double precision symmetric rank-1 update. Readability of the code is improved by casting computation in terms of routines that implement the operations that appear in the algorithm: dscal for $a_{21} = a_{21}/\alpha_{11}$ and dsyr for $A_{22} = -a_{21}a_{21}^T + A_{22}$.

The naming convention for Level-2 BLAS routines is given by

```
_XXYY,
```

where

- “_” can take on the values s, d, c, z.
- XX indicates the shape of the matrix:

XX	matrix shape
ge	<u>g</u> eneral (<u>r</u> ectangular)
sy	<u>s</u> ymmetric
he	<u>H</u> ermitian
tr	<u>t</u> riangular

In addition, operations with banded matrices are supported, which we do not discuss here.

- YY indicates the operation to be performed:

YY	matrix shape
mv	<u>m</u> atrix <u>v</u> ector multiplication
sv	<u>s</u> olve <u>v</u> ector
r	<u>r</u> ank-1 update
r2	<u>r</u> ank-2 update

A representative call to a Level-2 BLAS operation is given by

```
dsyr( uplo, n, alpha, x, incx, A,
      lda )
```

which implements the operation $A = \alpha xx^T + A$, updating the lower or upper triangular part of A by choosing uplo as ‘Lower triangular’ or ‘Upper triangular’, respectively. The parameter lda (the

leading dimension of matrix A) indicates the increment by which memory has to be traversed in order to address successive elements in a row of matrix A .

The following table gives the most commonly used Level-2 BLAS operations:

Routine/ Function	Operation
<code>_gemv</code>	general <u>matrix-vector</u> multiplication
<code>_symv</code>	symmetric <u>matrix-vector</u> multiplication
<code>_trmv</code>	triangular <u>matrix-vector</u> multiplication
<code>_trsv</code>	triangular <u>solve vector</u>
<code>_ger</code>	general <u>rank-1 update</u>
<code>_syr</code>	symmetric <u>rank-1 update</u>
<code>_syr2</code>	symmetric <u>rank-2 update</u>

There are also interfaces for operation with banded matrices stored in packed format as well as for operations with Hermitian matrices.

Matrix-Matrix Operations (Level-3 BLAS)

The problem with vector operations and matrix–vector operations is that they perform $O(n)$ computations with $O(n)$ data and $O(n^2)$ computations with $O(n^2)$ data, respectively. This makes it hard, if not impossible, to leverage cache memory now that processing speeds greatly outperform memory speeds, unless the problem size is relatively small (fits in cache memory).

The solution is to cast computation in terms of matrix-matrix operations like matrix–matrix multiplication. Consider again Cholesky factorization. Partition

$$A \rightarrow \left(\begin{array}{c|c} A_{11} & * \\ \hline A_{21} & A_{22} \end{array} \right) \quad \text{and} \quad L \rightarrow \left(\begin{array}{c|c} L_{11} & 0 \\ \hline L_{21} & L_{22} \end{array} \right),$$

where A_{11} and L_{11} are $n_b \times n_b$ submatrices. Then

$$\begin{aligned} \left(\begin{array}{c|c} A_{11} & * \\ \hline A_{21} & A_{22} \end{array} \right) &= \\ \left(\begin{array}{c|c} L_{11} & 0 \\ \hline L_{21} & L_{22} \end{array} \right) \left(\begin{array}{c|c} L_{11} & 0 \\ \hline L_{21} & L_{22} \end{array} \right)^T &= \\ \left(\begin{array}{c|c} L_{11}L_{11}^T & * \\ \hline L_{21}L_{11}^T & L_{21}L_{21}^T + L_{22}L_{22}^T \end{array} \right) & \end{aligned}$$

This yields the algorithm

- $A_{11} = L_{11}$ where $A_{11} = L_{11}L_{11}^T$ (Cholesky factorization of a smaller matrix).
- $A_{21} = L_{21}$ where $L_{21}L_{11}^T = A_{21}$ (triangular solve with multiple right-hand sides).
- $A_{22} = -L_{21}L_{21}^T + A_{22}$, updating only the lower triangular part of A_{22} (symmetric rank-k update).
- Continue by overwriting A_{22} with L_{22} where $A_{22} = L_{22}L_{22}^T$.

A representative code in Fortran is given by

```
do j=1, n, nb
    jb = min( nb, n-j+1 )
    call chol( jb, A( j, j ), lda )

    call dtrsm( 'Right', 'Lower
                triangular',
                'Transpose',
                'Nonunit diag',
                J-JB+1, JB,
                1.0d00, A( j, j ),
                lda, A( j+jb, j ),
                lda )

    call dsyrk( 'Lower triangular',
                'No transpose',
                J-JB+1, JB,
                -1.0d00,
                A( j+jb, j ), lda,
                1.0d00,
                A( j+jb, j+jb ),
                lda )
enddo
```

Here subroutine `chol` performs a Cholesky factorization; `dtrsm` and `dsyrk` are level-3 BLAS routines:

- The call to `dtrsm` implements $A_{21} \leftarrow L_{21}$ where $L_{21}L_{11}^T = A_{21}$.
- The call to `dsyrk` implements $A_{22} \leftarrow -L_{21}L_{21}^T + A_{22}$.

The bulk of the computation is now cast in terms of matrix–matrix operations which can achieve high performance.

The naming convention for Level-3 BLAS routines are similar to those for the Level-2 BLAS. A representative call to a Level-3 BLAS operation is given by

```
dsyrk( uplo, trans, n, k, alpha, A,
       lda, beta, C, ldc )
```

which implements the operation $C \leftarrow \alpha AA^T + \beta C$ or $C \leftarrow \alpha A^T A + \beta C$ depending on whether `trans` is chosen as ‘No transpose’ or ‘Transpose,’ respectively. It updates the lower or upper triangular part of C depending on whether `uplo` equal ‘Lower triangular’ or ‘Upper triangular,’ respectively. The parameters `lda` and `ldc` are the leading dimensions of arrays A and C , respectively.

The following table gives the most commonly used Level-3 BLAS operations:

Routine/ Function	Operation
<code>_gemm</code>	<u>general matrix-matrix multiplication</u>
<code>_symm</code>	<u>symmetric matrix-matrix multiplication</u>
<code>_trmm</code>	<u>triangular matrix-matrix multiplication</u>
<code>_trsm</code>	<u>triangular solve with multiple right-hand sides</u>
<code>_syrk</code>	<u>symmetric rank-k update</u>
<code>_syr2k</code>	<u>symmetric rank-2k update</u>

Impact on Performance

Figure 1 illustrates the performance benefits that come from using the different levels of BLAS on a typical architecture.

BLAS-Like Interfaces

CBLAS

A C interface for the BLAS, CBLAS, has also been defined to simplify the use of the BLAS from C and C++. The CBLAS support matrices stored in row and column major format.

Libflame

The libflame library that has resulted from the FLAME project encompasses the functionality of the BLAS as well as higher level linear algebra operations. It uses an object-based interface so that a call to a BLAS routine like `_syrk` becomes

```
FLA_Syrk( uplo, trans, alpha, A,
           beta, C )
```

thus hiding many of the dimension and indexing details.

Sparse BLAS

Several efforts were made to define interfaces for BLAS-like operations with sparse matrices. These do not seem to have caught on, possibly because the storage of sparse matrices is much more complex.

Parallel BLAS

Parallelism with BLAS operations can be achieved in a number of ways.

Multithreaded BLAS

On shared-memory architectures multithreaded BLAS are often available. Such implementations achieve parallelism within each BLAS call without need for changing code that is written in terms of the interface. Figure 2 shows the performance of the Cholesky factorization codes when multithreaded BLAS are used on a multi-core architecture.

PBLAS

As part of the ScaLAPACK project, an interface for distributed memory parallel BLAS was proposed, the PBLAS. The goal was to make this interface closely resemble the traditional BLAS. A call to `dsyrk` becomes

```
pdsyrk(uplo, trans, n, k, alpha, A,
        iA, jA, descA, beta, C, iC, jC,
        descC)
```

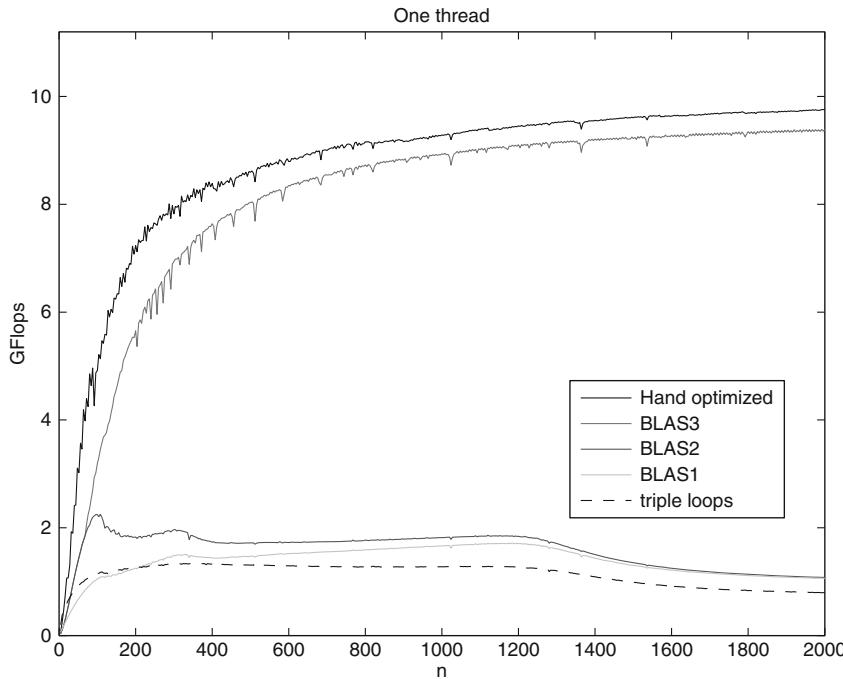

where the new parameters `iA`, `jA`, `descA`, etc., encapsulate information about the submatrix with which to multiply and the distribution to a logical two-dimensional mesh of processing nodes.

PLAPACK

The PLAPACK project provides an alternative to ScaLAPACK. It also provides BLAS for distributed memory architectures, but (like libflame) goes one step further toward encapsulation. The call for parallel symmetric rank-k update becomes

```
PLA_Syrk( uplo, trans, alpha, A,
           beta, C )
```

where all information about the matrices, their distribution, and the storage of local submatrices are encapsulated in the parameters A and C .

BLAS (Basic Linear Algebra Subprograms). Fig. 1 Performance of the different implementations of Cholesky factorization that use different levels of BLAS. The target processor has a peak of 11.2 Gflops (billions of floating point operations per second). BLAS1, BLAS2, and BLAS3 indicate that the bulk of computation was cast in terms of Level-1, -2, or -3 BLAS, respectively

Available Implementations

Many of the software and hardware vendors market high-performance implementations of the BLAS. Examples include IBM's ESSL, Intel's MKL, AMD's ACML, NEC's MathKeisan, and HP's MLIB libraries. Widely used open source implementations include ATLAS and the GotoBLAS. Comparisons of performance of some of these implementations are given in Figs. 3 and 4.

The details about the platform on which the performance data was gathered nor the versions of the libraries that were used are given because architectures and libraries continuously change and therefore which is faster or slower can easily change with the next release of a processor or library.

Bibliographic Notes and Further Reading

What came to be called the Level-1 BLAS were first published in 1979, followed by the Level-2 BLAS in 1988 and Level-3 BLAS in 1990 [4, 5, 10].

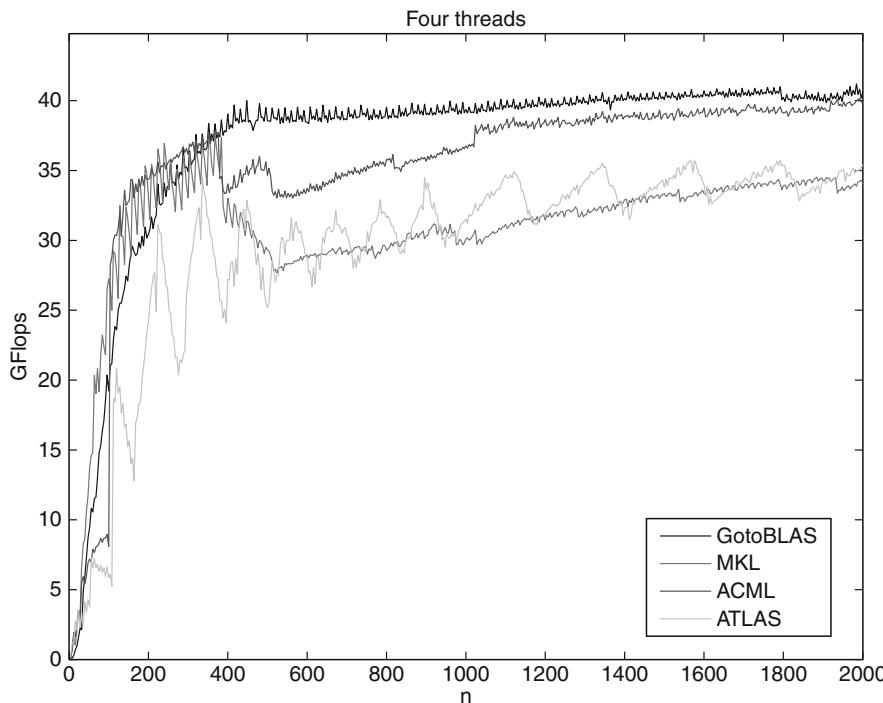

Matrix-matrix multiplication (`_gemm`) is considered the most important operation, since high-performance implementations of the other Level-3 BLAS can be coded in terms of it [9]. Many implementations of `_gemm` are now based on the techniques developed by Kazushige Goto [8]. These techniques extend to the high-performance implementation of other Level-3 BLAS [7] and multithreaded architectures [11]. Practical algorithms for the distributed memory parallel implementation of matrix-matrix multiplication, used by ScaLAPACK and PLAPACK, were first discussed in [1, 12] and for other Level-3 BLAS in [3].

BLAS (Basic Linear Algebra Subprograms). Fig. 3 Performance of different BLAS libraries for matrix–matrix multiplication (dgemm)

BLAS (Basic Linear Algebra Subprograms). Fig. 4 Parallel performance of different BLAS libraries for matrix–matrix multiplication (d_{gemm})

As part of the BLAS Technical Forum, an effort was made in the late 1990s to extend the BLAS interfaces to include additional functionality [2]. Outcomes included the CBLAS interface, which is now widely supported, and an interface for Sparse BLAS [6].

Blue CHiP project; CHiP architecture; CHiP computer; Configurable, Highly parallel computer; Programmable interconnect computer; Reconfigurable computer

Definition

The CHiP Computer is the Configurable, Highly Parallel architecture, a multiprocessor composed of processor-memory elements in a lattice of programmable switches [1]. Designed in 1980 to exploit Very Large Scale Integration (VLSI), the switches are set under program control to connect and reconnect processors. Though the CHiP architecture was the first use of programmable interconnect, it has since been applied most widely in Field Programmable Gate Arrays (FPGAs). The Blue CHiP Project, the effort to investigate and develop the CHiP architecture, took Carver Mead's "tall, thin man" vision as its methodology. Accordingly, it studied "How best to apply VLSI technology" from five research perspectives: VLSI, architecture, software, algorithms, and theory.

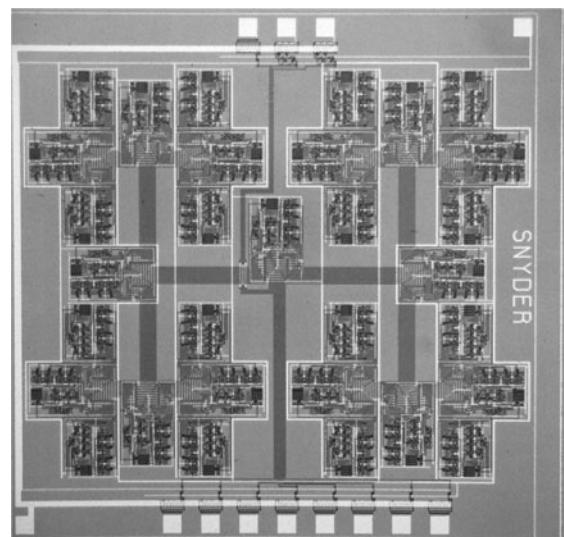

Discussion

Background and Motivation

In the late 1970s as VLSI densities were improving to allow significant functionality on a chip, Caltech's Carver Mead offered a series of short courses at several research universities [2]. He taught the basics of chip design to computer science grad students and faculty. In his course, which required students to do a project fabricated using ARPA's multi-project chip facility, Mead argued that the best way to leverage VLSI technology was for a designer to be a "tall, thin man," a person knowledgeable in the entire chip development stack: electronics, circuits, layout, architecture, algorithms, software, and applications. "Thin" implied that the person had a working knowledge of each level, but might not be an expert. The Blue CHiP project adopted Mead's idea: Use the "tall, thin man" approach to create new ways to apply VLSI technology.

The Blue CHiP Project and the CHiP architecture were strongly influenced by ideas tested in a design included in the MPC-79 multi-project chip, a batch of chip designs created by Mead's students [3]. That design, called the Tree Organized Processor Structure (referenced as AG-4 in the archive [3]), was a height 5 binary tree with field-programmable processors for evaluating Boolean expressions [4]. Though the design used field-effect programmability, the binary tree was embedded directly into the layout; see Fig. 1. Direct embedding seemed unnecessarily restrictive. The lattice structure of the CHiP architecture, developed in Spring, 1980, was to provide a more flexible communication capability.

Because parallel computation was not well understood, because the CHiP computer was an entirely new architecture, because nothing was known about programmable interconnect, and because none of the "soft" parts of the project (algorithms, OS, languages, applications) had ever been considered in the context of configurability, there was plenty of research to do. And it involved so many levels that Mead's "tall, thin man" approach was effectively a requirement. Having secured Office of Naval Research funding for the Blue CHiP Project in Fall, 1980, work began at the start of 1981.

Blue CHiP. Fig. 1 The tree organized processor structure, an antecedent to the CHiP architecture [1]; the root is in the center and its children are to its left and right

The CHiP Architecture Overview and Operation

The focal point of the Blue CHiP project was the Configurable, Highly Parallel (CHiP) computer [5]. The CHiP architecture used a set of processor elements (PEs) – 32-bit processors with random access memory for program and data – embedded in a regular grid, or *lattice*, of wires and programmable switches. Interprocessor communication was implemented by setting the switches under program control to connect PEs with direct, circuit-switched channels. The rationale was simple: Processor design was well understood, so a specific hardware implementation made sense, but the optimal way to connect together parallel processors was not known. Building a dynamically configurable switching fabric that could reconnect processes as the computation progressed permitted optimal communication.

Phases

The CHiP architecture exploited the observation that large computations (worthy of parallel processing) are typically expressed as a sequence of algorithms, or *phases*, that perform the major steps of the computation. Each phase – matrix multiplication, FFT, pivot selection, etc. – is a building block for the overall computation. The phases execute one after another, often being repeated for iterative methods, simulations, approximations, etc. Phases tend to have a specific characteristic communication structure. For example, FFT uses the butterfly graph to connect processors; the Kung-Leiserson systolic array matrix multiplication uses a “hex array” interconnect [MC80]; parallel prefix computations use a complete binary tree, etc. Rather than trying to design a one-size-fits-all interconnect, the CHiP architecture provides the mechanism to program it.

From an OS perspective a parallel computation on the CHiP machine proceeds as follows:

```

Load switch memories in the lattice
with configuration settings for all
phases
Load PE memories with binary object
code for all phases
i = 0
while phases not complete {
    Select the lattice configuration

```

```

        connecting processors as
        required for Phase[i]
        Run Phase[i] to completion
        i=i+1
    }
}
```

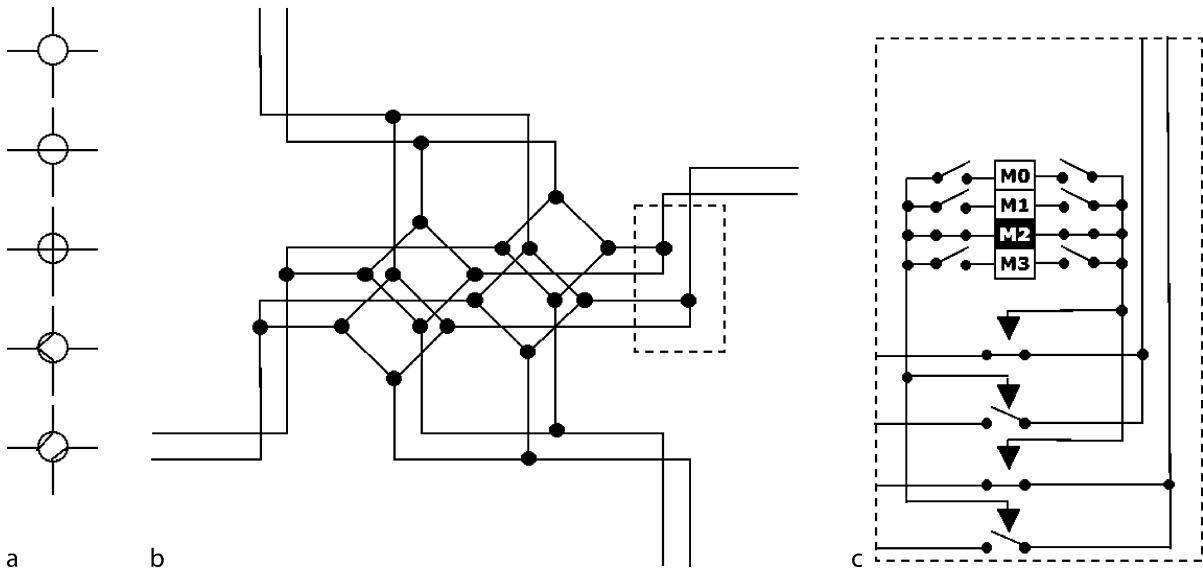

Notice that lattice configurations are typically reused during a program execution.

Configuration

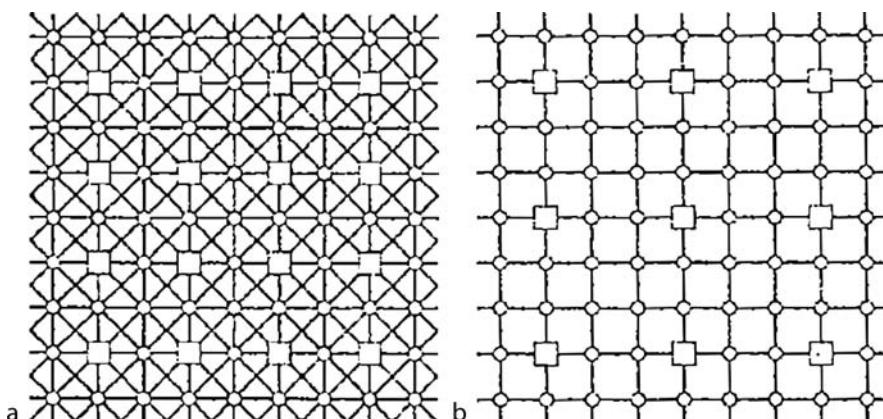

Configuring a communication structure works as follows: The interconnection graph structure, or configuration, is stored in the lattice, and when selected, it remains in effect for the period of that phase of execution, allowing the PEs to communicate and implement the algorithm. PE-to-PE communication is realized by a direct circuit-switched connection [1]. The overall graph structure is realized by setting each switch appropriately.

A switch has circuitry to connect its $2d$ incident edges (bit-parallel data wires), allowing up to d communication paths to cross the switch independently. See [Figure 2](#). A switch has memory to store the settings needed for a set of configurations. Each switch stores its setting for configuration i in its memory location i . The lattice implements configuration i by selecting the i th memory location for all switches.

[Figure 2](#) shows schematic diagrams of a degree 4 switch capable of 2 independent connections, that is, paths that can crossover. Interconnections are programmed graphically, using an iconography shown in [Fig. 2a](#) (and [Fig. 3](#)). [Figure 2b](#) shows the connectivity allowing the wires to connect arbitrarily. Notice that fan-out is possible. The independent connections require separate buses, shown as paired, overlapping diamonds. Higher degree switches (more incident edges) require more buses; wider datapaths (2-wide is shown) require more diamonds. [Figure 2c](#) shows the configuration setting in memory location M2 asserting the connection of the east edge to the right bus. Notice that memory is provided to store the connections for each bus, and that there are three states: disconnected, connect to left, and connect to right. Not shown in the figure is the logic to select a common memory location on all switches, that is, the logic selecting M2, as well as circuitry to insure the quality of the signals.

Blue CHiP. Fig. 2 A schematic diagram for a degree four switch: (a) iconography used in programming interconnection graphs; from top, unconnected, east-west connection, east-west and north-south connections, fan-out connection, two corner-turning connections; (b) wire arrangement for four incident edges (2-bit-parallel wires); the buses implementing the connection are shown as overlapping diamonds; (c) detail for making a connection of the east edge to the right bus per configuration stored in memory location M2

Blue CHiP. Fig. 3 Sample switch lattices in which processors are represented by squares and switches by circles; (a) an 8-degree, single wide lattice; (b) a 4-degree, double wide lattice [6]

As a final detail, notice that connections can cause the order of the wires of a datapath to be flipped. Processor ports contain logic to flip the order of the bits to the opposite of the order it received. When a new configuration comes into effect, each connection sends/receives an lsb 1, revealing whether the bits are true or reversed, allowing the ports to select/deselect the flipping hardware.

Processor Elements

Each PE is a computer, a processor with memory, in which all input and output is accessible via ports. (Certain “edge PEs” also connect to external I/O devices.) A lattice with switches having $2d$ incident edges hosts PEs with $2d$ incident edges, and therefore $2d$ ports. Programs communicate simply by sending and receiving through the ports; since the lattice implements

circuit-switched communication, the values can be sent directly with little “packetizing” beyond a task designation in the receiving processor.

Each PE has its own memory, so in principle each PE can execute its own computation in each phase; that is, the CHiP computer is a MIMD, or multiple-instruction, multiple-data, computer. As phase-based parallel algorithms became better understood, it became clear that PEs typically execute only a few different computations to implement a phase. For example, in parallel-prefix algorithms, which have tree-connected processors, the root, the interior nodes, and the leaves execute slightly different computations. Because these are almost always variations of each other, a single program, multiple data (SPMD) model was adopted.

The Controller

The orchestration of phase execution is performed by an additional processor, a “front end” machine, called the *controller*. The controller loads the configuration settings into the switches, and loads the PEs with their code for each phase. It then steps through the phase execution logic (see “Phases”), configuring the lattice for a phase and executing it to completion; processors use the controller’s network to report completion.

The controller code embodies the highest-level logic of a computation, which tends to be very straightforward. The controller code for the Simple Benchmark [7]

for $m := o$ **to** m_{max} **do**

begin

```
    phase(hydro);
    phase(viscos);
    phase(new_Δt);
    phase(thermo);
    phase(row_solve);
    phase(column_solve);
    phase(energy_bal);
```

end.

illustrates this point and is typical.

Blue CHiP Project Research

The Blue CHiP Project research, following Mead, conducted research in five different topic areas: VLSI, architecture, software, algorithms, and theory. These five topics provide an appropriate structure for the remainder of this entry, when extended with an additional section to summarize the ideas. Though much of

the work was targeted at developing a CHiP computer, related topics were also studied.

VLSI: Programmable Interconnect

Because the CHiP concept was such a substantial departure from conventional computers and the parallel computers that preceded it, initial research focused less on building chips, that is, the VLSI, and more on the overall properties of the lattice that were the key to exploiting VLSI. A simple field-effect programmable switch had been worked out in the summer of 1980, giving the team confidence that fabricating a production switch would be doable when the overall lattice design was complete.

The CHiP computer’s lattice is a regular grid of (data) wires with switches at the cross points and processors inset at regular intervals. The lattice abstraction uses circles for switches and squares for processors. An important study was to understand how a given size lattice hosted various graphs; see Fig. 3 for typical abstractions. The one layer metal processes of the early 1980s caused the issue of lattice bandwidth to be a significant concern.

Lattice Properties Among the key parameters [6] that describe a lattice are the *degree* of the nodes, that is, the number of incident edges and *corridor width*, the number of switches separating two PEs. The architectural question is: What is a sufficiently rich lattice to handle most interconnection graphs? This is a graph embedding question, and though graph embedding was an active research area at the time, asymptotic results were not helpful. Rather, it was important for us to understand graph embeddings for a limited number of nodes, say 256 or fewer, of the sort of graphs arising in phase-based parallel computation.

What sort of communication graphs do parallel algorithms use? Table 1 lists some typical graphs and algorithms that use them; there are other, less familiar graphs. Since lattices permit nonplanar embeddings, that is, wires can cross over, a sufficiently wide corridor lattice of sufficiently high degree switches can embed any graph in our domain. But economy is crucial, especially with VLSI technologies with few layers.

Embeddings It was found that graphs could be embedded in very economical lattices. Examples of two of the less obvious embeddings are shown in Fig. 4. The embedding of the binary tree is an adaptation of the “H-embedding” of a binary tree into the plane. The

shuffle exchange graph for 64 nodes of a single wide lattice is quite involved – shuffle edges are solid, exchange edges are dashed. Shuffle exchange on 256 nodes is not known to be embeddable in a *single* wide lattice, and was assumed to require corridor width of 2. Notice that once a graph has been embedded in a lattice, it can be placed in a library for use by those who prefer to program using the logical communication structure rather than the implementing physical graph.

Techniques Most graphs are easy to layout because most parallel computations use sparse graphs with little complexity. In programming layouts, however, one is often presented with the same problem repeatedly. For example, laying out a torus is easy, but minimizing the

wire length – communication time is proportional to length – takes some technique. See Fig. 5. An interleaving of the row and column PEs of a torus by “folding” at the middle vertically, and then “folding” at the middle horizontally, produces a torus with interleaved processors. Each of a PE’s four neighbors is at most three switches away. Opportunities to use this “trick” of interleaving PEs to shorten long wires arise in other cases. A related idea (Fig. 5b) is to “lace” the communication channels in a corridor to maximize the number of datapaths used.

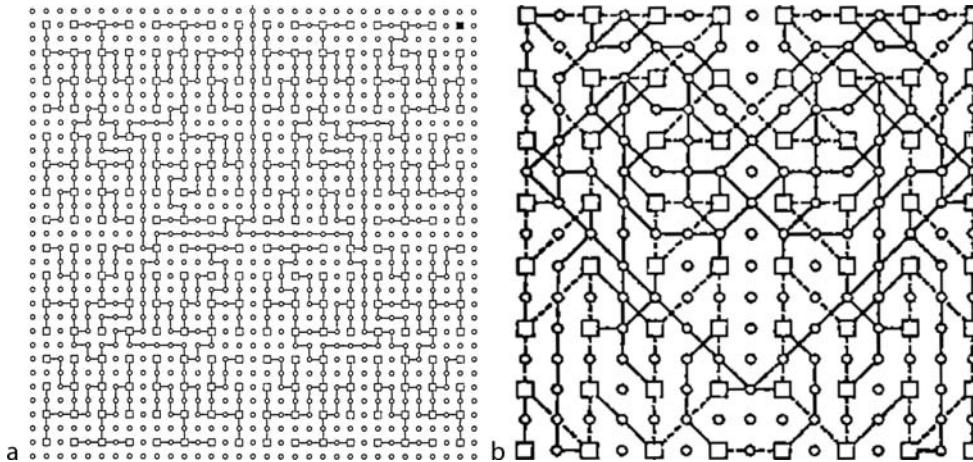

The conclusion from the study of lattice embeddings indicated, generally, that the degree should be 8, and that corridor width is sufficiently valuable that it should be “as wide as possible.” Given the limitations of VLSI technology at the time, only 2 was realistic.

Blue CHiP. Table 1 Communication graph families and parallel algorithms that communicate using those graphs

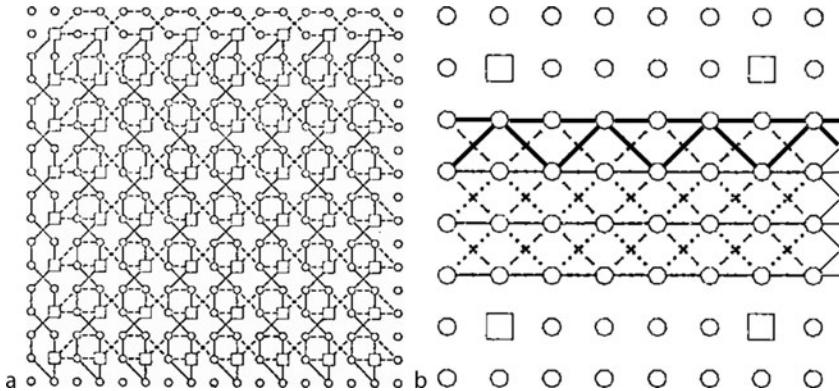

Communication Graph	Parallel Applications
4-degree, 8-degree mesh	Jacobi relaxation for Laplace equations
4-degree, 6-degree mesh	Matrix multiplication, dynamic programming
Binary tree	Aggregation (sum, max), parallel prefix
Toroidal 4-degree, 8-degree mesh	Simulations with periodic boundaries
Butterfly graph	Fast Fourier transform
Shuffle-exchange graph	Sorting

Architecture: The Pringle

When the project began VLSI technology did not yet have the densities necessary to build a prototype CHiP computer beyond single-bit processors; fitting one serious processor on a die was difficult enough, much less a lattice and multiple processors. Nevertheless, the Roadmap of future technology milestones was promising, so the project opted to make a CHiP simulator to use while waiting for technology to improve. The simulated CHiP was called the Pringle [8] in reference to the snack food by that name that also approximates a chip.

Blue CHiP. Fig. 4 Example embeddings; (a) a 255-node binary tree embedded in a 256 node, 4-degree, single wide lattice; (b) a 64-node shuffle exchange graph embedded in a 64 node, 8-degree, single wide lattice

Blue CHiP. Fig. 5 Embedding techniques; (a) a 4-degree torus embedded using “alternating PE positions” to reduce the length of communication paths to 3 switches; solid lines are vertical connections, dashed lines are horizontal connections; (b) “lacing” a width 4 corridor to implement 10 independent datapaths, two of which have been highlighted in bold

Blue CHiP. Table 2 The Pringle datasheet; Pringle was an emulator for the CHiP architecture with an 8-bit datapath

Processor Elements		Switch	
Number of PEs	64	Switch structure	Polled Bus
PE microprocessor	Intel 8031	Switch clock rate	8 MHz
PE datapath width	8-bits	Bus Bandwidth	64 Mb/s
PE floating point chip	Intel 8231	Switch Datapath	8 bits
PE RAM size	2 Kb		
PE EPROM size	4 Kb	Controller	
PE clock rate	12 MHz	Controller microprocessor	Intel 8086

The Pringle was designed to behave like a CHiP computer except that instead of using a lattice for inter-processor communication, it simulated the lattice with a polled bus structure. Of course, this design serializes the CHiP’s parallel communication, but the Pringle could potentially advance 64 separate communications in one polling sweep. The switch controller stored multiple configurations in its memory (up to 11), implementing one per phase. See the datasheet in [Table 2](#).

Two copies of Pringle were eventually built, one for Purdue University and one for the University of Washington. Further data on the Pringle is available in the reports [8].

Software: Poker

The primary software effort was building the Poker Parallel Programming Environment [9]. Poker was targeted at programming the CHiP Computer, which informed

the structure of the programming system substantially. But there were other influences as well.

For historical context the brainstorming and design of Poker began at Purdue in January 1982 in a seminar dedicated to that purpose. At that point, Xerox PARC’s Alto was well established as the model for building a modern workstation computer. It had introduced bit-mapped graphic displays, and though they were still extremely rare, the Blue CHiP Project was committed to using them. The Alto project also supported interactive programming environments such as SmallTalk80 and Interlisp. It was agreed that Poker needed to support interactive programming, too, but the principles and techniques for building windows, menus, etc., were not yet widely understood. Perhaps the most radical aspect of the Alto, which also influenced the project, was dedicating an entire computer to support the work of one user. It was decided to use a VAX 11/780 for that purpose. This decision was greeted with widespread

astonishment among the Purdue CS faculty, because all of the rest of the departmental computing was performed by another time-shared VAX 11/780.

The Poker Parallel Programming Environment opened with a “configuration” screen, called CHiP Params, that asked programmers for the parameters of the CHiP computer they would be programming. Items such as the number of processors, the degree of the switches, etc. were requested. Most of this information would not change in a production setting using a physical computer, but for a research project, it was important.

Programming the CHiP machine involved developing phase programs for specific algorithms such as matrix multiplication, and then assembling these phase pieces into the overall computation [10]. Each phase program requires these components:

- Switch Settings (SS) specification – defines the interconnection graph
- Code Names (CN) specification – assigns a process to each PE, together with parameters
- Port Names (PN) specification – defines the names used by each PE to refer to its neighbors
- I/O Names (IO) specification – defines the external data files used and created by the phase
- Text files – process code written in an imperative language (XX or C)

Not all phases read or write external files, so IO is not always needed; all of the other specifications are required.

Poker emphasized graphic programming and minimized symbolic programming. Programmers used one of several displays – full-screen windows – to program the different types of information describing a computation. Referring to Fig. 6, the windows were: Switch Settings for defining the interconnection graph (Fig. 6a), Code Names for assigning a process (and parametric data) to each processing element (Fig. 6b), Port Names for naming a PE’s neighbors (Fig. 6c), I/O Names for reading and writing to standard in and out, and Trace View (Fig. 6d) for seeing the execution in the same form as used in the “source” code.

In addition to the graphic display windows, a text editor was used to write the process code, whose names are assigned in the Code Names window. Process code was written in a very simple language called XX. (The

letters XX were used until someone could think of an appropriate name for the language, but soon it was simply called Dos Equis.) Later, a C-preprocessor called Poker C was also implemented. One additional facility was a Command Request window for assembling phases.

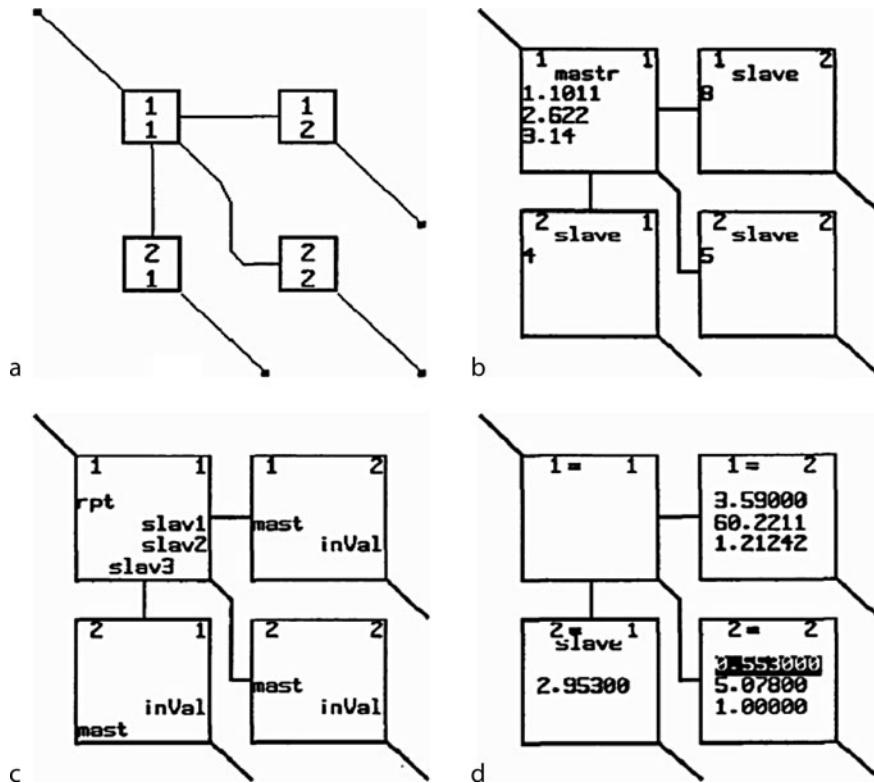

After building a set of phases, programmers needed to assemble them, using the Command Request (CR) interface, into a sequence of phase invocations to solve the problem. This top-level logic is critical because when a phase change occurs – for example, moving from a pivot selection step to an elimination step – the switches in the lattice typically change.

The overall structure of the Poker Environment is shown in Fig. 7 [11]. The main target of CHiP programs was a generic simulator, since production level computations were initially not needed. The Cosmic Cube from Caltech and the Sequent were contemporary parallel machines that were also targeted [12].

Algorithms: Simple

In terms of developing CHiP-appropriate algorithms, the Blue CHiP Project benefited from the wide interest at the time in systolic array computation. Systolic arrays are data parallel algorithms that map easily to a CHiP computer phase [13]. Other parallel algorithms of the time – parallel prefix, nearest neighbor iterative relaxation algorithms, etc., – were also easy to program. So, with basic building blocks available, project personnel split their time between composing these known algorithms (phases) into complete computations, and developing new parallel algorithms. The SIMPLE computation illustrates the former activity.

SIMPLE The SIMPLE computation is, as its name implies, a simple example of a Lagrangian hydrodynamics computation developed by researchers at Livermore National Labs to illustrate the sorts of computations of interest to them that would benefit from performance improvements. The program existed only in Fortran, so the research question became developing a clean parallel solution that eventually became the top-level logic of the earlier Section “The Controller.” Phases had to be defined, interconnection graphs had to be created, data flow between phases had to be managed, and so forth. This common task – converting from sequential to parallel for the CHiP machine – is fully described for SIMPLE in a very nice paper by Gannon and Panetta [7].

Blue CHiP. Fig. 6 Poker screen shots of a phase program for a 4 processor CHiP computer for a master/slave computation; (a) Switch Settings (1,1 is the master), editing mode for SS is shown in Fig. 4a; (b) Code Names; (c) Port Names; and (d) Trace View midway through the (interpreted) computation

New Algorithms Among the new algorithms were image-processing computations, since they were thought to be a domain benefiting from CHiP-style parallelism [14]. One particularly elegant connected components counting algorithm illustrates the style.

Using a 4-degree version of a morphological transformation due to Levialdi, a bit array is modified using two transformations applied at all positions,

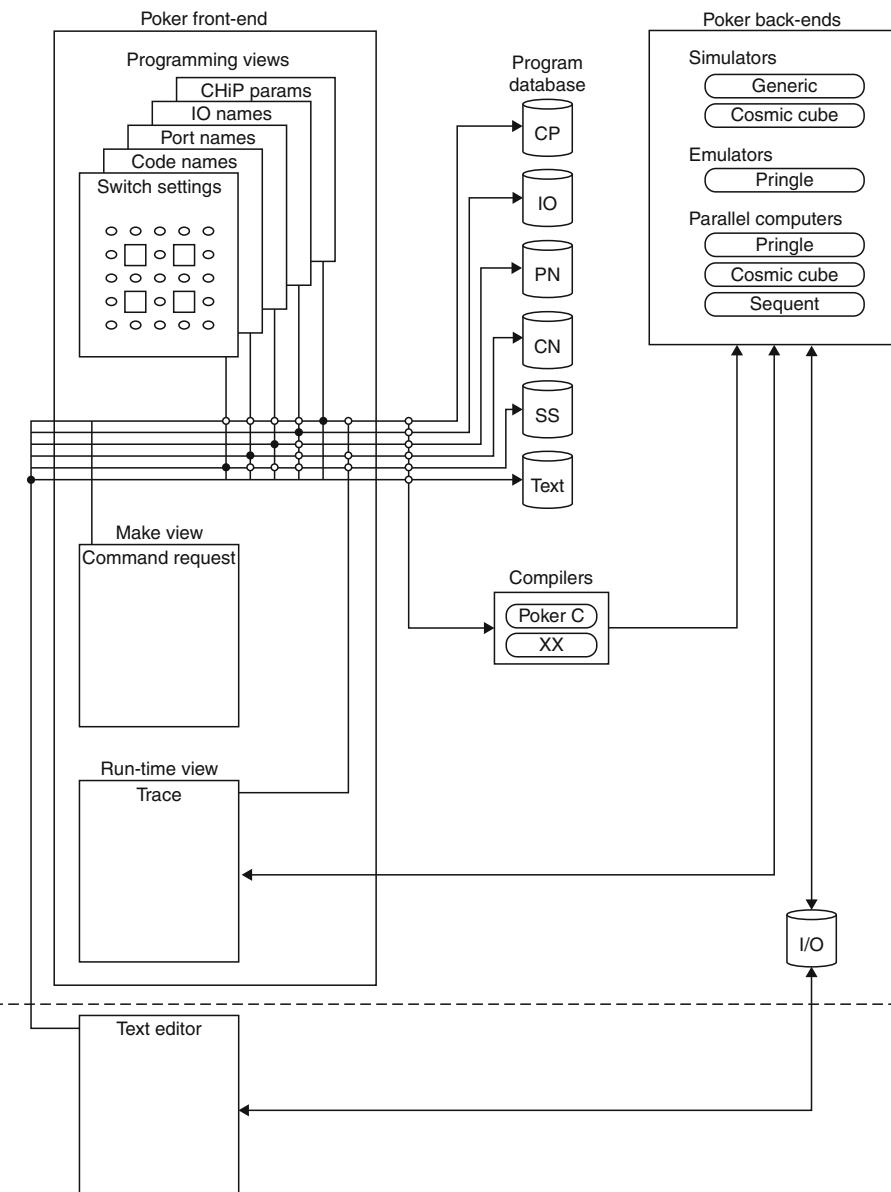

producing a series of morphed arrays. In words, the first rule specifies that a 1-bit adjacent to 0-bits to its north, northwest, and west becomes a 0-bit in the next generation; the second rule specifies that a 0-bit adjacent to 1-bits to its north and west becomes a 1-bit in the next generation; all other bits are unchanged; an isolated bit

that is about to disappear due to the first rule should be counted as a component. See Fig. 8.

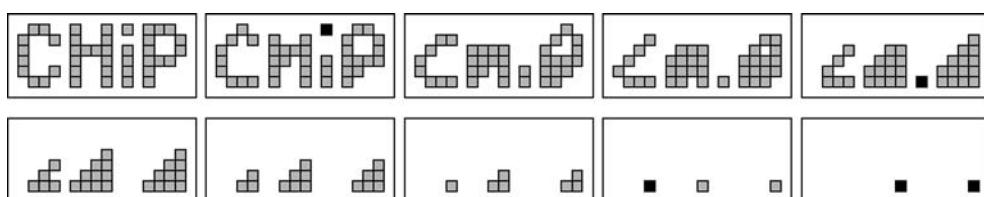

The CHiP phase for the counting connected components computation assigns a rectangular subarray of pixels to each processor, and uses a 4-degree mesh interconnection. PEs exchange bits around the edge of their subarray with adjacent neighbors, and then apply the rules to create the next iteration, repeating. As is typical the controller is not involved in the phase until all processors signal that they have no more bits left in their subarray, at which point the phase ends.

Theory: Graphs

Though the project emphasized the practical task of exploiting VLSI, a few theorems were proved, too. Two research threads are of interest. The first concerned properties of algorithms to convert data-driven programs to loop programs. Data-driven is an asynchronous communication protocol where, for example,

Blue CHiP. Fig. 7 Structure of the Poker parallel programming environment. The “front end” was the portion visible in the graphic user interface; the “back ends” were the “platforms” on which a Poker program could be “run”

Blue CHiP. Fig. 8 The sequence of ten-bit arrays produced using Levialdi’s transformation; pixels are blackened when counted. The algorithm “melts” a component to the lower right corner of its bounding box, where it is counted

reads to a port prior to data arrival stall. The CHiP machine was data driven, but the protocol carries overhead. The question was whether data-driven programs could be more synchronous. The theorems concerned properties of an algorithm to convert from data-driven to synchronous; the results were reported [15] and implemented in Poker, but not heavily used.

The second thread turned out to be rather long. It began with an analysis of yield in VLSI chip fabrication. Called the Tile Salvage Problem, the analysis concerned how the chips on a wafer, some of which had tested faulty, could be grouped into large working blocks [16]. The solution found that matching working pairs is in polynomial time, but finding 2×2 working blocks is NP hard; an optimal-within-2 approximation was developed for 2×2 blocks. When the work was shown to Tom Leighton, he found closely related planar graph matching questions, and added/strengthened some results. He told Peter Shor, who did the same. And finally, David Johnson made still more improvements. The work was finally published as Generalized Planar Matching [17].

Summary

The Blue CHiP Project, which ran for six years, produced a substantial amount of research, most of which is not reviewed here. Much of the research was integrated across multiple topics by applying Mead's "tall, thin man" approach. The results in the hardware domain included a field programmable switch, a programmable communication fabric (lattice), an architecture, wafer-scale integration studies, and a hardware emulator (Pringle) for the machine. The results in the software domain included the Poker Parallel Programming Environment that was built on a graphic workstation, communication graph layouts, programs for the machine, and new parallel algorithms. Related research included studies in wafer scale integration, both theory and design, as well as the extension of the CHiP approach to signal processing and other domains. The work was never directly applied because the technology of the day was not sufficiently advanced; 25 years after the conception of the CHiP architecture, however, the era of multiple-cores-per-chip offers suitable technology.

Apart from the nascent state of the technology, an important conclusion of the project was that the problem in parallel computing is not a hardware problem,

but a software problem. The two key challenges were plain:

- Performance – developing highly parallel computations that *exploit locality*,
- Portability – expressing parallel computations at a high enough level of abstraction that a compiler can target to any MIMD machine.

The two challenges are enormous, and largely remain unsolved into the twenty-first century. Regarding the first, exploiting locality was a serious concern for the CHiP architecture with its tight VLSI connection, making us very sensitive to the issue. But it was also clear that locality is always essential in parallelism, and valuable for all computation. Regarding the second, it was clear in retrospect that the project's programming and algorithm development were very tightly coupled to the machine, as were other projects of the day. Whereas CHiP computations could usually be hosted effectively on other computers, the converse was not true. Shouldn't all code be machine independent? The issue in both cases concerned the parallel programming model.

These conclusions were embodied in a paper known as the "Type Architecture" paper [18]. (Given the many ways "type" is used in computer science, it was not a good name; in this case it meant "characteristic form" as in *type species* in biology.) The paper, among other things, predicts the rise of message passing programming, and criticizes contemporary programming approaches. Most importantly, it defines a machine model – a generic parallel machine – called the CTA. This machine plays the same role that the RAM or von Neumann machine plays in sequential computing. The CTA is visible today in applications ranging from message passing programming to LogP analysis.

Bibliographic Notes and Additional Reading

The focal point of the project, the machine, and its software were strongly influenced by VLSI technology, but the technology was not yet ready for a direct application of the approach; it would take until roughly 2005. The ideas that the project developed – phase-based parallelism, high level parallel language, emphasis on locality, emphasis on data parallelism, etc. – turned out to drive the follow-on research much more than VLSI. Indeed, there were several follow-on efforts to develop high performance, machine independent parallel languages [19], and eventually, ZPL [20]. The problem has not yet been completely solved, but the Chapel [21] language is the latest to embody these ideas.

Branch Predictors

ANDRÉ SEZNEC
IRISA/INRIA, Rennes, Rennes, France

Definition

The branch predictor is a hardware mechanism that predicts the address of the instruction following the branch. For respecting the sequential semantic of a program, the instructions should be fetched, decoded, executed, and completed in the order of the program. This would lead to quite slow execution. Modern processors implement many hardware mechanisms to execute concurrently several instructions while still respecting the sequential semantic. Branch instructions cause a particular burden since their result is needed to begin the execution of the subsequent instructions. To avoid stalling the processor execution on every branch, branch predictors are implemented in hardware. The branch predictor predicts the address of the instruction following the branch.

Discussion

Introduction

Most instruction set architectures have a sequential semantic. However, most processors implement pipelining, instruction level parallelism, and out-of-order execution. Therefore on state-of-the-art processors, when an instruction completes, more than one hundred of subsequent instructions may already be in progress in the processor pipeline. Enforcing the semantic of a branch is therefore a major issue: The address of the instruction following a branch instruction is normally unknown before the branch completes. Control flow instructions are quite frequent, up to 30% in some applications. Therefore to avoid stalling the issuing of subsequent instructions until the branch completes, microarchitects invented *branch prediction*,

i.e., the address of the instruction following a branch B is predicted. Then the instructions following the branch can speculatively progress in the processor pipeline without waiting for the completion of the execution of branch B.

Anticipating the address of the next instruction to be executed was recognized as an important issue very early in the computer industry back in the late 1950s. However, the concept of branch prediction was really introduced around 1980 by Smith in [21]. On the occurrence of a branch, the effective information that must be predicted is the address of the next instruction. However, in practice several different informations are predicted in order to predict the address of the next instruction. First of all, it is impossible to know that an instruction is a branch before it has been decoded, that is the branch nature of the instruction must be known or predicted before fetching the next instruction. Second, on taken branches, the branch target is unknown at instruction fetch time, that is the potential target of the branch must be predicted. Third, most branches are conditional, the direction of the branch taken or not-taken must be predicted.

It is important to identify that not all information is of equal importance for performance. Failing to predict that an instruction is a branch means that instructions are fetched in sequence until the branch instruction is decoded. Since decoding is performed early in the pipeline, the instruction fetch stream can be repaired very quickly. Likewise, failing to predict the target of the direct branch is not very dramatic. The effective target of a direct branch can be computed from the instruction codeop and its address, thus the branch can be computed very early in the pipeline — generally, it becomes available at the end of the decode stage. On the other hand, the direction of a conditional branch and the target of an indirect branch are only known when the instruction has been executed, i.e., very late in the pipeline, thus potentially generating very long misprediction penalties, sometimes 30 or 50 cycles.

Since in many applications most branches are conditional and the penalty on a direction misprediction is high, when one refers to branch prediction, one generally refers to predicting directions of conditional branches. Therefore, most of this article is dedicated to conditional branch predictions.

General Hardware Branch Prediction Principle

Some instruction sets have included some software hints to help branch prediction. Hints like “likely taken” and “likely not-taken” have been added to the encoding of the branch instruction. These hints can be inserted by the compilers based on application knowledge, e.g., a loop branch is likely to be taken, or on profiling information. However, the most efficient schemes are essentially hardware and do not rely on any instruction set support.

The general principle that has been used in hardware branch prediction scheme is to predict that the behavior of the branch to be executed will be a replay of its past behavior. Therefore, hardware branch predictors are based on memorization of the past behavior of the branches and some limited hardware logic.

Predicting Branch Natures and Direct Branch Targets

For a given static instruction, its branch nature (is it a branch or not) remains unchanged all along the program life, apart in case of self-modifying code. This stands also for targets of direct branches. The Branch Target Buffer, or BTB [11], is a special cache which aims at predicting whether an instruction is a branch and its potential target. At fetch time, the BTB is checked with the instruction Program Counter. On a hit, the instruction is predicted to be a branch and the address stored in the hitting line of the BTB is assessed to be the potential target of the branch. The nature of the branch (unconditional, conditional, return, indirect jumps) is also read from the BTB.

A branch may miss the BTB, e.g., on its first execution or after its eviction on a conflict miss. In this case, the branch is written in the BTB: its kind and its target are stored in association with its Program Counter. Note that on a BTB hit, the target may be mispredicted on indirect branches and returns. This will shortly be presented in section on “Predicting Indirect Branch Targets”.

Predicting Conditional Branch Directions

Most branches are conditional branches and the penalty on mispredicting the direction of a conditional branch is really high on modern processors. Therefore, predicting the direction of conditional branches has received

a lot of attention from the research community in the 1990s and the early 2000s.

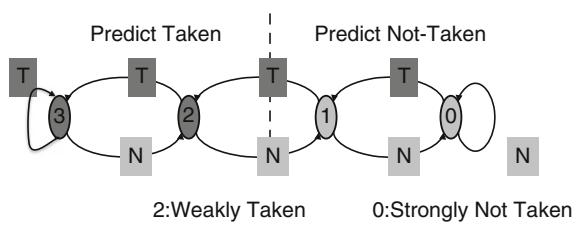

B

PC-Based Prediction Schemes

It is natural to predict a branch based on its program counter. When introducing conditional branch prediction [21], Smith immediately introduced two schemes that capture the most frequent behaviors of the conditional branches.

Since most branches in a program tend to be biased toward taken or not-taken, the simplest scheme consisting to predict that a branch will follow the same direction than the last time it has been executed is quite natural. Hardware implementation of this simple scheme necessitates to store only one bit per branch. When a conditional branch is executed, its direction is recorded, e.g., in the BTB along with the branch target. A single bit is used: 0 encodes not-taken and 1 encodes taken. The next time the branch is fetched, the direction stored in the BTB is used as a prediction. This scheme is surprisingly efficient on most programs often achieving accuracy higher than 90%. However, for branches that privilege one direction and from time to time branch in the other direction, this 1-bit scheme tends to predict the wrong direction twice in a row. This is the case for instance, for loop branches which are taken except the last iteration. The 1-bit scheme fails to predict the first iteration and the last iteration.

Smith [21] proposed a slightly more complex scheme based on a saturated 2-bit counter automaton (Fig. 1): The counter is incremented on a taken branch and decremented on a not-taken branch. The most significant bit of the counter is used as the prediction. On branches exhibiting a strong bias, the 2-bit scheme avoids to encounter two successive mispredictions after one occurrence of the non-bias direction. This 2-bit

Branch Predictors. Fig. 1 A 2-bit counter automaton

counter predictor is often referred to as a 2-bit bimodal predictor.

History-Based Conditional Branch Prediction Schemes

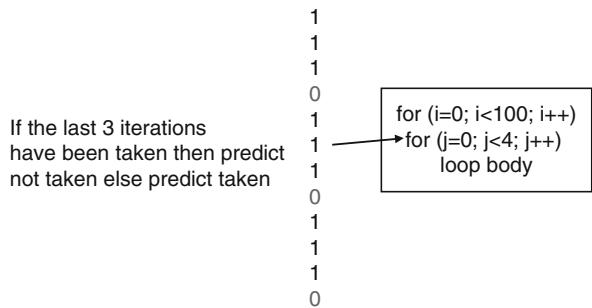

In the early 1990s, branch prediction accuracy became an important issue. The performance of superscalar processors is improved by any reduction of branch misprediction rate. The 1-bit and 2-bit prediction schemes use a very limited history of the behavior of a program to predict the outcome direction of a branch. Yeh and Patt [24] and Pan and So [14] proposed to use more information on the passed behavior of the program, trying to better isolate the context in which the branch is executed.

Two families of predictors were defined. Local history predictors use only the past behavior of the program on the particular branch. Global history predictors use the past behavior of the whole program on all branches.

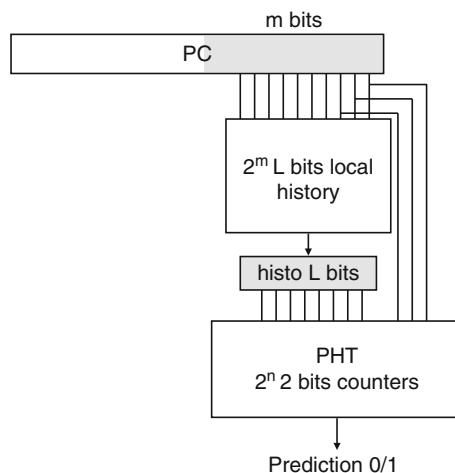

Local History Predictors

Using the past behavior of the branch to be predicted appears attractive. For instance, on the loop nest illustrated on Fig. 2, the number of iterations in the inner loop is fixed (4). When the outcome of the last three occurrences of the branch are known, the outcome of the present occurrence is completely determined: If the last three occurrences of the branch were taken then the current occurrence is the last iteration, therefore is not-taken otherwise the branch is taken. Local history is not limited to capturing the behavior of branches with fixed number of iterations. For instance, it can capture the behavior of any branch exhibiting a periodic behavior as long as the history length is equal or longer than the period.

A local history predictor can be implemented as illustrated Fig. 3. For each branch, the history of its past behavior is recorded as a vector of bits of length L and stored in a local history table. The branch program counter is used as an index to read the local history table. Then the branch history is associated with the program counter to read the prediction table. The prediction table entries are generally saturated 2-bit counters. The history vector must be adapted on each branch occurrence and stored back in the local history table.

Branch Predictors. Fig. 2 A loop with four iterations

Branch Predictors. Fig. 3 A local history predictor

Effective implementation of local history predictors is quite difficult. First the prediction requires to chain two successive table reads, thus creating a difficult latency issue for providing prediction in time for use. Second, in aggressive superscalar processors, several branches (sometimes tens) are progressing speculatively in the pipeline. Several instances of the same branch could have been speculatively fetched and predicted before the first occurrence is finally committed. The branch prediction should be executed using the speculative history. Thus, maintaining correct speculative history for local history predictors is very complex for wide-issue superscalar processors.

Global History Predictors

The outcome of a branch is often correlated with the outcome of branches that have been recently executed.

For instance, in the example illustrated in Fig. 4, the outcome of the third branch is completely determined by the outcome of the first two branches.

First generation global history predictors such as GAs [25] or gshare [12] (Fig. 5) are associating with a fixed length global history vector and the program counter of the branch to index a prediction table. These predictors were shown to suffer from two antagonistic phenomena. First, it was shown that using a very long history is sometimes needed to capture correlation. Second, using a long history results in possible destructive conflicts on a limited size prediction table.

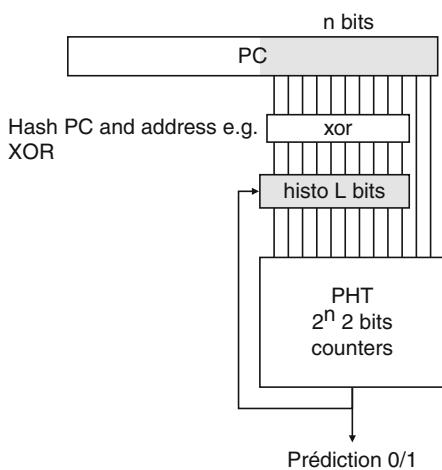

A large body of research in the mid-1990s was dedicated to reduce the impact of these destructive conflicts or aliasing [4, 10, 13, 22].

By the end of the 1990s, these dealiased global history predictors were known to be more accurate at equal storage complexity than local predictors.

Path or global history predictor: In some cases, the global conditional branch history vector does not uniquely determine the instruction path that leads to a particular branch; e.g., an indirect branch or a return

```
B1: if cond1 then ..
B2: if cond2 then ..
B3: if cond1 and cond 2 then ..
```

Branch Predictors. Fig. 4 Branch correlation: outcome of branch 3 is uniquely determined by the outcomes of branches 1 and 2

Branch Predictors. Fig. 5 The gshare predictor

may have occurred and two paths can be represented by the same global history vector. The path vector combining all the addresses of the last control flow instructions that lead to a branch is unique. Using the path history instead of the global history vector generally results in a slightly higher accuracy [15].

Hybrid Predictors

Global history predictors and local history predictors were shown to capture different branch behaviors. In 1993, McFarling [12] proposed to combine several predictors to improve their accuracy. Even combining a global history predictor with a simple bimodal predictor was shown to provide enhanced prediction accuracy.

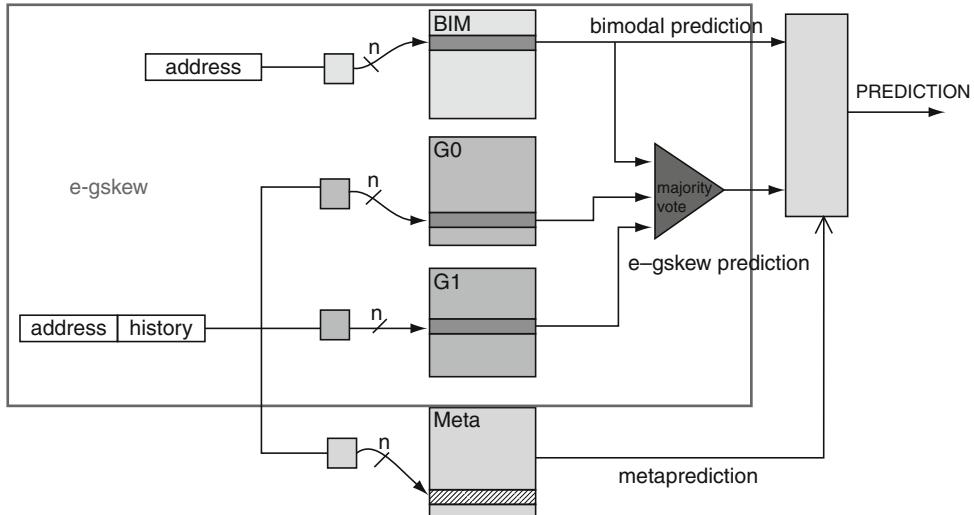

The first propositions of hybrid predictors were to use a metapredictor to select a prediction. The metapredictor is also indexed with the program counter and the branch history. The metapredictor learns which predictor component is more accurate. The *2bc-gskew* predictor 6 proposed for the cancelled Compaq EV8 processor [2] leveraged hybrid prediction to combine several global history predictors including a majority vote *gskew* predictor with different history lengths. However, a metapredictor is not a cost-effective solution to select among more than two predictions [5].

Toward Using Very Long Global History

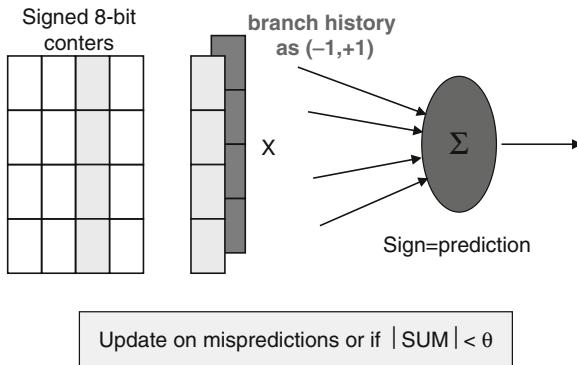

While some applications will be very accurately predicted using a short branch history length, limit studies were showing that some benchmarks would benefit from using very long history in 100s of bit range.

In 2001, Jimenez and Lin [7] proposed to use neural nets inspired techniques to combine predictions. On perceptron predictors, the prediction is computed as the sign of a dot-product of a vector of signed prediction counters read in parallel by the branch history vector (Fig. 7). Perceptron predictors allow to use very long global history vectors, e.g., 50 bits, but suffer from a long latency prediction computation and require huge predictor table volumes.

Building on top of the neural net inspired predictors, the GEometric History Length or GEHL predictor (Fig. 8) was proposed in 2004 [15]. This predictor combines a few global history predictors (typically from 5

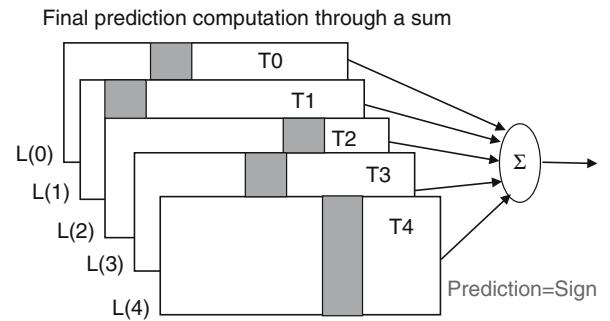

Branch Predictors. Fig. 6 The 2bc-gskew predictor

Branch Predictors. Fig. 7 The perceptron predictor

to 8) indexed with different history lengths. The prediction is computed as the sign of the sum of the read predictions. The set of history lengths forms a geometric series, for instance, 0, 2, 4, 8, 16, 32, 64, 128. The use of such a geometric series allows to concentrate most of the storage budget on short histories while still capturing long-run correlations on very long histories. Using a medium number of predictor tables (4–8) and maximal history length of more than 200 bits was shown to be realistic.

While using an adder tree was shown as an effective final prediction computation function by the GEHL predictor, partial tag matching may be even more storage effective. The TAGE predictor (Fig. 9) proposed in 2006 [19] uses the geometric history length principle,

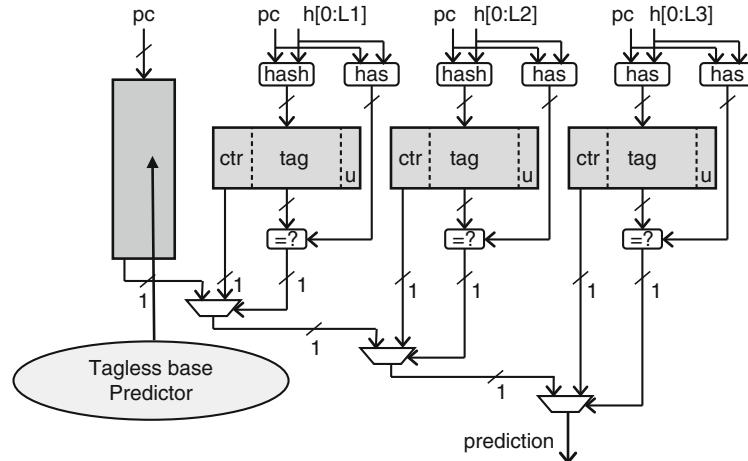

Branch Predictors. Fig. 8 The GEHL predictor: tables are indexed using different global history length that forms a geometric series

but relies on partial tag matching for final prediction computation. Each table in the predictor is read and the prediction is provided by the hitting predictor component with the longest history. If there is no hitting component then the prediction is provided by the default predictor.

Realistic size TAGE currently represents the state of the art in conditional branch predictors [17] and its misprediction rate is within 20% of the currently known limits for conditional branch predictability [16].

Predicting Indirect Branch Targets

Return and indirect jump targets are also only known at execution time and must be predicted.

Branch Predictors. Fig. 9 The TAGE predictor: partial tag match determines the prediction

Predicting Return Targets

Kaeli and Emma [9] remarked that, in most cases and particularly for compiler generated code the return address of procedure calls obey a very simple *call-return* rule: The return address target is the address just following the call instruction. They also remarked that the return addresses of the procedures could be predicted through a simple return address stack (RAS). On a call, the address of the next instruction in sequence is pushed on the top of the stack. On a return, the target of the return is popped from the top of the stack.

When the code is generated following the *call-return* rule and if there is no branch misprediction between the call and the return, an infinite size RAS predicts the return target with a 100% accuracy. However, several difficulties arise for practical implementation. The *call-return* rule is not always respected. The RAS is size limited, but in practice a 32-entry RAS is sufficient for most applications. The main difficulty is associated with the speculative execution: When on the wrong path returns are fetched followed by one or more calls, valid RAS entries are corrupted with wrong information, thus generating mispredictions on the returns on the right path. Several studies [8, 20, 23] have addressed this issue, and the effective accuracy of return target prediction is close to perfect.

Indirect Jump Target Predictions

To predict the targets of indirect jumps, one can use the same kind of information that can be used for

predicting the direction of the conditional branches, i.e., the global branch history or program path history.

First it was proposed to use the last encountered target, i.e., just the entry in the BTB. Chang et al. [1] proposed to use a predictor indexed by the global history and the program counter. Driesen and Holzle [3] proposed to use an hybrid predictor based on tag matching. Finally Seznec and Michand [19] proposed ITTAGE, a multicomponent indirect jump predictor, based on partial tag matching and the use of geometric history length as TAGE.

Conclusion

In the modern processors, the whole set of branch predictors (conditional, returns, indirect jumps, BTB) is an important performance enabler. They are particularly important on deep pipelined wide-issue superscalar processors, but they are also becoming important in low power embedded processors as they are also implementing instruction-level parallelism.

A large body of research has addressed branch prediction during the 1990s and the early 2000s and complex predictors inspired by this research have been implemented in processors during the last decade. Current state-of-the-art branch predictors combine multiple predictions and rely on the use of global history. These predictors cannot deliver a prediction in a single cycle. Since, prediction is needed on the very next cycle, various techniques such as overriding predictors [6] or ahead pipelined predictors [18] were proposed and implemented.

Branch predictor accuracy seems to have reached a plateau since the introduction of TAGE. Radically new predictor ideas, probably new sources of predictability, will probably be needed to further increase the predictor accuracy.

Brent's Law

► Brent's Theorem

Brent's Theorem

JOHN L. GUSTAFSON
Intel Corporation, Santa Clara, CA, USA

Synonyms

Brent's law

Definition

Assume a parallel computer where each processor can perform an arithmetic operation in unit time.

Further, assume that the computer has exactly enough processors to exploit the maximum concurrency in an algorithm with N operations, such that T time steps suffice. Brent's Theorem says that a similar computer with fewer processors, P , can perform the algorithm in time

$$T_P \leq T + \frac{N - T}{P},$$

where P is less than or equal to the number of processors needed to exploit the maximum concurrency in the algorithm.

Discussion

Brent's Theorem assumes a PRAM (Parallel Random Access Machine) model [3, 7]. The PRAM model is an idealized construct that assumes any number of processors can access any items in memory instantly, but then take unit time to perform an operation on those items. Thus, PRAM models can answer questions about how much arithmetic parallelism one can exploit in an algorithm if the communication cost were zero. Since many algorithms have very large amounts of theoretical PRAM-type arithmetic concurrency, Brent's Theorem bounds the theoretical time the algorithm would take on a system with fewer processors.

Example

Suppose the task is to solve the following system of two equations in two unknowns, u and v :

$$au + bu = x$$

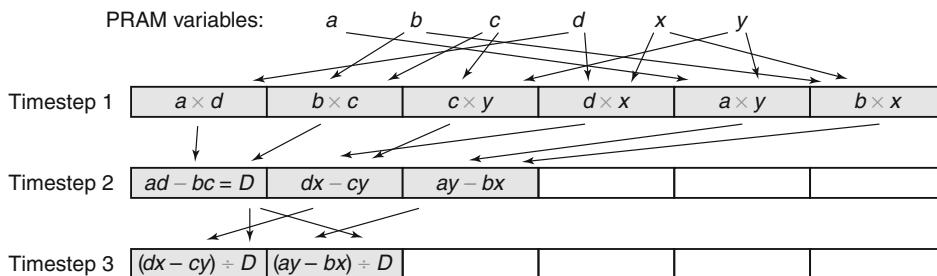

$$cu + du = y$$

One solution method is *Cramer's Rule*, which is far less efficient than Gaussian elimination in general, but exposes so much parallelism that it can take less time on a PRAM computer. Figure 1 shows how a PRAM with six processors can calculate the solution values, u and v in only three time steps:

Thus, $T = 3$ time steps, and $P \leq 6$, the amount of concurrency in the first time step. The total number of arithmetic operations, N , is 11 (six multiplications, followed by three subtractions, followed by two divisions). Brent's Theorem tells us an upper bound on the time a PRAM with *four* processors would take to perform the algorithm:

$$T_P \leq T + \frac{N - T}{P}, \text{ so}$$

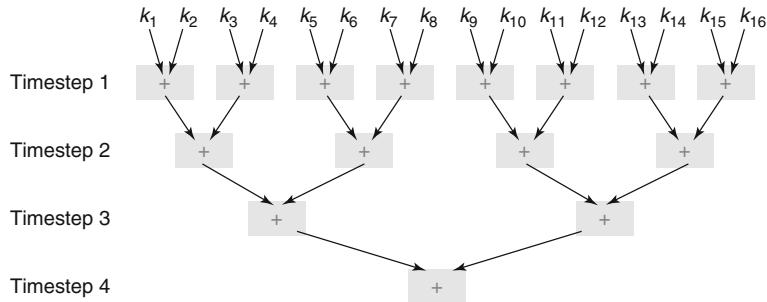

$$T_4 \leq 3 + \frac{11 - 3}{4} = 5.$$

Brent's Theorem. Fig. 1 Concurrency of a solver for two equations in two unknowns

Timestep 1	$a \times d$	$b \times c$	$c \times y$	$d \times x$	
Timestep 2	$a \times y$	$b \times x$			
Timestep 3	$ad - bc = D$	$dx - cy$	$ay - bx$		
Timestep 4	$(dx - cy) \div D$	$(ay - bx) \div D$			

Brent's Theorem. Fig. 2 Linear solver on only four processors

Brent's Theorem. Fig. 3 Binary sum collapse with a maximum parallelism of eight processors

Figure 1 shows that four time steps suffice in this case, fewer than the five in the bound predicted by Brent's Theorem. The figure omits dataflow arrows, for clarity.

Brent's Theorem says the four-processor system should require no more than five time steps, and Fig. 1 shows this is clearly the case.

Asymptotic Example: Parallel Summation

A common use of Brent's Theorem is to place bounds on the applicability of parallelism to problems parameterized by size. For example, to find the sum of a list of n numbers, a PRAM can add the numbers in pairs, then the resulting sums in pairs, and so on until the result is a single summation value. Figure 3 shows such a binary sum collapse for a set of 16 numbers.

In the following discussion, the notation

$\lg(x)$ denotes the logarithm base 2 of x , and the notation $[X]$ denotes the “ceiling” function, the smallest integer larger than x .

If n is exactly a power of 2, such that $n = 2^T$, then the PRAM can complete the sum in T time steps. That is, $T = \lg(n)$. If n is not an integer power of 2, then $T = [\lg(n)]$ because the summation takes one additional step. The total number of arithmetic operations for the summation of n numbers is $n - 1$ additions.

The maximum parallelism occurs in the first time step, when $n/2$ processors can operate on the list concurrently. If the number of processors in a PRAM is P , and P is less than $n/2$, then Brent's Theorem shows [2] that the execution time can be made less than or equal to

$$T_P = \lceil \lg(n) \rceil + \frac{(n - 1) - |\lg(n)|}{P}.$$

For values of n much larger than P , the above formula shows $T_P \approx \frac{n}{P}$.

Proof of Brent's Theorem

Let n_j be the number of operations in step j that the PRAM can execute concurrently, where j is $1, 2, \dots, T$. Assume the PRAM has P processors, where $P \leq \max_j(n_j)$.

A property of the ceiling function is that for any two positive integers k and m ,

$$\left\lceil \frac{k}{m} \right\rceil \leq \frac{k + m - 1}{m}.$$

Hence, the time for the PRAM to perform each time step j has the following bound:

$$\left\lceil \frac{n_j}{P} \right\rceil \leq \frac{n_j + P - 1}{P}.$$

The time for all time steps has the bound

$$\begin{aligned} T_P &\leq \sum_{j=1}^T \left\lceil \frac{n_j}{P} \right\rceil \leq \sum_{j=1}^T \frac{n_j + P - 1}{P} \\ &= \sum_{j=1}^T \frac{n_j}{P} + \sum_{j=1}^T \frac{P}{P} - \sum_{j=1}^T \frac{1}{P}. \end{aligned}$$

Since the sum of the n_j is the total number of operations N , and the sum of 1 for T steps is simply T , this simplifies to

$$T_P \leq \frac{\sum n_j}{P} + \sum_{j=1}^T 1 - \frac{\sum 1}{P} = T + \frac{N - T}{P}.$$

Application to Superlinear Speedup

Ideal speedup is speedup that is linear in the number of processors. Under the strict assumptions of Brent's Theorem, superlinear speedup (or superunitary efficiency,

sometimes erroneously termed superunitary speedup) is impossible.

Superlinear speedup means that the time to perform an algorithm on a single processor is more than P times as long as the time to perform it on P processors. In other words, P processors are more than P times as fast as a single processor. According to Brent's Theorem with $P = 1$,

$$T_1 \leq T + \frac{N - T}{1} = N.$$

Speedup greater than the number of processors means $T_1 > P \cdot T_P$. Brent's Theorem says this is mathematically impossible. However, Brent's Theorem is based on the assumptions of the PRAM model that have little resemblance to real computer design, such as the assumptions that every arithmetic operation requires the same amount of time, and that memory access has zero latency and infinite bandwidth. The debate over the possibility of superlinear speedup first appeared in 1986 [4, 6], and the debate highlighted the oversimplification of the PRAM model for parallel computing performance analysis.

Perspective

The PRAM model used by Brent's Theorem assumes that communication has zero cost, and arithmetic work constitutes all of the work of an algorithm. The opposite is closer to the present state of computer technology (see *Memory Wall*), which greatly diminishes the usefulness of Brent's Theorem in practical problem solving. It is so esoteric that it does not even provide useful upper or lower bounds on how parallel processing might improve execution time, and modern performance analysis seldom uses it. Brent's Theorem is a mathematical model more related to graph theory and partial orderings than to actual computer behavior. When Brent constructed his model in 1974, most computers took longer to perform arithmetic on operands than they took to fetch and store the operands, so the approximation was appropriate. More recent abstract models of parallelism take into account communication costs, both bandwidth and latency, and thus can provide better guidance for the parallel performance bounds of current architectures.

Bibliographic Notes and Further Reading

As explained above, Brent's Theorem reflects the computer design issues of the 1970s, and readers should view Brent's original 1974 paper in this context. It was in 1986 that the esoteric nature of the PRAM model became clear, in the opposing papers [4] and [6]. Faber, Lubeck, and White [4] assumed the PRAM model to state that one cannot obtain superlinear speedup since computing resources increase linearly with the number of processors. Parkinson [6], having had experience with the ICL Distributed Array Processor (DAP), based his model and experience on premises very different from the hypothetical PRAM model used in Brent's Theorem. Parkinson noted that simple constructs like the sum of two vectors could take place superlinearly faster on P processors because a shared instruction to add, sent to the P processors, does not require the management of a loop counter and address increment that a serial processor requires. The 1989 work *Introduction to Algorithms* by Cormen, Leiserson, and Rivest [3] is perhaps the first textbook to formally recognize that the PRAM model is too simplistic, and thus Brent's Theorem has diminished predictive value.

One-to-all broadcast; Copy

Definition

Among a group of processing elements (nodes), a designated *root* node has a data item to be communicated (copied) to all other nodes. The broadcast operation performs this collective communication operation.

Discussion

The reader may consider first visiting the entry on [►Collective Communication](#).

Let p be the number of nodes in the group that participate in the broadcast operation and number these nodes consecutively from 0 to $p - 1$. One node, the root with index r , has a vector of data, x of size n , to be communicated to the remainder $p - 1$ nodes:

Before			After		
Node r	Node 1	Node 2	Node r	Node 1	Node 2
x			x	x	x

All nodes are assumed to explicitly take part in the broadcast operation. It is generally assumed that before its execution all nodes know the index of the designated *root* node as well as the the amount n of data to be broadcast. The data item x may be either a single, atomic unit or divisible into smaller, disjoint pieces. The latter can be exploited algorithmically when n is large.

Broadcast is a key operation on parallel systems with distributed memory. On shared memory systems, broadcast can be beneficial for improving locality and/or avoiding memory conflicts.

Lower Bounds

To obtain some simple lower bounds, it is assumed that

- All nodes can communicate through a communication network.
- Individual nodes perform communication operations that send and/or receive individual messages.
- Communication is through a single *port*, such that a node can be involved in at most one communication operation at a time. Such an operation can be either a send to or a receive from another node (unidirectional communication), a combined send to and receive from another node (bidirectional, telephone like communication), or a send to and receive from two possibly different nodes (simultaneous send-receive, fully bidirectional communication).
- It is assumed that the communication medium is homogeneous and fully connected such that all nodes can communicate with the same costs and any maximal set of pairs of disjoint nodes can communicate simultaneously.
- A reasonable first approximation for the time for transferring a message of size n between (any) two nodes is $\alpha + n\beta$ where α is the start-up cost (latency) and β is the cost per item transferred (inverse of the bandwidth).

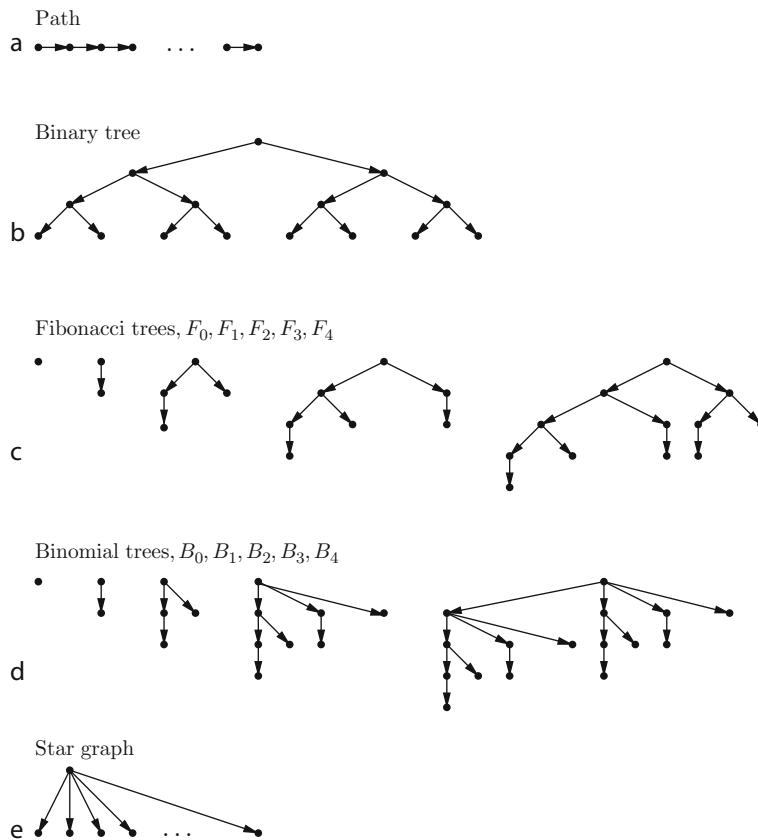

Under these assumptions, two lower bounds for the broadcast operation can be easily justified, the first for the α term and the second for the β term:

- $\lceil \log_2 p \rceil \alpha$. Define a round of communication as a period during which each node can send at most one message and receive at most one message. In each round, the number of nodes that know message x can at most double, since each node that has x can send x to a new node. Thus, a minimum of $\lceil \log_2 p \rceil$ rounds are needed to broadcast the message. Each round costs at least α .
- $n\beta$. If $p > 1$ then the message must leave the root node, requiring a time of at least $n\beta$.

When assumptions about the communication system change, these lower bounds change as well. Lower bounds for mesh and torus networks, hypercubes, and many other communication networks are known.

Tree-Based Broadcast Algorithms

A well-known algorithm for broadcasting is the so-called Minimum Spanning Tree (MST) algorithm

Broadcast. Fig. 1 Commonly used broadcast trees: (a) Path; (b) Binary Tree; (c) Fibonacci trees, the i th Fibonacci tree for $i > 1$ consists of a new root node connected to Fibonacci trees F_{i-1} and F_{i-2} ; (d) Binomial trees, the i th binomial tree for $i > 0$ consists of a new root with children B_{i-1}, B_{i-2}, \dots ; (e) Star

(which is a misnomer, since all broadcast trees are spanning trees and minimum for homogeneous communication media), which can be described as follows:

- Partition the set of nodes into two roughly equal-sized subsets.
- Send x from the root to a node in the subset that does not include the root. The receiving node will become a *local root* in that subset.
- Recursively broadcast x from the (local) root nodes in the two subsets.

Under the stated communication model, the total cost of the MST algorithm is $\lceil \log_2 p \rceil(\alpha + n\beta)$. It achieves the lower bound for the α term but not for the β term for which it is a logarithmic factor off from the lower bound.

If the data transfer between two nodes is represented by a communication edge between the two nodes, the MST algorithm constructs a *binomial* spanning tree over the set of nodes. An equivalent (also recursive) construction is as follows. The 0th binomial tree B_0 consists of a single node. For $i > 0$ the i th binomial tree B_i consists of the root with i children B_j for $j = i - 1, \dots, 0$. The number of nodes in B_i is 2^i . It can be seen that the number of nodes at level i is $\binom{i}{\log_2 p}$ from which the term originates.

The construction and structure of the binomial (MST) tree is shown in Fig. 1d.

Pipelining

For large item sizes, pipelining is a general technique to improve the broadcast cost. Assume first that the nodes

are communicating along a directed path with node 0 being the root and node i sending to node $i + 1$ for $0 \leq i < p - 1$ (node $p - 1$ only receives data). This is shown in Fig. 1a. The message to be broadcast is split into k blocks of size n/k each. In the first round of the algorithm, the first block is sent from node 0 to node 1. In the second round, this block is forwarded to node 2 while the second block is sent to node 1. In this fashion, a pipeline is established that communicates the blocks to all nodes.

Under the prior model, the cost of this algorithm is

$$\begin{aligned} (k+p-2)\left(\alpha + \frac{n}{k}\beta\right) &= (k+p-2)\alpha + \frac{k+p-2}{k}n\beta \\ &= (p-2)\alpha + n\beta + k\alpha + \frac{p-2}{k}n\beta. \end{aligned}$$

It takes $p - 1$ communication rounds for the first piece to reach node $p - 1$, which afterward in each successive round receives a new block. Thus, an additional $k - 1$ rounds are required for a total of $k + p - 2$ rounds. Balancing the $k\alpha$ term against the $\frac{p-2}{k}n\beta$ term gives a minimum time of

$$\left(\sqrt{(p-2)\alpha} + \sqrt{\beta n}\right)^2 = (p-2)\alpha + 2\sqrt{(p-2)n\alpha\beta} + n\beta.$$

and best possible number of blocks $k = \sqrt{\frac{(p-2)\beta n}{\alpha}}$. This meets the lower bound for the β term, but not for the α term. For very large n compared to p the linear pipeline can be a good (practical) algorithm. It is straightforward to implement and has very small extra overhead.

For the common case where p and/or the start-up latency α is large compared to n , the linear pipeline suffers from the nonoptimal $(p-2)\alpha$ term, and algorithms with a shorter longest path from root node to receiving nodes will perform better. Such algorithms can apply pipelining using different, fixed degree trees, as illustrated in Fig. 1a–c. For instance, with a balanced binary tree as shown in Fig. 1b the broadcast time becomes

$$2(\log_2 p - 1) + 4\sqrt{(\log p - 1)\alpha} \sqrt{\beta n} + 2\beta n.$$

The latency of this algorithm is significantly better than the linear pipeline, but the β term is a factor of 2 off from optimal. By using instead skewed trees, the time at which the last node receives the first block of x can be improved which affects both α and β terms. The Fibonacci tree shown in Fig. 1c for instance achieves a

broadcast cost of

$$(\log_\Theta p - 2)\alpha + 2\sqrt{2(\log_\Theta p - 2)\alpha} \sqrt{\beta n} + 2\beta n,$$

where $\Theta = \frac{1+\sqrt{5}}{2}$. Finally it should be noted that pipelining cannot be employed with any advantage for trees with nonconstant degrees like the binomial tree and the degenerated star tree shown in Fig. 1d–e.

A third lower bound for broadcasting of data k items can be justified similarly to the two previously introduced bounds, and is applicable to algorithms that apply pipelining.

- $k - 1 + \lceil \log_2 p \rceil$ rounds. First $k - 1$ items have to leave the root, and the number of rounds for the last item to arrive at some last node is an additional $\lceil \log_2 p \rceil$.

With this bound, the best possible broadcast cost in the linear cost model is therefore $(k - 1 + \log_2 p)(\alpha + \beta n/k)$ when x is (can be) divided into k roughly equal-sized blocks of size at most $\lceil n/k \rceil$. Balancing the $k\alpha$ term against the $(\log_2 p - 1)\beta n/k$ term achieves a minimum time of

$$\begin{aligned} \left(\sqrt{(\log_2 p - 1)\alpha} + \sqrt{\beta n}\right)^2 &= (\log_2 p - 1)\alpha \\ &\quad + 2\sqrt{(\log_2 p - 1)\alpha} \sqrt{\beta n} + \beta n \end{aligned}$$

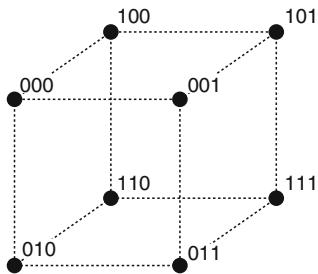

with the best number blocks being $k = \sqrt{\frac{(\log_2 p - 1)\beta n}{\alpha}}$.

Simultaneous Trees

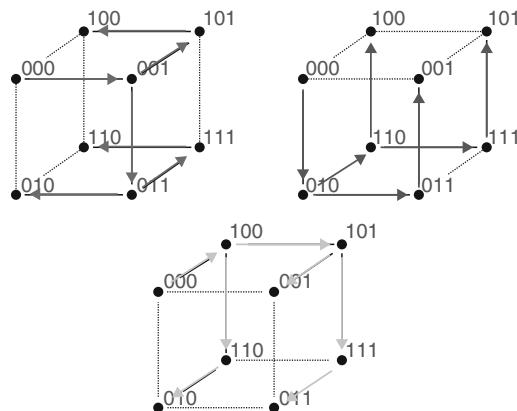

None of the tree-based algorithm were optimal in the sense of meeting the lower bound for both the α and the β terms. A practical consequence of this is that broadcast implementations become cumbersome in that algorithms for different combinations of p and n have to be maintained. The breakthrough results of Johnsson and Ho [17] show how employing multiple, simultaneously active trees can be used to overcome these limitations and yield algorithms that are optimal in the number of communication rounds. The results were at first formulated for hypercubes or fully connected communication networks where p is a power of two, and (much) later extended to communication networks with arbitrary number of nodes. The basic idea can also be employed for meshes and hypercubes.

The idea is to embed simultaneous, edge disjoint spanning trees in the communication network, and use each of these trees to broadcast different blocks of the

input. If this embedding can be organized such that each node has the same number of incoming edges (from different trees) and outgoing edges (to possibly different trees), a form of pipelining can be employed, even if the individual trees are not necessarily fixed degree trees. To illustrate the idea, consider the three-dimensional hypercube, and assume that an infinite number of blocks have to be broadcast.

Let the nodes be numbered in binary with the broadcast root being node 000. The three edge-disjoint trees used for broadcasting blocks $0, 3, 6, \dots; 1, 4, 7, \dots$ and $2, 5, 8, \dots$; respectively, are as shown below:

The trees are in fact constructed as edge disjoint spanning trees excluding node 000 rooted at the root hypercube neighbors 001, 010, and 100. The root is connected to each of these trees. In round 0, block 0 is sent to the first tree, which in rounds 1, 2, and 3 is responsible for broadcasting to its spanning subtree. In round 1, block 1 is sent to the second tree which uses rounds 2, 3, and 4 to broadcast, and in round 2 block 2 is sent to the third tree which uses rounds 3, 4, and 5 to broadcast this block. In round 3, the root sends the third block, the broadcasting of which takes place simultaneously with the broadcasting of the previous

blocks, and so on. The broadcasting is done along a regular pattern, which is symmetric for all nodes. For a d -dimensional hypercube, node i in round t , $t \geq 0$, sends and receives a block to and from the node found by toggling bit $t \bmod d$. As can be seen, each node is a leaf in tree j if bit j of i is 0, otherwise an internal node in tree j . Leaves in tree $j = t \bmod d$ receive block $t - d$ in round d . When node i is an internal node in tree j , the block received in round j is sent to the children of i which are the nodes found by toggling the next, more significant bits after j until the next position in i that is a 1. Thus, to determine which blocks are received and sent by node i in each round, the number of zeroes from each bit position in i until the next, more significant 1 will suffice.

The algorithm for broadcasting k blocks in the optimal $k - 1 + \log_2 p$ number of rounds is given formally in Fig. 2. To turn the description above into an algorithm for an arbitrary, finite number of blocks, the following modifications are necessary. First, any block with a negative number is neither sent nor received. Second, for blocks with a number larger than $k - 1$, block $k - 1$ is taken instead. Third, if $k - 1$ is not a multiple of $\log_2 p$ the broadcast is started at a later round f such that indeed $k + f - 1$ is a multiple of $\log_2 p$. The table $\text{BitDistance}_i[j]$ stores for each node i the distance from bit position j in i to the next 1 to the left of position j (with wrap around after d bits). The root 000 has no ones. This node only sends blocks, and therefore $\text{BitDistance}_{00}[k] = k$ for $0 \leq k < d$. For each i , $0 \leq i < p$ the table can be filled in $O(\log_2 p)$ steps.

Composing from Other Collective Communications

Another approach to implementing the broadcast operation follows from the observation that data can be broadcast to p nodes by scattering p disjoint blocks of x of size n/p across the nodes, and then reassembling the blocks at each node by an allgather operation. On a network that can host a hypercube, the scatter and allgather operations can be implemented at a cost of $(\log_2 p)\alpha + \frac{p-1}{p}n\beta$ each, under the previously used communication cost model (see entries on scatter and allgather). This yields a cost of

$$2\log_2 p\alpha + 2\frac{p-1}{p}n\beta.$$

```

 $f \leftarrow ((k \bmod d) + d - 1) \bmod d$  /* Start round for first phase */
 $t \leftarrow 0$ 
while  $t < k + d - 1$  do
    /* New phase consisting of (up to)  $d$  rounds */
    for  $j \leftarrow f$  to  $d - 1$ 
         $s \leftarrow t - d + (1 - i_j) * \text{BitDistance}_i[j]$  /* block to send */
         $r \leftarrow t - d + i_j * \text{BitDistance}_i[j]$  /* block to receive */
        if  $s \geq k$  then  $s \leftarrow k - 1$ 
        if  $r \geq k$  then  $r \leftarrow k - 1$ 
        par/* simultaneous send-receive with neighbor */
            if  $s \geq 0$  then Send block  $s$  to node ( $i \bmod 2^d$ )
            if  $r \geq 0$  then Receive block  $r$  from node ( $i \bmod 2^d$ )
        end par
         $t \leftarrow t + 1$  /* next round */
    end for
     $f \leftarrow 0$  /* next phases start from 0 */
endwhile

```

Broadcast. Fig. 2 The algorithm for node i , $0 \leq i < p$ for broadcasting k blocks in a d -dimensional hypercube or fully connected network with $p = 2^d$ nodes. The algorithm requires the optimal number of $k - 1 + d$ rounds. The j th bit of i is denoted i_j and is used to determine the hypercube neighbor of node i for round j

The cost of this algorithm is within a factor two of the lower bounds for both the α and β term and is considerably simpler to implement than approaches that use pipelining.

General Graphs

Good broadcast algorithms are known for many different communication networks under various cost models. However, the problem of finding a best broadcast schedule for an arbitrary communication network is a hard problem. More precisely, the following problem of determining whether a given number of rounds suffices to broadcast in an arbitrary, given graph is NP-complete [13, Problem ND49]: Given an undirected graph $G = (V, E)$, a *root* vertex $r \in V$, and an integer k (number of rounds), is there a sequence of vertex and edge subsets $\{r\} = V_0, E_1, V_1, V_2, E_2, \dots, E_k, V_k = V$ with $V_i \subseteq V$, $E_i \subseteq E$, such that each $e \in E_i$ has one endpoint in V_{i-1} and one in V_i , no two edges of E_i share an endpoint, and $V_i = V_{i-1} \cup \{w | (v, w) \in E_i\}$?

Bibliographic Notes and Further Reading

Broadcast is one of the most thoroughly studied collective communication operations. Classical surveys with extensive treatment of broadcast (and allgather/gossiping) problems under various communication and network assumptions can be found in [11, 14]. For a survey of broadcasting in distributed systems, which raises many issues not discussed here, see [9]. Well-known algorithms that have been implemented in, for instance, Message Passing Interface (MPI) libraries include the MST algorithm, binary trees, and scatter-allgather approaches. Fibonacci trees for broadcast were explored in [6]. Another skewed, pipelined tree structure termed fractional trees that yield close to optimal results for certain ranges of p and n was proposed in [22].

The basic broadcast techniques discussed in this entry date back to the early days of parallel computing [10, 21]. The scatter/allgather algorithm was already discussed in [10] and was subsequently popularized for mesh architectures in [3]. It was further popularized for use in MPI implementations in [25]. A different implementation of this paradigm was given in [26]. Modular construction of hybrid algorithms from MST broadcast and scatter/allgather is discussed in [7].

The classical paper by Johnsson and Ho [17] introduced the simultaneous tree algorithm that was

discussed, which they call the n -ESBT algorithm. This algorithm can be used for networks that can host a hypercube and has been used in practice for hypercubes and fully connected systems. It achieves the lower bound on the number of communication rounds needed to broadcast k blocks of data. The exposition given here is based on [16, 27]. It was for a number of years an open problem how to achieve similar optimality for arbitrary p (and k). The first round-optimal algorithms were given in [2, 18], but these seem not to have been implemented. A different, explicit construction was found and described in [27], and implemented in an MPI library. A very elegant (and practical) extension of the hypercube n -ESBT algorithm to arbitrary p was presented in [16]. That algorithm uses the hypercube algorithm for the largest i such that $2^i \leq p$. Each node that is not in the hypercube is paired up with a hypercube node and the two nodes in each such pair in an alternating fashion jointly carry out the work of a hypercube node. Yet another, optimal to a lower-order term algorithm based on using two edge-disjoint binary trees was given in [23]. Disjoint spanning tree algorithms for multidimensional mesh and torus topologies were given in [28].

The linear model used for modeling communication (transfer) costs is folklore. An arguably more accurate performance model of communication networks is the so-called LogGP model (and its variants), which account more accurately for the time in which processors are involved in data transfers. With this model, yet other broadcast tree structures yield best performance [8, 24]. The so-called postal model in which a message sent at some communication round is received a number of rounds λ later at the destination was used in [1, 5] and gives rise to yet more tree algorithms.

Broadcasting in heterogeneous systems has recently received renewed attention [4, 19, 20].

Finding minimum round schedules for broadcast remain NP-hard for many special networks [15]. General approximation algorithms have been proposed for instance in [12].

BSP (Bulk Synchronous Parallelism)

ALEXANDER TISKIN

University of Warwick, Coventry, UK

Definition

Bulk-synchronous parallelism is a type of coarse-grain parallelism, where inter-processor communication follows the discipline of strict barrier synchronization. Depending on the context, BSP can be regarded as a computation model for the design and analysis of parallel algorithms, or a programming model for the development of parallel software.

Discussion

Introduction

The model of *bulk-synchronous parallel (BSP) computation* was introduced by Valiant [77] as a “bridging model” for general-purpose parallel computing.

The BSP model can be regarded as an abstraction of both parallel hardware and software, and supports an approach to parallel computation that is both architecture-independent and scalable. The main principles of BSP are the treatment of a communication medium as an abstract fully connected network, and the decoupling of all interaction between processors into point-to-point asynchronous data communication and barrier synchronization. Such a decoupling allows an explicit and independent cost analysis of local computation, communication, and synchronization, all of which are viewed as limited resources.

BSP Computation

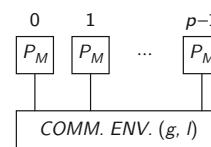

The BSP Model

A *BSP computer* (see Fig. 1) contains

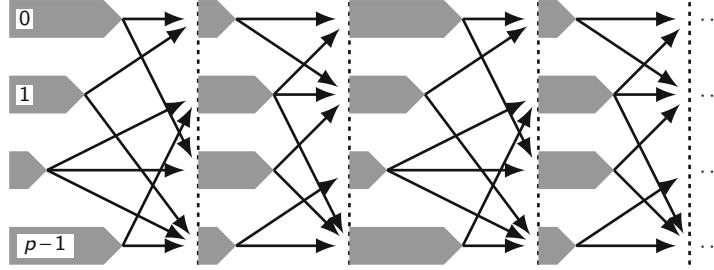

- p *Processors*; each processor has a local memory and is capable of performing an elementary operation or a local memory access every time unit.
- A *communication environment*, capable of accepting a word of data from every processor, and delivering a word of data to every processor, every g time units.
- A *barrier synchronization* mechanism, capable of synchronizing all the processors simultaneously every l time units.

The processors may follow different threads of computation, and have no means of synchronizing with one another apart from the global barriers.

A BSP computation is a sequence of *supersteps* (see Fig. 2). The processors are synchronized between supersteps; the computation within a superstep is completely asynchronous. Consider a superstep in which every processor performs a maximum of w local operations, sends a maximum of h_{out} words of data, and receives a maximum of h_{in} words of data. The value w is the *local computation cost*, and $h = h_{\text{out}} + h_{\text{in}}$ is the *communication cost* of the superstep. The total superstep cost is defined

BSP (Bulk Synchronous Parallelism). Fig. 1 The BSP computer

BSP (Bulk Synchronous Parallelism). Fig. 2 BSP computation

as $w + h \cdot g + l$, where the *communication gap* g and the *latency* l are parameters of the communication environment. For a computation comprising S supersteps with local computation costs w_s and communication costs h_s , $1 \leq s \leq S$, the total cost is $W + H \cdot g + S \cdot l$, where

- $W = \sum_{1 \leq s \leq S} w_s$ is the total *local computation cost*.
- $H = \sum_{s=1 \leq s \leq S} h_s$ is the total *communication cost*.
- S is the *synchronization cost*.

The values of W , H , and S typically depend on the number of processors p and on the problem size.

In order to utilize the computer resources efficiently, a typical BSP program regards the values p , g , and l as configuration parameters. Algorithm design should aim to minimize local computation, communication, and synchronization costs for any realistic values of these parameters. The main BSP design principles are

- Load balancing, which helps to minimize both the local computation cost W and the communication cost H
- Data locality, which helps to minimize the communication cost H
- Coarse granularity, which helps to minimize (or sometimes to trade off) the communication cost H and the synchronization cost S

The term “data locality” refers here to placing a piece of data in the local memory of a processor that “needs it most.” It has nothing to do with the locality of a processor in a specific network topology, which is actively discouraged from use in the BSP model. To distinguish these concepts, some authors use the terms “strict locality” [38] or “co-locality” [67].

The values of network parameters g , l for a specific parallel computer can be obtained by *benchmarking*. The benchmarking process is described in [8]; the

resulting lists of machine parameters can be found in [8, 63].

BSP vs Traditional Parallel Models

Traditionally, much of theoretical research in parallel algorithms has been done using the Parallel Random Access Machine (PRAM), proposed initially in [25]. This model contains

- A potentially unlimited number of *processors*, each capable of performing an elementary operation every time unit
- Global shared memory, providing uniform access for every processor to any location in one time unit

A PRAM computation proceeds in a sequence of synchronous parallel *steps*, each taking one time unit. Concurrent reading or writing of a memory location by several processors within the same step may be allowed or disallowed. The number of processors is potentially unbounded, and is often considered to be a function of the problem size. If the number of processors p is fixed, the PRAM model can be viewed as a special case of the BSP model, with $g = l = 1$ and communication realized by reading from/writing to the shared memory.

Since the number of processors in a PRAM can be unbounded, a common approach to PRAM algorithm design is to associate a different processor with every data item. Often, the processing of every item is identical; in this special case, the computation is called *data-parallel*. Programming models and languages designed for data-parallel computation can benefit significantly from the BSP approach to cost analysis; see [39] for a more detailed discussion.

It has long been recognized that in order to be practical, a model has to impose a certain structure on the

communication and/or synchronization patterns of a parallel computation. Such a structure can be provided by defining a restricted set of collective communication primitives, called *skeletons*, each with an associated cost model (see, e.g., [16]). In this context, a BSP superstep can be viewed as a simple generalized skeleton (see also [39]). However, current skeleton proposals concentrate on more specialized, and somewhat more arbitrary, skeleton sets (see, e.g., [17]).

The CTA/Phase Abstractions model [1], which underlies the ZPL language, is close in spirit to skeletons. A CTA computation consists of a sequence of *phases*, each with a simple and well-structured communication pattern. Again, the BSP model takes this approach to the extreme, where a superstep can be viewed as a phase allowing a single generic asynchronous communication pattern, with the associated cost model.

Memory Efficiency

The original definition of BSP does not account for memory as a limited resource. However, the model can be easily extended by an extra parameter m , representing the maximum capacity of each processor's local memory. Note that this approach also limits the amount of communication allowed within a superstep: $h \leq m$. One of the early examples of memory-sensitive BSP algorithm design is given by [59].

An alternative approach to reflecting memory cost is given by the model CGM, proposed in [20]. A CGM is essentially a memory-restricted BSP computer, where memory capacity and maximum superstep communication are determined by the size of the input/output: $h \leq m = O(N/p)$. A large number of algorithms have been developed for the CGM, see, e.g., [68].

Memory Management

The BSP model does not directly support shared memory, a feature that is often desirable for both algorithm design and programming. Furthermore, the BSP model does not properly address the issue of input/output, which can also be viewed as accessing an external shared memory. Virtual shared memory can be obtained by PRAM simulation, a technique introduced in [77]. An efficient simulation on a p -processor BSP computer is possible if the simulated virtual PRAM has at least

$p \log p$ processors, a requirement known as *slackness*. Memory access in the randomized simulation is made uniform by *address hashing*, which ensures a nearly random and independent distribution of virtual shared memory cells.

In the *automatic mode* of BSP programming proposed in [77] (see also [24]), shared memory simulation completely hides the network and processors' local memories. The algorithm designer and the programmer can enjoy the benefits of virtual shared memory; however, data locality is destroyed, and, as a result, performance may suffer. A useful compromise is achieved by the BSPRAM model, proposed in [70]. This model can be seen as a hybrid of BSP and PRAM, where each processor keeps its local memory, but in addition there is a uniformly accessible shared (possibly external) memory. Automatic memory management can still be achieved by the address-hashing technique of [77]; additionally, there are large classes of algorithms, identified by [70], for which simpler, slackness-free solutions are possible.

In contrast to the standard BSP model, the BSPRAM is meaningful even with a single processor ($p = 1$). In this case, it models a sequential computation that has access both to main and external memory (or the cache and the main memory). Further connections between parallel and external-memory computations are explored, e.g., in [66].

Paper [19] introduced a more elaborate model EM-BSP, where each processor, in addition to its local memory, can have access to several external disks, which may be private or shared. Paper [78] proposed a restriction of BSPRAM, called BSPGRID, where only the external memory can be used for persistent data storage between supersteps – a requirement reflecting some current trends in processor architecture. Paper [64] proposed a shared-memory model QSM, where normal processors have communication gap g , and each shared memory cell is essentially a “mini-processor” with communication gap d . Naturally, in a superstep every such “mini-processor” can “send” or “receive” at most p words (one for each normal processor), hence the model is similar to BSPRAM with communication gap g and latency $dp + l$.

Virtual shared memory is implemented in several existing or proposed programming environments offering BSP-like functionality (see, e.g., [49, 54]).

Heterogeneity

In the standard BSP model, all processors are assumed to be identical. In particular, all have the same local processing speed (which is an implicit parameter of the model), and the same communication gap g . In practice, many parallel architectures are heterogeneous, i.e., include processors with different speeds and communication performances. This fact has prompted heterogeneous extensions of the BSP model, such as HBSP [79], and HCGM [61]. Both these extended models introduce a processor's speed as an explicit parameter. Each processor has its own speed and communication gap; these two parameters can be either independent or linked (e.g., proportional). The barrier structure of a computation is kept in both models.

Other Variants of BSP

The BSP^* model [7] is a refinement of the BSP model with an alternative cost formula for small-sized h -relations. Recognizing the fact that communication of even a small amount of data incurs a constant-sized overhead, the model introduces a parameter b , defined as the minimum communication cost of any, even zero-sized, h -relation. Since the overhead reflected by the parameter b can also be counted as part of superstep latency, the BSP^* computer with communication gap g and latency l is asymptotically equivalent to a standard BSP computer with gap g and latency $l + b$.

The E-BSP model [46] is another refinement of the BSP model, where the cost of a superstep is parameterized separately by the maximum amount of data sent, the maximum amount of data received, the total volume of communicated data, and the network-specific maximum distance of data travel. The OBSP * model [10] is an elaborate extension of BSP, which accounts for varying computation costs of individual instructions, and allows the processors to run asynchronously while maintaining “logical supersteps”. While E-BSP and OBSP * may be more accurate on some architectures (in [46], a linear array and a 2D mesh are considered), they lack the generality and simplicity of pure BSP. A simplified version of E-BSP, asymptotically equivalent to pure BSP, is defined in [47].

The PRO approach [26] is introduced as another parallel computation model, but can perhaps be better understood as an alternative BSP algorithm design philosophy. It requires that algorithms are work-optimal,

disregards point-to-point communication efficiency by setting $g = 1$, and instead puts the emphasis on synchronization efficiency and memory optimality.

BSP Algorithms

Basic Algorithms

As a simple parallel computation model, BSP lends itself to the design of efficient, well-structured algorithms. The aim of BSP algorithm design is to minimize the resource consumption of the BSP computer: the local computation cost W , the communication cost H , the synchronization cost S , and also sometimes the memory cost M . Since the aim of parallel computation is to obtain speedup over sequential execution, it is natural to require that a BSP algorithm should be work-optimal relative to a particular “reasonable” sequential algorithm, i.e., the local computation cost W should be proportional to the running time of the sequential algorithm, divided by p . It is also natural to allow a reasonable amount of slackness: an algorithm only needs to be efficient for $n \gg p$, where n is the problem size. The asymptotic dependence of the minimum value of n on the number of processors p must be clearly specified by the algorithm.

Assuming that a designated processor holds a value a , the *broadcasting* problem asks that a copy of a is obtained by every processor. Two natural solutions are possible: either direct or binary tree broadcast.

In the direct broadcast method, a designated processor makes $p - 1$ copies of a and sends them directly to the destinations. The BSP costs are $W = O(p)$, $H = O(p)$, $S = O(1)$. In the binary tree method, initially, the designated processor is defined as being *awake*, and the other processors as *sleeping*. The processors are woken up in $\log p$ rounds. In every round, every awake processor makes a copy of a and sends it to a sleeping processor, waking it up. The BSP costs are $W = O(p)$, $H = O(\log p)$, $S = O(\log p)$. Thus, there is a trade-off between the direct and the binary tree broadcast methods, and no single method is optimal (see [30, 77]).

The *array broadcasting* problem asks, instead of a single value, to broadcast an array a of size $n \geq p$. In contrast with the ordinary broadcast problem, there exists an optimal method for array broadcast, known as two-phase broadcast (a folklore result, described, e.g., in [8]). In this method, the array is partitioned into p

blocks of size n/p . The blocks are scattered across the processors; then, a total-exchange of the blocks is performed. Assuming sufficient slackness, the BSP costs are $W = O(n/p)$, $H = O(n/p)$, $S = O(1)$.

Many computational problems can be described as computing a directed acyclic graph (dag), which characterizes the problem's data dependencies. From now on, it is assumed that a BSP algorithm's input and output are stored in the external memory. It is also assumed that all problem instances have sufficient slackness.

The *balanced binary tree dag* of size n consists of $2n - 1$ nodes, arranged in a rooted balanced binary tree with n leaves. The direction of all edges can be either top-down (from root to leaves), or bottom-up (from leaves to root). By partitioning into appropriate blocks, the balanced binary tree dag can be computed with BSP costs $W = O(n/p)$, $H = O(n/p)$, $S = O(1)$ (see [8, 77]).

The *butterfly dag* of size n consists of $n \log n$ nodes, and describes the data dependencies of the Fast Fourier Transform algorithm on n points. By partitioning into appropriate blocks, the butterfly dag can be computed with BSP costs $W = O(n \log n/p)$, $H = O(n/p)$, $S = O(1)$ (see [8, 77]).

The *ordered 2D grid dag* of size n consists of n^2 nodes arranged in an $n \times n$ grid, with edges directed top-to-bottom and left-to-right. The computation takes $2n$ inputs to the nodes on the left and top borders, and returns $2n$ outputs from the nodes on the right and bottom borders. By partitioning into appropriate blocks, the ordered 2D grid dag can be computed with BSP costs $W = O(n^2/p)$, $H = O(n)$, $S = O(p)$ (see [57]).

The *ordered 3D grid dag* of size n consists of n^3 nodes arranged in an $n \times n \times n$ grid, with edges directed top-to-bottom, left-to-right, and front-to-back. The computation takes $3n^2$ inputs to the nodes on the front, left, and top faces, and returns $3n^2$ outputs from the nodes on the back, right, and bottom faces. By partitioning into appropriate blocks, the ordered 3D grid dag can be computed with BSP costs $W = O(n^3/p)$, $H = O(n^2/p^{1/2})$, $S = O(p^{1/2})$ (see [57]).

Further Algorithms

The design of efficient BSP algorithms has become a well-established topic. Some examples of BSP algorithms proposed in the past include list and tree contraction [29], sorting [28, 30, 32, 70, 77], convex hull

computation [15, 21, 23, 32, 45, 65, 73], and selection [28, 76]. In the area of matrix algorithms, some examples of the proposed algorithms include matrix–vector and matrix–matrix multiplication [9, 56, 59], Strassen-type matrix multiplication [59], triangular system solution and several versions of Gaussian elimination [30, 56, 75], and orthogonal matrix decomposition [13, 75]. In the area of graph algorithms, some examples of the proposed algorithms include Boolean matrix multiplication [69], minimum spanning tree [12], transitive closure [2], the algebraic path problem and the all-pairs shortest path problems [71], and graph coloring [27]. In the area of string algorithms, some examples of the proposed algorithms include the longest common subsequence and edit distance problems [3–5, 51, 53, 74], and the longest increasing subsequence problem [52].

BSP Programming

The BSPlib Standard

Based on the experience of early BSP programming tools [34, 58, 60], the BSP programming community agreed on a common library standard *BSPlib* [42]. The aim of BSPlib is to provide a set of BSP programming primitives, striking a reasonable balance between simplicity and efficiency. BSPlib is based on the *single program/multiple data* (SPMD) programming model, and contains communication primitives for *direct remote memory access* (DRMA) and *bulk-synchronous message passing* (BSMP). Experience shows that DRMA, due to its simplicity and deadlock-free semantics, is the method of choice for all but the most irregular applications. Routine use of DRMA is made possible by the barrier synchronization structure of BSP computation.

The two currently existing major implementations of BSPlib are *the Oxford BSP toolset* [63] and *the PUB library* [11]. Both provide a robust environment for the development of BSPlib applications, including mechanisms for optimizing communication [22, 43], load balancing, and fault tolerance [40]. The PUB library also provides a few additional primitives (oblivious synchronization, processor subsets, multithreading). Both the Oxford BSP toolset and the PUB library include tools for performance analysis and prediction. Recently, new approaches have been developed to BSPlib implementation [48, 50, 62] and performance analysis [41, 80].

Beyond BSPlib

The Message Passing Interface (MPI) is currently the most widely accepted standard of distributed-memory parallel programming. In contrast to BSPlib, which is based on a single programming paradigm, MPI provides a diverse set of parallel programming patterns, allowing the programmer to pick-and-choose a paradigm most suitable for the application. Consequently, the number of primitives in MPI is an order of magnitude larger than in BSPlib, and the responsibility to choose the correct subset of primitives and to structure the code rests with the programmer. It is not surprising that a carefully chosen subset of MPI can be used to program in the BSP style; an example of such an approach is given by [8].

The ZPL language [14] is a global-view array language based on a BSP-like computation structure. As such, it can be considered to be one of the earliest high-level BSP programming tools. Another growing trend is the integration of the BSP model with modern programming environments. A successful example of integrating BSP with Python is given by the package Scientific Python [44], which provides high-level facilities for writing BSP code, and performs communication by calls to either BSPlib or MPI. Tools for BSP programming in Java have been developed by projects NestStep [49] and JBSP [35]; a Java-like multi-threaded BSP programming model is proposed in [72]. A functional programming model for BSP is given by the BSMLlib library [36]; a constraint programming approach is introduced in [6]. Projects InteGrade [31] and GridNestStep [55] are aiming to implement the BSP model using Grid technology.

Synonyms

Bus: Shared channel; Shared interconnect; Shared-medium network; Crossbar; Interconnection network; Point-to-point switch; Switched-medium network

Definition

Bus: A bus is a shared interconnect used for connecting multiple components of a computer on a single chip or across multiple chips. Connected entities either place signals on the bus or listen to signals being transmitted on the bus, but signals from only one entity at a time can be transported by the bus at any given time. Buses are popular communication media for broadcasts in computer systems.

Crossbar: A crossbar is a non-blocking switching element with N inputs and M outputs used for connecting multiple components of a computer where, typically, $N = M$. The crossbar can simultaneously transport signals on any of the N inputs to any of the M outputs as long as multiple signals do not compete for the same input or output port. Crossbars are commonly used as basic switching elements in switched-media network routers.

Discussion

Introduction

Every computer system is made up of numerous components such as processor chips, memory chips, peripherals, etc. These components communicate with each other via interconnects. One of the simplest interconnects used in computer systems is the *bus*. The bus is a shared medium (usually a collection of electrical

wires) that allows one sender at a time to communicate with all sharers of that medium. If the interconnect must support multiple simultaneous senders, more scalable designs based on switched-media must be pursued. The *crossbar* represents a basic switched-media building block for more complex but scalable networks.

In traditional multi-chip multiprocessor systems (c. 2000), buses were primarily used as off-chip interconnects, for example, front-side buses. Similarly, crossbar functionality was implemented on chips that were used mainly for networking. However, the move to multi-core technology has necessitated the use of networks even within a mainstream processor chip to connect its multiple cores and cache banks. Therefore, buses and crossbars are now used within mainstream processor chips as well as chip sets. The design constraints for on-chip buses are very different from those of off-chip buses. Much of this discussion will focus on on-chip buses, which continue to be the subject of much research and development.

Basics of Bus Design

A bus comprises a shared medium with connections to multiple entities. An interface circuit allows each of the entities either to place signals on the medium or sense (listen to) the signals already present on the medium. In a typical communication, one of the entities acquires ownership of the bus (the entity is now known as the *bus master*) and places signals on the bus. Every other entity senses these signals and, depending on the content of the signals, may choose to accept or discard them. Most buses today are *synchronous*, that is, the start and end of a transmission are clearly defined by the edges of a shared clock. An *asynchronous* bus would require an acknowledgment from the receiver so the sender knows when the bus can be relinquished.

Buses often are collections of electrical wires, (Alternatively, buses can be a collection of optical waveguides over which information is transmitted phototonically [9]) where each wire is typically organized as “data,” “address,” or “control.” In most systems, networks are used to move messages among entities on the *data* bus; the *address* bus specifies the entity that must receive the message; and the *control* bus carries auxiliary signals such as arbitration requests and error correction codes. There is another nomenclature that readers may also encounter. If the network is used to implement a

cache coherence protocol, the protocol itself has three types of messages: (1) *DATA*, which refers to blocks of memory; (2) *ADDRESS*, which refers to the memory block's address; and (3) *CONTROL*, which refers to auxiliary messages in the protocol such as acknowledgments. Capitalized terms as above will be used to distinguish message types in the coherence protocol from signal types on the bus. For now, it will be assumed that all three protocol message types are transmitted on the *data* bus.

Arbitration Protocols

Since a bus is a shared medium that allows a single master at a time, an arbitration protocol is required to identify this bus master. A simple arbitration protocol can allow every entity to have ownership of the bus for a fixed time quantum, in a round-robin manner. Thus, every entity can make a local decision on when to transmit. However, this wastes bus bandwidth when an entity has nothing to transmit during its turn.

The most common arbitration protocol employs a central arbiter; entities must send their bus requests to the arbiter and the arbiter sends explicit messages to grant the bus to requesters. If the requesting entity is not aware of its data bus occupancy time beforehand, the entity must also send a bus release message to the arbiter after it is done. The request, grant, and release signals are part of the control network. The request signal is usually carried on a dedicated wire between an entity and the arbiter. The grant signal can also be implemented similarly, or as a shared bus that carries the ID of the grantee. The arbiter has state to track data bus occupancy, buffers to store pending requests, and policies to implement priority or fairness. The use of pipelining to hide arbitration delays will be discussed shortly.

Arbitration can also be done in a distributed manner [5], but such methods often incur latency or bandwidth penalties. In one example, a shared arbitration bus is implemented with wired-OR signals. Multiple entities can place a signal on the bus; if any entity places a “one” on the bus, the bus carries “one,” thus using wires to implement the logic of an *OR* gate. To arbitrate, all entities place their IDs on the arbitration bus; the resulting signal is the OR of all requesting IDs. The bus is granted to the entity with the largest ID and this is determined by having each entity sequentially drop

out if it can determine that it is not the largest ID in the competition.

B

Pipelined Bus

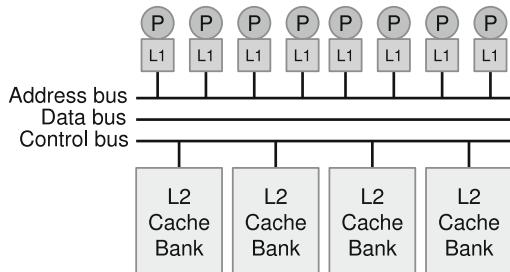

Before a bus transaction can begin, an entity must arbitrate for the bus, typically by contacting a centralized arbiter. The latency of request and grant signals can be hidden with pipelining. In essence, the arbitration process (that is handled on the *control* bus) is overlapped with the data transmission of an earlier message. An entity can send a bus request to the arbiter at any time. The arbiter buffers this request, keeps track of occupancy on the *data* bus, and sends the grant signal one cycle before the *data* bus will be free. In a heavily loaded network, the *data* bus will therefore rarely be idle and the arbitration delay is completely hidden by the wait for the *data* bus. In a lightly loaded network, pipelining will not hide the arbitration delay, which is typically at least three cycles: one cycle for the request signal, one cycle for logic at the arbiter, and one cycle for the grant signal.

Case Study: Snooping-Based Cache Coherence Protocols

As stated earlier, the bus is a vehicle for transmission of messages within a higher-level protocol such as a cache coherence protocol. A single *transaction* within the higher-level protocol may require multiple messages on the bus. Very often, the higher-level protocol and the bus are codesigned to improve efficiency. Therefore, as a case study, a snooping bus-based coherence protocol will be discussed.

Consider a single-chip multiprocessor where each processor core has a private L1 cache, and a large L2 cache is shared by all the cores. The multiple L1 caches and the multiple banks of the L2 cache are the entities connected to a shared bus (Fig. 1). The higher-level coherence protocol ensures that data in the L1 and L2 caches is kept coherent, that is, a data modification is eventually seen by all caches and multiple updates to one block are seen by all caches in exactly the same order.

A number of coherence protocol operations will now be discussed. When a core does not find its data in its local L1 cache, it must send a request for the data block to other L1 caches and the L2 cache. The core's L1 cache first sends an arbitration request for the bus to the

Buses and Crossbars. Fig. 1 Cores and L2 cache banks connected with a bus. The bus is composed of wires that handle data, address, and control

arbiter. The arbiter eventually sends the grant signal to the requesting L1. The arbitration is done on the *control* portion of the bus. The L1 then places the ADDRESS of the requested data block on the *data* bus. On a synchronous bus, we are guaranteed that every other entity has seen the request within one bus cycle. Each such “snooping” entity now checks its L1 cache or L2 bank to see if it has a copy of the requested block. Since every lookup may take a different amount of time, a wired-AND signal is provided within the *control* bus so everyone knows that the snoop is completed. This is an example of bus and protocol codesign (a protocol CONTROL message being implemented on the bus’ *control* bus). The protocol requires that an L1 cache respond with data if it has the block in “modified” state, else, the L2 cache responds with data. This is determined with a wired-OR signal; all L1 caches place the outcome of their snoop on this wired-OR signal and the L2 cache accordingly determines if it must respond. The responding entity then fetches data from its arrays and places it on the *data* bus. Since the bus is not released until the end of the entire coherence protocol transaction, the responder knows that the *data* bus is idle and need not engage in arbitration (another example of protocol and bus codesign). *Control* signals let the requester know that the data is available and the requester reads the cache block off the bus.

The use of a bus greatly simplifies the coherence protocol. It serves as a serialization point for all coherence transactions. The timing of when an operation is visible to everyone is well known. The broadcast of operations allows every cache on the bus to be self-managing. Snooping bus-based protocols are therefore

much simpler than directory-based protocols on more scalable networks.

As described, each coherence transaction is handled atomically, that is, one transaction is handled completely before the bus is released for use by other transactions. This means that the *data* bus is often idle while caches perform their snoops and array reads. Bus utilization can be improved with a *split transaction bus*. Once the requester has placed its request on the *data* bus, the *data* bus is released for use by other transactions. Other transactions can now use the *data* bus for their requests or responses. When a transaction’s response is ready, the *data* bus must be arbitrated for. Every request and response must now carry a small tag so responses can be matched up to their requests. Additional tags may also be required to match the wired-OR signals to the request.

The split transaction bus design can be taken one step further. Separate buses can be implemented for ADDRESS and DATA messages. All requests (ADDRESS messages) and corresponding wired-OR CONTROL signals are carried on one bus. This bus acts as the serialization point for the coherence protocol. Responders always use a separate bus to return DATA messages. Each bus has its own separate arbiter and corresponding control signals.

Bus Scalability

A primary concern with any bus is its lack of scalability. First, if many entities are connected to a bus, the bus speed reduces because it must drive a heavier load over a longer distance. In an electrical bus, the higher capacitive load from multiple entities increases the RC-delay; in an optical bus, the reduced photons received at photodetectors from dividing the optical power budget among multiple entities likewise increases the time to detect bus signals. Second, with many entities competing for the shared bus, the wait-time to access the bus increases with the number of entities. Therefore, conventional wisdom states that more scalable switched-media networks are preferred when connecting much more than 8 or 16 entities [4]. However, the simplicity of bus-based protocols (such as the snooping-based cache coherence protocol) make it attractive for small- or medium-scale symmetric multiprocessing (SMP) systems. For example, the IBM POWER7™ processor chip supports 8 cores on its SMP bus [12]. Buses

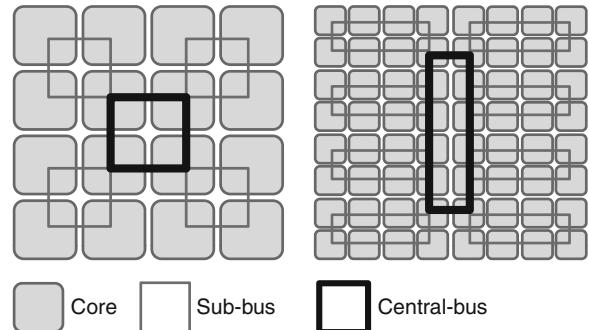

are also attractive because, unlike switched-media networks, they do not require energy-hungry structures such as buffers and crossbars. Researchers have considered multiple innovations to extend the scalability of buses, some of which are discussed next.

One way to scale the number of entities connected using buses is, simply, to provide multiple buses, for example, dual-independent buses or quad-independent buses. This mitigates the second problem listed above regarding the high rate of contention on a single bus, but steps must still be taken to maintain cache coherency via snooping on the buses. The Sun Starfire multiprocessor [3], for example, uses four parallel buses for ADDRESS requests, wherein each bus handles a different range of addresses. Tens of dedicated buses are used to connect up to 32 IBM POWER7TM processor chips in a coherent SMP system [12]. While this option has high cost for off-chip buses because of pin and wiring limitations, a multi-bus for an on-chip network is not as onerous because of plentiful metal area budgets.

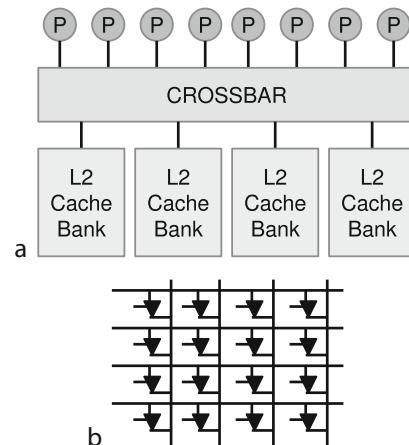

Some recent works have highlighted the potential of bus-based on-chip networks. Das et al. [6] argue that buses should be used within a relatively small cluster of cores because of their superior latency, power, and simplicity. The buses are connected with a routed mesh network that is employed for communication beyond the cluster. The mesh network is exercised infrequently because most applications exhibit locality. Udupi et al. [14] take this hierarchical network approach one step further. As shown in Fig. 2, the intra-cluster buses are themselves connected with an inter-cluster bus. Bloom filters are used to track the buses that have previously handled a given address. When coherence transactions are initiated for that address, the Bloom filters ensure that the transaction is broadcasted only to the buses that may find the address relevant. Locality optimizations such as page coloring help ensure that bus broadcasts do not travel far, on average. Udupi et al. also employ multiple buses and low-swing wiring to further extend bus scalability in terms of performance and energy.

Crossbars

Buses are used as a shared fabric for communication among multiple entities. Communication on a bus

Buses and Crossbars. Fig. 2 A hierarchical bus structure that localizes broadcasts to relevant clusters

Buses and Crossbars. Fig. 3 (a) A "dance-hall" configuration of processors and memory. (b) The circuit for a 4 × 4 crossbar

is always broadcast-style, *i.e.*, even though a message is going from entity-A to entity-B, all entities see the message and no other message can be simultaneously in transit. However, if the entities form a "dance hall" configuration (Fig. 3a) with processors on one side and memory on the other side, and most communication is between processors and memory, a crossbar interconnect becomes a compelling choice. Although crossbars incur a higher wiring overhead than buses, they allow multiple messages simultaneously to be in transit, thus increasing the network bandwidth. Given this, crossbars serve as the basic switching element within switched-media network routers.

A crossbar circuit takes N inputs and connects each input to any of the M possible outputs. As shown in Fig. 3b, the circuit is organized as a grid of wires, with inputs on the left, and outputs on the bottom. Each wire can be thought of as a bus with a unique master, that is, the associated input port. At every intersection of wires, a pass transistor serves as a *crosspoint connector* to short the two wires, if enabled, connecting the input to the output. Small buffers can also be located at the crosspoints in *buffered crossbar* implementations to store messages temporarily in the event of contention for the intended output port. A crossbar is usually controlled by a centralized arbiter that takes output port requests from incoming messages and computes a viable assignment of input port to output port connections. This, for example, can be done in a crossbar *switch allocation* stage prior to a crossbar *switch traversal* stage for message transport. Multiple messages can be simultaneously in transit as long as each message is headed to a unique output and each emanates from a unique input. Thus, the crossbar is *non-blocking*. Some implementations allow a single input message to be routed to multiple output ports.

A crossbar circuit has a cost that is proportional to $N \times M$. The circuit is replicated W times, where W represents the width of the link at one of the input ports. It is therefore not a very scalable circuit. In fact, larger centralized switches such as Butterfly and Benes switch fabrics are constructed hierarchically from smaller crossbars to form *multistage indirect networks* or *MINs*. Such networks have a cost that is proportional to $N \log(M)$ but have a more restrictive set of messages that can be routed simultaneously without blocking.

A well-known example of a large-scale on-chip crossbar is the Sun Niagara processor [10]. The crossbar connects eight processors to four L2 cache banks in a “dance-hall” configuration. A recent example of using a crossbar to interconnect processor cores in other switched point-to-point configurations is the Intel QuickPath Interconnect [7]. More generally, crossbars find extensive use in network routers. Meshes and tori, for example, implement a 5×5 crossbar in router switches where the five input and output ports correspond to the North, South, East, West neighbors and the node connected to each router. The mesh-connected Tilera Tile-GxTM 100-core processor is a recent example [13].

Bibliographic Notes and Further Reading

For more details on bus design and other networks, readers are referred to the excellent textbook by Dally and Towles [5]. Recent papers in the architecture community that focus on bus design include those by Udupi et al. [14], Das et al. [6], and Kumar et al. [11]. Kumar et al. [11] articulate some of the costs of implementing buses and crossbars in multi-core processors and argue that the network must be codesigned with the core and caches for optimal performance and power. A few years back, S. Borkar made a compelling argument for the widespread use of buses within multi-core chips that is highly thought provoking [1, 2]. The paper by Charlesworth [3] on Sun’s Starfire, while more than a decade old, is an excellent reference that describes considerations when designing a high-performance bus for a multi-chip multiprocessor. Future many-core processors may adopt photonic interconnects to satisfy the high memory bandwidth demands of the many cores. A single photonic waveguide can carry many wavelengths of light, each carrying a stream of data. Many receiver “rings” can listen to the data transmission, each ring contributing to some loss in optical energy. The Corona paper by Vantrease et al. [15] and the paper by Kirman et al. [9] are excellent references for more details on silicon photonics, optical buses, and optical crossbars.

The basic crossbar circuit has undergone little change over the last several years. However, given the recent interest in high-radix routers which increase the input/output-port degree of the crossbar used as the internal router switch, Kim et al. [8] proposed hierarchical crossbar and buffered crossbar organizations to facilitate scalability. Also, given the relatively recent shift

in focus to energy-efficient on-chip networks, Wang et al. [16] proposed techniques to reduce the energy usage within crossbar circuits. They introduced a cut-through crossbar that is optimized for traffic that travels in a straight line through a mesh network's router. The design places some restrictions on the types of message turns that can be simultaneously handled. Wang et al. also introduce a segmented crossbar that prevents switching across the entire length of wires when possible.

C

C*

GUY L. STEELE JR.
Oracle Labs, Burlington, MA, USA

Definition

C* (pronounced “see-star”) refers to two distinct data-parallel dialects of C developed by Thinking Machines Corporation for its Connection Machine supercomputers. The first version (1987) is organized around the declaration of *domains*, similar to classes in C++, but when code associated with a domain is activated, it is executed in parallel within *all* instances of the domain, not just a single designated instance. Compound assignment operators such as `+ =` are extended in C* to perform parallel reduction operations. An elaborate theory of control flow allows use of C control statements in a MIMD-like, yet predictable, fashion despite the fact that the underlying execution model is SIMD. The revised version (1991) replaces domains with *shapes* that organize processors into multidimensional arrays and abandons the MIMD-like control-flow theory.

Discussion

Of the four programming languages (*Lisp, C*, CM Fortran, and CM-Lisp) provided by Thinking Machines Corporation for Connection Machine Systems, C* was the most clever (indeed, perhaps too clever) in trying to extend features of an already existing sequential language for parallel execution. To quote the language designers:

- ▶ C* is an extension of the C programming language designed to support programming in the data parallel style, in which the programmer writes code as if a processor were associated with every data element. C* features a single new data type (based on classes in C++), a synchronous execution model, and a minimal number of extensions to C statement and expression

syntax. Rather than introducing a plethora of new language constructs to express parallelism, C* relies on existing C operators, applied to parallel data, to express such notions as broadcasting, reduction, and interprocessor communication in both regular and irregular patterns [5, 6, 8].

The original proposed name for the language was *C, not only by analogy with *Lisp, but with a view for the potential of making a similarly data-parallel extension to the C++ language, which would then naturally be called *C++. However, the marketing department of Thinking Machines Corporation decided that “C*” sounded better. This inconsistency in the placement of the “*” did confuse many Thinking Machines customers and others, resulting in frequent references to “*C” anyway, and even to “Lisp*” on occasion.

The Initial Design of C*

The basic idea was to start with the C programming language and then augment it with the ability to declare something like a C++ class, but with the keyword `class` replaced with the keyword `domain`. As in C++, a domain could have functions as well as variables as members. However, the notion of method invocation (calling a member function on a single specific instance) was replaced by the notion of domain activation (calling a member function, or executing code, on *all instances* simultaneously and synchronously). Everything else in the language was driven by that one design decision, that one metaphor.

Two new keywords, `mono` and `poly`, were introduced to describe in which memory data resided – the front-end computer or the Connection Machine processors, respectively. Variables declared within sequential code were `mono` by default, and variables declared within parallel code were `poly` by default, so the principal use of these keywords was in describing pointer types; for example, the declaration

```
mono int *poly p;
```

indicates that p is a poly pointer to a mono int (i.e., p holds many values, all stored in the Connection Machine processors, one in each instance of the current domain; and each of these values is a pointer to an integer that resides in the front-end processor, but each of these pointers might point to a different front-end integer).

C^* systematically extended the standard operators in C to have parallel semantics by applying two rules: (1) if a binary operator has a scalar operand and a parallel operand, the scalar value is automatically replicated to form a parallel value (an idea previously seen in both APL and Fortran 8x), and (2) an operator applied to parallel operands is executed for all active processors *as if* in some serial order. In this way, binary operators such as $+$ and $-$ and $\%$ can be applied elementwise to many sets of operands at once, and binary operators with side effects – the compound assignment operators – are guaranteed to have predictable sensible behavior; e.g., if a is a scalar variable and b is a parallel variable, then the effect of $a += b$ is to add every active element of b into a , because it must behave as if each active element of b were added into a in some sequential order. (In practice, the implementation used a parallel algorithm to sum the elements of b and then added that sum into a .)

C^* makes two extensions to the standard set of C operators, both motivated by a desire to extend the parallel functionality provided by the standard operators in a consistent manner. Two common arithmetic operations, \min and \max , are provided in C as preprocessor macros rather than as operators; one disadvantage of a macro is that it cannot be used as part of a compound assignment operator, and so one cannot write $a \max= b$ in the same way that one can write $a += b$. C^* introduces operators $<?$ and $>?$ to serve as \min and \max operations. The designers commented:

- ▶ They may be understood in terms of their traditional macro definitions

```
a <? b means ((a) < (b)) ? (a) : (b)
a >? b means ((a) > (b)) ? (a) : (b)
```

but of course the operators, unlike the macro definitions, evaluate each argument exactly once. The operators $<?$ and $>?$ are intended as mnemonic reminders of these definitions. (Such mnemonic reminders are important. The original design of C^* used $><$ and $<>$

for the maximum and minimum operators. We quickly discovered that users had some difficulty remembering which was which.) [5, 6]

In addition, most of the binary compound operators are pressed into service as unary reduction operators. Thus $+ = b$ computes the sum of all the active values in b and returns that sum as a mono value; similarly $>=? b$ finds the largest active value in b .

C^* also added a modulus operator $\% \%$ because of the great utility of modulus, as distinguished from the remainder operator $\%$, in performing array index calculations: when k is zero, the expression $(k - 1) \% n$ produces a much more useful result, namely, $k - 1$, than does the expression $(k - 1) \% n$, which produces -1 .

Because a processor can contain pointers to variables residing in other processors, interprocessor communication can be expressed simply by dereferencing such pointers. Thus if p is a poly pointer to a poly int, then $*p$ causes each active processor to fetch an int value through its own p pointer, and $*p = b$ causes each active processor to store its b value indirectly through p (thus “sending a message” to some other processor). The “combining router” feature of the Connection Machine could be invoked by an expression such as $*p += b$, which might cause the b values to be sent to some smaller number of destinations, resulting in the summing (in parallel) of various subsets of the b values into the various individual destinations.

C^* has an elaborate theory of implicitly synchronized control flow that allows the programmer to code, for the most part, as if each Connection Machine processor were executing its own copy of parallel code independently as if it were ordinary sequential C code. The idea is that each processor has its own program counter (a “virtual PC”), but can make no progress until a “master PC” arrives at that point in the code, at which point that virtual PC (as well every other virtual PC waiting at that particular code location) becomes active, joining the master PC and participating in SIMD execution. Whenever the master PC reaches a conditional branch, each active virtual PC that takes the branch becomes inactive (thus, e.g., in an `if` statement, after evaluation of the test expression, processors that need to execute the `else` part take an implicit branch to the `else` part and wait while other processors possibly

proceed to execute the “then” part). Whenever the master PC reaches the end of a statement, every virtual PC becomes inactive, and the master PC is transferred from the current point to a new point in the code, namely, the *earliest* point that has waiting program counters, within the *innermost* statement that has waiting program counters within it, that contains the current point. Frequently this new point is the same as the current point, and frequently this fact can be determined at compile time; but in general the effect is to keep trying to pull lagging program counters forward, in such a way that once the master PC enters a block, it does not leave the block until every virtual PC has left the block. Thus this execution rule respects block structure (and subroutine call structure) in a natural manner, while allowing the programmer to make arbitrary use of `goto` statements if desired. (This theory of control flow was inspired by earlier investigations of a SIMD-like theory giving rise to a superficially MIMD-like control structure in Connection Machine Lisp [7].)

A compiler for this version of C* was independently implemented at the University of New Hampshire [4] for a MIMD multicomputer (an N-Cube 3200, whose processors communicated by message passing through a hypercube network).

Figure 1 shows an early (1987) example of a C* program that identifies prime numbers by the method of the Sieve of Eratosthenes, taken (with one minor correction) from [10]. In typical C style, `N` is defined to be a preprocessor name that expands to the integer literal `100000`. The name `bit` is then defined to be a synonym for the type of 1-bit integers. The `domain` declaration defines a parallel processing domain named `SIEVE` that has a field named `prime` of type `bit`, and then declares an array named `sieve` of length `N`, each element of which is an instance of this domain. (This single statement could instead have been written as two statements:

```
domain SIEVE { bit prime; };
domain SIEVE sieve[N];
```

In this respect `domain` declarations are very much like C `struct` declarations.) The function `find_primes` is declared within the domain `SIEVE`, so when it is called, its body is executed within every instance of that domain, with a distinct virtual processor of the Connection Machine containing and processing

each such instance. The “magic identifier” `this` is a pointer to the current domain instance, and its value is therefore different within each executing instance; subtracting from it a pointer to the first instance in the array, namely, `&sieve[0]`, produces the index of that instance within the `sieve` array, by the usual process of C pointer arithmetic. Local variables `value` and `candidate` are declared within each instance of the domain, and therefore are parallel values. The `while` statement behaves in such a way that different domain instances can execute different number of iterations, as appropriate to the data within that instance; when an active instance computes a zero (false) value for the test expression `candidate`, that instance simply becomes inactive. When all instances have become inactive, then the `while` statement completes after making active exactly those instances that had been active when execution of the `while` statement began. The `mono` storage class keyword indicates that a variable should be allocated just once (in the front-end processor), not once within each domain instance. The unary operator `<?=` is the minimum-reduction operator, so the expression `(<?= value)` returns the smallest integer that any active domain instance holds in its `value` variable. The array `sieve` can be indexed in the normal C fashion, by either a `mono` (front-end) index, as in this example code, or by a `poly` (parallel) value, which can be used to perform inter-domain (i.e., inter-processor) communication. The `if` statement is handled in much the same way as the `while` statement: If an active instance computes a zero (false) value for the test expression `candidate`, that instance simply becomes inactive during execution of the “then” part of the `if` statement, and then becomes active again. (If an `if` statement has an `else` part, then processors that had been active for the “then” part become temporarily inactive during execution of the `else` part.).

The Revised Design of C*

In 1991, the C* language was revised substantially [1] to produce version 6.0; this version was initially implemented for the Connection Machine model CM-2 [9, 10] and later for the model CM-200 as well as the model CM-5 [11, 56]. This revised design was intended to be closer in style to ANSI C than to C++. The biggest change was to introduce the notion of a *shape*,

```

#define N 100000

typedef int bit:1;

domain SIEVE { bit prime; } sieve[N];

void SIEVE::find_primes() {
    int value = this - &sieve[0];
    bit candidate = (value >= 2);
    prime = 0;
    while (candidate) {
        mono int next_prime = (<?= value);
        sieve[next_prime].prime = 1;
        if (value % next_prime == 0) candidate = 0;
    }
}

```

C*. Fig. 1 Example version 5 C* program for identifying prime numbers

which essentially describes a (possibly multidimensional) array of virtual processors. An ordinary variable declaration may be tagged with the name of a shape, which indicates that the declaration is replicated for parallel processing, one instance for each position in the shape. Where the initial design of C* required that *all* instances of a domain be processed in parallel, the new design allows declaration of several different shapes (parallel arrays) having the same data layout, and different shapes may be chosen at different times for parallel execution. Parallel execution is initiated using a newly introduced *with* statement that specifies a shape:

with (shape) statement

The *statement* is executed with the specified *shape* as the “current shape” for parallel execution. C operators may be applied to parallel data much as in the original version of C*, but such data must have the current shape (a requirement enforced by the compiler at compile time).

Positions within shapes may be selected by indexing. In order to distinguish shape indexing from ordinary array indexing, shape subscripts are written to the left rather than to the right. Given these declarations:

```

shape [16] [16] [16] cube;
float:cube z;
int:cube a[10] [10];

```

then *cube* is a three-dimensional shape having 4,096 ($16 \times 16 \times 16$) distinct positions, *z* is a parallel variable consisting of one *float* value at each of these 4,096 shape positions, and *a* is a parallel array variable that has a 10×10 array of *int* values at each of 4,096 shape positions (for a total of 4,09,600 distinct *int* values). Then [3] [13] [5] *z* refers to one particular *float* value within *z* at position (3,13,5) within the *cube* shape, and [3] [13] [5] *a* [4] [7] refers to one particular *int* element within the particular 10×10 array at that same position. One may also write [3] [13] [5] *a* to refer to (the address of) that same 10×10 array. (This use of left subscripts to index “across processors” and right subscripts to index “within a processor” may be compared to the use of square brackets and parentheses to distinguish two sorts of subscript in Co-Array Fortran [3].)

Although pointers can be used for interprocessor communication exactly as in earlier versions of C*, such communication is more conveniently expressed in C* version 6.0 by shape indexing (writing [i] [j] [k] *z* = *b* rather than **p* = *b*, for example), thus affording a more array-oriented style of programming. Furthermore, version 6.0 of C* abandons the entire “master program counter” execution model that allowed all C control structures to be used for parallel execution. Instead, statements such as *if*, *while*, and *switch* are restricted to test nonparallel values, and a

newly introduced `where` statement tests parallel values, behaving very much like the `where` statement in Fortran 90. The net effect of all these revisions is to give version 6.0 of C* an execution model and programming style more closely resembling those of *Lisp and CM Fortran.

Figure 2 shows a rewriting of the code in Fig. 1 into C* version 6.0. The domain declaration is replaced by a `shape` declaration that specifies a one-dimensional shape named `SIEVE` of size `N`. The global variable `prime` of type `bit` is declared within shape `SIEVE`. The function `find_primes` is no longer declared within a domain. When it is called, the `with` statement establishes `SIEVE` as the current shape for parallel execution; conceptually, a distinct virtual processor of the Connection Machine is associated with each position in the current shape. The function `pcoord` takes an integer specifying an axis number and returns, at each position of the current shape, an integer indicating the index of the position along the specified axis; thus in this example `pcoord` returns values ranging from 0 to 99999. Local variables `value` and `candidate` are explicitly declared as belonging to shape `SIEVE`,

and therefore are parallel values. The `while` statement of Fig. 1 becomes a `while` statement and a `where` statement in Fig. 2; the new `while` statement uses an explicit OR-reduction operator `|=` to decide whether there are any remaining candidates; if there are, the `where` statement makes inactive every position in the shape for which its `candidate` value is zero. The declaration of local variable `next_prime` does not mention a `shape`, so it is not a parallel variable (note that the `mono` keyword is no longer used). A left subscript is used to assign 1 to a single value of `prime` at the position within shape `SIEVE` indicated by the value of `next_prime`.

The need to split what was a single `while` statement in earlier versions of C* into two nested statements (a `while` with an OR-reduction operator containing a `where` that typically repeats the same expression) has been criticized, as well as the syntax of type and shape declarations and the lack of nested parallelism [14].

Version 7.2 of C* [13] introduced a “global/local programming” feature, allowing C* to be used for MIMD programming on the model CM-5. A special “prototype file” is used to specify which functions are local

```
#define N 100000

typedef int bit:1;

shape [N]SIEVE;
bit:SIEVE prime;

void find_primes() {
    with (SIEVE) {
        int:SIEVE value = pcoord(0);
        bit:SIEVE candidate = (value >= 2);
        prime = 0;
        while (|= candidate) {
            where (candidate) {
                int next_prime = (<?= value);
                [next_prime]prime = 1;
                if (value % next_prime == 0) candidate = 0;
            }
        }
    }
}
```

C*. Fig. 2 Example version 6 C* program for identifying prime numbers

and the calling interface to be used when global code calls each local function. The idea is that a local function executes on a single processing node but can use all the facilities of C*, including parallelism (which might be implemented on the model CM-5 through SIMD vector accelerator units). This facility is very similar to “local subprograms” in High Performance Fortran [2].

Cache Coherence

XIAOWEI SHEN
IBM Research, Armonk, NY, USA

Definition

A shared-memory multiprocessor system provides a global address space in which processors can exchange information and synchronize with one another. When shared variables are cached in multiple caches simultaneously, a memory store operation performed by one processor can make data copies of the same variable in other caches out of date. Cache coherence ensures a coherent memory image for the system so that each processor can observe the semantic effect of memory access operations performed by other processors in time.

Discussion

The cache coherence mechanism plays a crucial role in the construction of a shared-memory system, because of its profound impact on the overall performance and implementation complexity. It is also one of the most complicated problems in the design, because an efficient cache coherence protocol usually incorporates various optimizations.

Cache Coherence and Memory Consistency

The cache coherence protocol of a shared-memory multiprocessor system implements a memory consistency model that defines the semantics of memory access instructions. The essence of memory consistency is the

correspondence between each load instruction and the store instruction that supplies the data retrieved by the load instruction. The memory consistency model of uniprocessor systems is intuitive: a load operation returns the most recent value written to the address, and a store operation binds the value for subsequent load operations. In parallel systems, however, notions such as “the most recent value” can become ambiguous since multiple processors access memory concurrently.

An ideal memory consistency model should allow efficient implementations while still maintaining simple semantics for the architect and the compiler writer to reason about. Sequential consistency [1] is a dominant memory model in parallel computing for decades due to its simplicity. A system is sequentially consistent if the result of any execution is the same as if the operations of all the processors were executed in some sequential order, and the operations of each individual processor appear in this sequence in the order specified by its program.

Sequential consistency is easy for programmers to understand and use, but it often prohibits many architectural and compiler optimizations. The desire to achieve higher performance has led to relaxed memory models, which can provide more implementation flexibility by exposing optimizing features such as instruction reordering and data caching. Modern microprocessors [2, 3] support selected relaxed memory consistency models that allow memory accesses to be reordered, and provide memory fences that can be used to ensure proper memory access ordering constraints whenever necessary.

It is worth noting that, as a reaction to ever-changing memory models and their complicated and imprecise definitions, there is a desire to go back to the simple, easy-to-understand sequential consistency, even though there are a plethora of problems in its high-performance implementation [4]. Ingenious solutions have been devised to maintain the sequential consistency semantics so that programmers cannot detect if and when the memory accesses are out of order or nonatomic. For example, advances in speculative execution may permit memory access reordering without affecting the semantics of sequential consistency.

Sometimes people may get confused between memory consistency models and cache coherence protocols. A memory consistency model defines the semantics of memory operations, in particular, for each memory load operation, the data value that should be provided by the memory system. The memory consistency model is a critical part of the semantics of the Instruction-Set Architecture of the system, and thus should be exposed to the system programmer. A cache coherence protocol, in contrast, is an implementation-level protocol that defines how caches should be kept coherent in a multiprocessor system in which data of a memory address can be replicated in multiple caches, and thus should be made transparent to the system programmer. Generally speaking, in a shared-memory multiprocessor system, the underlying cache coherence protocol, together with some proper memory operation reordering constraint often enforced when memory operations are issued, implements the semantics of the memory consistency model defined for the system.

Snoopy Cache Coherence

A symmetric multiprocessor (SMP) system generally employs a snoopy mechanism to ensure cache coherence. When a processor reads an address not in its cache, it broadcasts a read request on the bus or network, and the memory or the cache with the most up-to-date copy can then supply the data. When a processor broadcasts its intention to write an address which it does not own exclusively, other caches need to invalidate or update their copies.

With snoopy cache coherence, when a cache miss occurs, the requesting cache sends a cache request to the memory and all its peer caches. When a peer cache receives the cache request, it performs a cache snoop operation and produces a cache snoop response indicating whether the requested data is found in the peer cache and the state of the corresponding cache line. A combined snoop response can be generated based on cache snoop responses from all the peer caches. If the requested data is found in a peer cache, the peer cache can source the data to the requesting cache via a cache-to-cache transfer, which is usually referred to as a cache intervention. The memory is responsible for supplying the requested data if the combined snoop

response shows that the data cannot be supplied by any peer cache.

Example: The MESI Cache Coherence Protocol

A number of snoopy cache coherence protocols have been proposed. The MESI coherence protocol and its variations have been widely used in SMP systems. As the name suggests, MESI has four cache states, modified (M), exclusive (E), shared (S), and invalid (I).

- I (invalid): The data is not valid. This is the initial state or the state after a snoop invalidate hit.
- S (shared): The data is valid, and can also be valid in other caches. This state is entered when the data is sourced from the memory or another cache in the modified state, and the corresponding snoop response shows that the data is valid in at least one of the other caches.
- E (exclusive): The data is valid, and has not been modified. The data is exclusively owned, and cannot be valid in another cache. This state is entered when the data is sourced from the memory or another cache in the modified state, and the corresponding snoop response shows that the data is not valid in another cache.
- M (modified): The data is valid and has been modified. The data is exclusively owned, and cannot be valid in another cache. This state is entered when a store operation is performed on the cache line.

With the MESI protocol, when a read cache miss occurs, if the requested data is found in another cache and the cache line is in the modified state, the cache with the modified data supplies the data via a cache intervention (and writes the most up-to-date data back to the memory). However, if the requested data is found in another cache and the cache line is in the shared state, the cache with the shared data does not supply the requested data, since it cannot guarantee from the shared state that it is the only cache that is to source the data. In this case, the memory will supply the data to the requesting cache. When a write cache miss occurs, if data of the memory address is cached in one or more other caches in the shared state, all those cached copies in other caches are invalidated before the write operation can be performed in the local cache.

It should be pointed out that the MESI protocol described above is just an exemplary protocol to show the essence of cache coherence operations. It can be modified or tailored in various ways for implementation optimization. For example, one can imagine that a cache line in a shared state can provide data for a read cache miss, rather than letting the memory provide the data. This may provide better response time for a system in which cache-to-cache data transfer is faster than memory-to-cache data transfer. Since there can be more than one cache with the requested data in the shared state, the cache coherence protocol needs to specify which cache in the shared state should provide the data, or how extra data copies should be handled in case multiple caches provide the requested data at the same time.

Example: An Enhanced MESI Cache Coherence Protocol

In modern SMP systems, when a cache miss occurs, if the requested data is found in both the memory and a cache, supplying the data via a cache intervention is often preferred over supplying the data from the memory, because cache-to-cache transfer latency is usually smaller than memory access latency. Furthermore, when caches are on the same die or in the same package module, there is usually more bandwidth available for cache-to-cache transfers, compared with the bandwidth available for off-chip DRAM accesses.

The IBM Power-4 system [5], for example, enhances the MESI coherence protocol to allow more cache interventions. Compared with MESI, an enhanced coherence protocol allows data of a shared cache line to be sourced via a cache intervention. In addition, if data of a modified cache line is sourced from one cache to another, the modified data does not have to be written back to the memory immediately. Instead, a cache with the most up-to-date data can be held responsible for memory update when it becomes necessary to do so. An exemplary enhanced MESI protocol employing seven cache states is as follows.

- I (invalid): The data is invalid. This is the initial state or the state after a snoop invalidate hit.
- SL (shared, can be sourced): The data is valid and may also be valid in other caches. The data can

be sourced to another cache in the same module via a cache intervention. This state is entered when the data is sourced from another cache or from the memory.

- S (shared): The data is valid, and may also be valid in other caches. The data cannot be sourced to another cache. This state is entered when a snoop read hit from another cache in the same module occurs on a cache line in the SL state.
- M (modified): The data is valid, and has been modified. The data is exclusively owned, and cannot be valid in another cache. The data can be sourced to another cache. This state is entered when a store operation is performed on the cache line.
- ME (exclusive): The data is valid, and has not been modified. The data is exclusively owned, and cannot be valid in another cache.
- MU (unsolicited modified): The data is valid and is considered to have been modified. The data is exclusively owned and cannot be valid in another cache.
- T (tagged): The data is valid and has been modified. The modified data has been sourced to another cache. This state is entered when a snoop read hit occurs on a cache line in the M state.

When data of a memory address is shared in multiple caches in a single module, the single module can include at most one cache in the SL state. The cache in the SL state is responsible for supplying the shared data via a cache intervention when a cache miss occurs in another cache in the same module. At any time, the particular cache that can source the shared data is fixed, regardless of which cache has issued the cache request. When data of a memory address is shared in more than one module, each module can include a cache in the SL state. A cache in the SL state can source the data to another cache in the same module, but cannot source the data to a cache in a different module.

In systems in which a cache-to-cache transfer can take multiple message-passing hops, sourcing data from different caches can result in different communication latency and bandwidth consumption. When a cache miss occurs in a requesting cache, if requested data is shared in more than one peer cache, a peer cache that is closest to the requesting cache is preferred to supply the

requested data to reduce communication latency and bandwidth consumption of cache intervention. Thus, it is probably desirable to enhance cache coherence mechanisms with cost-conscious cache-to-cache transfers to improve overall performance in SMP systems.

Broadcast-Based Cache Coherence Versus Directory-Based Cache Coherence

A major drawback of broadcast-based snoopy cache coherence protocols is that a cache request is usually broadcast to all caches in the system. This can cause serious problems to overall performance, system scalability, and power consumption, especially for large-scale multiprocessor systems. Further, broadcasting cache requests indiscriminately may consume enormous network bandwidth, while snooping peer caches unnecessarily may require excessive cache snoop ports. It is worth noting that servicing a cache request may take more time than necessary when far away caches are snooped unnecessarily.

Unlike broadcast-based snoopy cache coherence protocols, a directory-based cache coherence protocol maintains a directory entry to record the cache sites in which each memory block is currently cached [6]. The directory entry is often maintained at the site in which the corresponding physical memory resides. Since the locations of shared copies are known, the protocol engine at each site can maintain coherence by employing point-to-point protocol messages. The elimination of broadcast overcomes a major limitation on scaling cache coherent machines to large-scale multiprocessor systems.

Typical directory-based protocols maintain a directory entry for each memory block to record the caches in which the memory block is currently cached. With a full-map directory structure, for example, each directory entry comprises one bit for each cache in the system, indicating whether the cache has a data copy of the memory block. Given a memory address, its directory entry is usually maintained in a node in which the corresponding physical memory resides. This node is often referred to as the home of the memory address. When a cache miss occurs, the requesting cache sends a cache request to the home, which generates appropriate point-to-point coherence messages according to the directory information.

However, directory-based cache coherence protocols have various shortcomings. For example, maintaining a directory entry for each memory block usually results in significant storage overhead. Alternative directory structures may reduce the storage overhead with performance compromises. Furthermore, accessing directory can be time consuming since directory information is usually stored in DRAM. Caching recently used directory entries can potentially reduce directory access latencies but with increased implementation complexity.

Accessing directory causes three or four message-passing hops to service a cache request, compared with two message-passing hops with snoopy cache coherence protocols. Consider a scenario in which a cache miss occurs in a requesting cache, while the requested data is modified in another cache. To service the cache miss, the requesting cache sends a cache request to the corresponding home. When the home receives the cache request, it forwards the cache request to the cache that contains the modified data. When the cache with the modified data receives the forwarded cache request, it sends the requested data to the requesting cache (an alternative is to send the requested data to the home, which will forward the requested data to the requesting cache).

Cache Coherence for Network-Based Multiprocessor Systems

In a modern shared-memory multiprocessor system, caches can be interconnected with each other via a message-passing network instead of a shared bus to improve system scalability and performance. In a bus-based SMP system, the bus behaves as a central arbitrator that serializes all bus transactions. This ensures a total order of bus transactions. In a network-based multiprocessor system, in contrast, when a cache broadcasts a message, the message is not necessarily observed atomically by all the receiving caches. For example, it is possible that cache A multicasts a message to caches B and C, cache B receives the broadcast message and then sends a message to cache C, and cache C receives cache B's message before receiving cache A's multicast message.

Protocol correctness can be compromised when multicast messages can be received in different orders

at different receiving caches. Appropriate mechanisms are needed to guarantee correctness of cache coherence for network-based multiprocessor systems [7, 8].

Cache-Only Memory Architecture (COMA)

JOSEP TORRELLAS

University of Illinois at Urbana-Champaign, Urbana, IL, USA

Synonyms

[COMA \(Cache-only memory architecture\)](#)

Definition

A Cache-Only Memory Architecture (COMA) is a type of cache-coherent nonuniform memory access (CC-NUMA) architecture. Unlike in a conventional CC-NUMA architecture, in a COMA, every shared-memory module in the machine is a cache, where each memory line has a tag with the line's address and state.

As a processor references a line, it transparently brings it to both its private cache(s) and its nearby portion of the NUMA shared memory (*Local Memory*) – possibly displacing a valid line from its local memory. Effectively, each shared-memory module acts as a huge cache memory, giving the name COMA to the architecture. Since the COMA hardware automatically replicates the data and migrates it to the memory module of the node that is currently accessing it, COMA increases the chances of data being available locally. This reduces the possibility of frequent long-latency memory accesses. Effectively, COMA dynamically adapts the shared data layout to the application's reference patterns.

Discussion

Basic Concepts

In a conventional CC-NUMA architecture, each node contains one or more processors with private caches and a memory module that is part of the NUMA shared memory. A page allocated in the memory module of one node can be accessed by the processors of all other nodes. The physical page number of the page specifies the node where the page is allocated. Such node is referred to as the *Home Node* of the page. The physical address of a memory line includes the physical page number and the offset within that page.

In large machines, fetching a line from a remote memory module can take several times longer than fetching it from the local memory module. Consequently, for an application to attain high performance, the local memory module must satisfy a large fraction of the cache misses. This requires a good placement of the program pages across the different nodes. If the program's memory access patterns are too complicated for the software to understand, individual data structures may not end up being placed in the memory module of the node that access them the most. In addition, when a page contains data structures that are read and written by different processors, it is hard to attain a good page placement.

In a COMA, the hardware can transparently eliminate a certain class of remote memory accesses. COMA does this by turning memory modules into large caches called *Attraction Memory* (AM). When a processor requests a line from a remote memory, the line is

inserted in both the processor's cache and the node's AM. A line can be evicted from an AM if another line needs the space. Ideally, with this support, the processor dynamically attracts its working set into its local memory module. The lines the processor is not accessing overflow and are sent to other memories. Because a large AM is more capable of containing a node's current working set than a cache is, more of the cache misses are satisfied locally within the node.

There are three issues that need to be addressed in COMA, namely finding a line, replacing a line, and dealing with the memory overhead. In the rest of this article, these issues are described first, then different COMA designs are outlined, and finally further readings are suggested.

Finding a Memory Line

In a COMA, the address of a memory line is a global identifier, not an indicator of the line's physical location in memory. Just like a normal cache, the AM keeps a tag with the address and state of the memory line currently stored in each memory location. On a cache miss, the memory controller has to look up the tags in the local AM to determine whether or not the access can be serviced locally. If the line is not in the local AM, a remote request is issued to locate the block.

COMA machines have a mechanism to locate a line in the system so that the processor can find a valid copy of the line when a miss occurs in the local AM. Different mechanisms are used by different classes of COMA machines.

One approach is to organize the machine hierarchically, with the processors at the leaves of the tree. Each level in the hierarchy includes a directory-like structure, with information about the status of the lines present in the subtree extending from the leaves up to that level of the hierarchy. To find a line, the processing node issues a request that goes to successively higher levels of the tree, potentially going all the way to the root. The process stops at the level where the subtree contains the line. This design is called Hierarchical COMA [2, 7].

Another approach involves assigning a home node to each memory line, based on the line's physical address. The line's home has the directory entry for the line. Memory lines can freely migrate, but directory entries do not. Consequently, to locate a memory line,

a processor interrogates the directory in the line's home node. The directory always knows the state and location of the line and can forward the request to the right node. This design is called Flat COMA [12].

Replacing a Memory Line

The AM acts as a cache, and lines can be displaced from it. When a line is displaced in a plain cache, it is either overwritten (if it is unmodified) or written back to its home memory module, which guarantees a place for the line.

A memory line in COMA does not have a fixed backup location where it can be written to if it gets displaced from an AM. Moreover, even an unmodified line can be the only copy of that memory line in the system, and it must not be lost on an AM displacement. Therefore, the system must keep track of the last copy of a line. As a result, when a modified or otherwise unique line is displaced from an AM, it must be relocated into another AM.

To guarantee that at least one copy of an unmodified line remains in the system, one of the line's copies is denoted as the *Master* copy. All other shared copies can be overwritten if displaced, but the master copy must always be relocated to another AM. When a master copy or a modified line is relocated, the problem is deciding which node should take the line in its AM. If other nodes already have one or more other shared copies of the line, one of them becomes the master copy. Otherwise, another node must accept the line. This process is called *Line Injection*.

Different line injection algorithms are possible. One approach is for the displacing node to send requests to other nodes asking if they have space to host the line [7]. Another approach is to force one node to accept the line. This, however, may lead to another line displacement. A proposed solution is to relocate the new line to the node that supplied the line that caused the displacement in the first place [8].

Dealing with Memory Overhead

A CC-NUMA machine can allocate all memory to application or system pages. COMA, however, leaves a portion of the memory unallocated to facilitate automatic data replication and migration. This unallocated space supports the replication of lines across AMs.

It also enhances line migration to the AMs of the referencing nodes because less line relocation traffic is needed.

Without unallocated space, every time a line is inserted in the AM, another line would have to be relocated. The ratio between the allocated data size and the total size of the AMs is called the *Memory Pressure*. If the memory pressure is 80%, then 20% of the AM space is available for data replication. Both the relocation traffic and the number of AM misses increase with the memory pressure [8]. For a given memory size, choosing an appropriate memory pressure is a trade-off between the effect on page faults, AM misses, and relocation traffic.

Different Cache-Only Memory Architecture Designs

Hierarchical COMA

The first designs of COMA machines follow what has been called Hierarchical COMA. These designs organize the machine hierarchically, connecting the processors to the leaves of the tree. These machines include the KSR-1 [2] from Kendall Square Research, which has a hierarchy of rings, and the Data Diffusion Machine (DDM) [7] from the Swedish Institute of Computer Science, which has a hierarchy of buses.

Each level in the tree hierarchy includes a directory-like structure, with information about the status of the lines extending from the leaves up to that level of the hierarchy. To find a line, the processing node issues a request that goes to successively higher levels of the tree, potentially going all the way to the root. The process stops at the level where the subtree contains the line.

In these designs, substantial latency occurs as the memory requests go up the hierarchy and then down to find the desired line. It has been argued that such latency can offset the potential gains of COMA relative to conventional CC-NUMA architectures [12].

Flat COMA

A design called Flat COMA makes it easy to locate a memory line by assigning a home node to each memory line [12] – based on the line's physical address. The line's home has the directory entry for the line, like in a conventional CC-NUMA architecture. The memory lines can freely migrate, but the directory entries of the memory lines are fixed in their home nodes. At a miss on a

line in an AM, a request goes to the node that is keeping the directory information about the line. The directory redirects the request to another node if the home does not have a copy of the line. In Flat COMA, unlike in a conventional CC-NUMA architecture, the home node may not have a copy of the line even though no processor has written to the line. The line has simply been displaced from the AM in the home node.

Because Flat COMA does not rely on a hierarchy to find a block, it can use any high-speed network.

Simple COMA

A design called Simple COMA (S-COMA) [10] transfers some of the complexity in the AM line displacement and relocation mechanisms to software. The general coherence actions, however, are still maintained in hardware for performance reasons. Specifically, in S-COMA, the operating system sets aside space in the AM for incoming memory blocks on a page- granularity basis. The local Memory Management Unit (MMU) has mappings only for pages in the local node, not for remote pages. When a node accesses for the first time a shared page that is already in a remote node, the processor suffers a page fault. The operating system then allocates a page frame locally for the requested line. Thereafter, the hardware continues with the request, including locating a valid copy of the line and inserting it, in the correct state, in the newly allocated page in the local AM. The rest of the page remains unused until future requests to other lines of the page start filling it. Subsequent accesses to the line get their mapping directly from the MMU. There are no AM address tags to check if the correct line is accessed.

Since the physical address used to identify a line in the AM is set up independently by the MMU in each node, two copies of the same line in different nodes are likely to have different physical addresses. Shared data needs a global identity so that different nodes can communicate. To this end, each node has a translation table that converts local addresses to global identifiers and vice versa.

Multiplexed Simple COMA

S-COMA sets aside memory space in page-sized chunks, even if only one line of each page is present.

Consequently, S-COMA suffers from memory fragmentation. This can cause programs to have inflated working sets that overflow the AM, inducing frequent page replacements and resulting in high operating system overhead and poor performance.

Multiplexed Simple COMA (MS-COMA) [1] eliminates this problem by allowing multiple virtual pages in a given node to map to the same physical page at the same time. This mapping is possible because all the lines on a virtual page are not used at the same time. A given physical page can now contain lines belonging to different virtual pages if each line has a short virtual page ID. If two lines belonging to different pages have the same page offset, they displace each other from the AM. The overall result is a compression of the application's working set.

Further Readings

There are several papers that discuss COMA and related topics. Dahlgren and Torrellas present a more in-depth survey of COMA machine issues [3]. There are several designs that combine COMA and conventional CC-NUMA architecture features, such as NUMA with Remote Caches (NUMA-RC) [9], Reactive NUMA [5], Excel-NUMA [14], the Sun Microsystems' WildFire multiprocessor design [6], the IBM Prism architecture [4], and the Illinois I-ACOMA architecture [13]. A model for comparing the performance of COMA and conventional CC-NUMA architectures is presented by Zhang and Torrellas [15]. Soundarajan et al. [11] describe the trade-offs related to data migration and replication in CC-NUMA machines.

Definition

A Car–Parrinello simulation is a molecular dynamics based calculation in which the finite-temperature dynamics of a system of N atoms is generated using forces obtained directly from electronic structure calculations performed “on the fly” as the simulation proceeds. A typical Car–Parrinello simulation employs a density functional description of the electronic structure, a plane-wave basis expansion of the single-particle orbitals, and periodic boundary conditions on the simulation cell. The original paper has seen an exponential rise in the number of citations, and the method has become a workhorse for studying systems which undergo nontrivial electronic structure changes.

Discussion

Introduction

Atomistic modeling of many systems in physics, chemistry, biology, and materials science requires explicit treatment of chemical bond-breaking and forming events. The methodology of *ab initio* molecular dynamics (AIMD), in which the finite-temperature dynamics of a system of N atoms is generated using forces obtained directly from the electronic structure calculations performed “on the fly” as the simulation proceeds, can describe such processes in a manner that

is both general and transferable from system to system. The Car–Parrinello method is one type of AIMD simulation.

Assuming that a physical system can be described classically in terms of its N constituent atoms, having masses M_1, \dots, M_N and charges Z_1e, \dots, Z_Ne , the classical microscopic state of the system is completely determined by specifying the Cartesian positions $\mathbf{R}_1, \dots, \mathbf{R}_N$ of its atoms and their corresponding conjugate momenta $\mathbf{P}_1, \dots, \mathbf{P}_N$ as functions of time. In a standard molecular dynamics calculation, the time evolution of the system is determined by solving Hamilton's equations of motion

$$\dot{\mathbf{R}}_I = \frac{\mathbf{P}_I}{M_I}, \quad \dot{\mathbf{P}}_I = \mathbf{F}_I$$

which can be combined into the second-order differential equations

$$M_I \ddot{\mathbf{R}}_I = \mathbf{F}_I$$

Here, $\dot{\mathbf{R}}_I = d\mathbf{R}_I/dt$, $\dot{\mathbf{P}}_I = d\mathbf{P}_I/dt$ are the first derivatives with respect to time of position and momentum, respectively, and $\ddot{\mathbf{R}}_I = d^2\mathbf{R}_I/dt^2$ is the second derivative of position with respect to time, and \mathbf{F}_I is the total force on atom I due to all of the other atoms in the system. The force \mathbf{F}_I is a function $\mathbf{F}_I(\mathbf{R}_1, \dots, \mathbf{R}_N)$ of all of the atomic positions, hence Newton's equations of motion constitute a set of $3N$ coupled second-order ordinary differential equations.

Any molecular dynamics calculation requires the functional form $\mathbf{F}_I(\mathbf{R}_1, \dots, \mathbf{R}_N)$ of the forces as an input to the method. In most molecular dynamics calculations, the forces are modeled using simple functions that describe bond stretching, angle bending, torsion, van der Waals, and Coulombic interactions and a set of parameters for these interactions that are fit either to experiment or to high-level *ab initio* calculations. Such models are referred to as *force fields*, and while force fields are useful for many types of applications, they generally are unable to describe chemical bond-breaking and forming events and often neglect electronic polarization effects. Moreover, the parameters cannot be assumed to remain valid in thermodynamic states very different from the one for which they were originally fit. Consequently, most force fields are unsuitable for studying chemical processes under varying external conditions.

An AIMD calculation circumvents the need for an explicit force field model by obtaining the forces $\mathbf{F}_I(\mathbf{R}_1, \dots, \mathbf{R}_N)$ at a given configuration $\mathbf{R}_1, \dots, \mathbf{R}_N$ of the nuclei from a quantum mechanical electronic structure calculation performed at this particular nuclear configuration. To simplify the notation, let \mathbf{R} denote the complete set $\mathbf{R}_1, \dots, \mathbf{R}_N$ nuclear coordinates. Suppose the forces on the Born–Oppenheimer electronic ground state surface are sought. Let $|\Psi_0(\mathbf{R})\rangle$ and $\hat{H}_{\text{el}}(\mathbf{R})$ denote, respectively, the ground-state electronic wave function and electronic Hamiltonian at the nuclear configuration \mathbf{R} . If the system contains N_e electrons with position operators $\hat{\mathbf{r}}_1, \dots, \hat{\mathbf{r}}_{N_e}$, then the electronic Hamiltonian in atomic units ($e = 1, \hbar = 1, m_e = 1, c = 1$) is

$$\hat{H}_{\text{el}} = -\frac{1}{2} \sum_{i=1}^{N_e} \nabla_i^2 + \sum_{i>j} \frac{1}{|\hat{\mathbf{r}}_i - \hat{\mathbf{r}}_j|} - \sum_{i=1}^{N_e} \sum_{I=1}^N \frac{Z_I}{|\hat{\mathbf{r}}_i - \mathbf{R}_I|}$$

where the first, second, and third terms are the electron kinetic energy, the electron–electron Coulomb repulsion, and the electron–nuclear Coulomb attraction, respectively. The interatomic forces are given exactly by

$$\begin{aligned} \mathbf{F}_I(\mathbf{R}) = & -\langle \Psi_0(\mathbf{R}) | \nabla_I \hat{H}_{\text{el}}(\mathbf{R}) | \Psi_0(\mathbf{R}) \rangle \\ & + \sum_{J \neq I} Z_I Z_J \frac{(\mathbf{R}_I - \mathbf{R}_J)}{|\mathbf{R}_I - \mathbf{R}_J|^3} \end{aligned}$$

by virtue of the Hellman–Feynman theorem.

In practice, it is usually not possible to obtain the exact ground-state wave function $|\Psi_0(\mathbf{R})\rangle$, and, therefore, an approximate electronic structure method is needed. The approximation most commonly employed in AIMD calculations is the Kohn–Sham formulation of density functional theory. In the Kohn–Sham theory, the full electronic wave function is replaced by a set $\psi_s(\mathbf{r})$, $s = 1, \dots, N_s$ of mutually orthogonal single-electron orbitals (denoted collectively as $\psi(\mathbf{r})$) and the corresponding electron density

$$n(\mathbf{r}) = \sum_{s=1}^{N_s} f_s |\psi_s(\mathbf{r})|^2$$

where f_s is the occupation number of the state s . In closed-shell calculations $N_s = N_e/2$ with $f_s = 2$, while for open-shell calculations $N_s = N_e$ with $f_s = 1$. The Kohn–Sham energy functional gives the total energy of the system as

$$E[\psi, \mathbf{R}] = T_s[\psi] + E_H[n] + E_{\text{ext}}[n] + E_{\text{xc}}[n]$$

where

$$\begin{aligned} T_s[\psi] &= -\frac{1}{2} \sum_{s=1}^{N_s} f_s \int d\mathbf{r} \psi_s^*(\mathbf{r}) \nabla^2 \psi_s(\mathbf{r}) \\ E_H[n] &= \frac{1}{2} \int d\mathbf{r} d\mathbf{r}' \frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \\ E_{\text{ext}}[n] &= -\sum_{I=1}^N \int d\mathbf{r} \frac{Z_I n(\mathbf{r})}{|\mathbf{r} - \mathbf{R}_I|} \end{aligned}$$

are the single-particle kinetic energy, the Hartree energy, and the external energy, respectively. The functional dependence of the term $E_{xc}[n]$, known as the exchange and correlation energy, is not known and must, therefore, be approximated. One of the most commonly used approximations is referred to as the *generalized gradient approximation*

$$E_{xc}[n] \approx \int d\mathbf{r} f(n(\mathbf{r}), \nabla n(\mathbf{r}))$$

where f is a scalar function of the density and its gradient. When the Kohn–Sham functional is minimized with respect to the electronic orbitals subject to the orthogonality condition $\langle \psi_s | \psi_{s'} \rangle = \delta_{ss'}$, then the interatomic forces are given by

$$\mathbf{F}_I(\mathbf{R}) = -\nabla_I E[\psi^{(0)}, \mathbf{R}] + \sum_{J \neq I} Z_I Z_J \frac{(\mathbf{R}_I - \mathbf{R}_J)}{|\mathbf{R}_I - \mathbf{R}_J|^3}$$

where $\psi^{(0)}$ denotes the set of orbitals obtained by the minimization procedure.

Most AIMD calculations use a basis set for expanding the Kohn–Sham orbitals $\psi_s(\mathbf{r})$. Because periodic boundary conditions are typically employed in molecular dynamics simulations, a useful basis set is a simple plane-wave basis. In fact, when the potential is periodic, the Kohn–Sham orbitals must be represented as Bloch functions, $\psi_s^{\mathbf{k}}(\mathbf{r}) = \exp(i\mathbf{k} \cdot \mathbf{r}) u_s(\mathbf{r})$, where \mathbf{k} is a vector in the first Brillouin zone. However, if a large enough simulation cell is used, \mathbf{k} can be taken to be $(0, 0, 0)$ (the Gamma-point) for many chemical systems, as will be done here. In this case, the plane-wave expansion of $\psi_s(\mathbf{r})$ becomes the simple Fourier representation

$$\psi_s(\mathbf{r}) = \frac{1}{\sqrt{V}} \sum_{\mathbf{g}} C_s(\mathbf{g}) e^{i\mathbf{g} \cdot \mathbf{r}}$$

where $\mathbf{g} = 2\pi\mathbf{in}/V^{1/3}$, with \mathbf{n} a vector of integers, denotes the Fourier-space vector corresponding to a cubic box of volume V , and the $\{C_s(\mathbf{g})\}$ is the set

of expansion coefficients. At the Gamma-point, the orbitals are purely real, and the coefficients satisfy the condition $C_s^*(\mathbf{g}) = C_s(-\mathbf{g})$, which means that only half of the reciprocal space is needed to reconstruct the full set of Kohn–Sham orbitals. A similar expansion

$$n(\mathbf{r}) = \frac{1}{V} \sum_{\mathbf{g}} \tilde{n}(\mathbf{g}) e^{i\mathbf{g} \cdot \mathbf{r}}$$

is employed for the electronic density. Note that the coefficients $\tilde{n}(\mathbf{g})$ depend on the orbital coefficients $C_s(\mathbf{g})$. Because the density is real, the coefficients $\tilde{n}(\mathbf{g})$ satisfy $\tilde{n}^*(\mathbf{g}) = \tilde{n}(-\mathbf{g})$. Again, this condition means that the full density can be reconstructed using only half of the reciprocal space. In order to implement these expansions numerically, they must be truncated. The truncation criterion is based on the plane-wave kinetic energy $|\mathbf{g}|^2/2$. Specifically, the orbital expansion is truncated at a value E_{cut} such that $|\mathbf{g}|^2/2 < E_{\text{cut}}$, and the density, being determined from the squares of the orbitals, is truncated using the condition $|\mathbf{g}|^2/2 < 4E_{\text{cut}}$. When the above two plane-wave expansions are substituted into the Kohn–Sham energy functional, the resulting energy is an ordinary function of the orbital expansion coefficients that must be minimized with respect to these coefficients subject to the orthonormality constraint $\sum_{\mathbf{g}} C_s^*(\mathbf{g}) C_{s'}(\mathbf{g}) = \delta_{ss'}$.

An alternative to explicit minimization of the energy was proposed by Car and Parrinello (see bibliographic notes) based on the introduction of an artificial dynamics for the orbital coefficients

$$\begin{aligned} \mu \ddot{C}_s(\mathbf{g}) &= -\frac{\partial E}{\partial C_s^*(\mathbf{g})} - \sum_{s'} \Lambda_{ss'} C_{s'}(\mathbf{g}) \\ M_I \ddot{\mathbf{R}}_I &= -\frac{\partial E}{\partial \mathbf{R}_I} \end{aligned}$$

In the above equations, known as the *Car–Parrinello equations*, μ is a mass-like parameter (having units of $\text{energy} \times \text{time}^2$) that determines the time scale on which the coefficients evolve, and $\Lambda_{ss'}$ is a matrix of Lagrange multipliers for enforcing the orthogonality condition as a constraint. The mechanism of the Car–Parrinello equations is the following: An explicit minimization of the energy with respect to the orbital coefficients is carried out at a given initial configuration of the nuclei. Following this, the Car–Parrinello equations are integrated numerically with a value of μ small enough to

ensure that the coefficients respond as quickly as possible to the motion of the nuclei. In addition, the orbital coefficients must be assigned a fictitious kinetic energy satisfying

$$\mu \sum_s \sum_{\mathbf{g}} |\dot{C}_s(\mathbf{g})|^2 \ll \sum_I M_I \dot{\mathbf{R}}_I^2$$

in order to ensure that the coefficients remain close to the ground-state Born–Oppenheimer surface throughout the simulation.

In a typical calculation containing 10^2 – 10^3 nuclei and a comparable number of Kohn–Sham orbitals, the number of coefficients per orbital is often in the range 10^5 – 10^7 , depending on the atomic types present in the system. Although this may seem like a large number of coefficients, the number would be considerably larger without a crucial approximation applied to the external energy $E_{\text{ext}}[n]$. Specifically, electrons in low-lying energy states, also known as *core electrons*, are eliminated in favor of an *atomic pseudopotential* that requires replacing the exact $E_{\text{ext}}[n]$ by a functional of the following form

$$\begin{aligned} E_{\text{ext}}[n, \psi] &\approx \sum_{I=1}^N \int d\mathbf{r} n(\mathbf{r}) v_{\bar{l}}(\mathbf{r} - \mathbf{R}_I) + E_{\text{nl}}[\psi] \\ &\equiv E_{\text{loc}}[n] + E_{\text{nl}}[\psi] \end{aligned}$$

where $E_{\text{loc}}[n]$ is a purely local energy term, and $E_{\text{nl}}[\psi]$ is an orbital-dependent functional known as the *nonlocal energy* given by

$$E_{\text{nl}}[\psi] = \sum_s \sum_I \sum_{l=0}^{\bar{l}-1} \sum_{m=-l}^l w_l |Z_{sIlm}|^2$$

with

$$Z_{sIlm} = \int d\mathbf{r} F_{lm}(\mathbf{r} - \mathbf{R}_I) \psi_s(\mathbf{r})$$

Here $F_{lm}(\mathbf{r})$ is a function particular to the pseudopotential, and l and m label angular momentum channels. The value of l is summed up to a maximum $\bar{l} - 1$. Typically, $\bar{l} = 1$ or 2 depending on the chemical composition of the system, but higher values can be included when necessary. Despite the pseudopotential approximation, AIMD calculations in a plane-wave basis are computationally very intensive and can benefit substantially from massive parallelization. In addition, a typical value of the integration time step in a Car–Parrinello AIMD simulation is 0.1 fs, which means that 10^5 – 10^6 or more electronic structure calculations are needed to generate

a trajectory of just 10–100 ps. Thus, the parallelization scheme must, therefore, be efficient and scale well with the number of processors. The remainder of this entry will be devoted to the discussion of the algorithm and parallelization techniques for it.

Outline of the Algorithm

The calculation of the total energy and its derivatives with respect to orbital expansion coefficients and nuclear positions consists of the following phases:

- Phase I: Starting with the orbital coefficients in reciprocal space, the electron kinetic energy and its coefficient derivatives are evaluated using the formula
- $$T_s = \frac{1}{2} \sum_{s=1}^{N_s} f_s \sum_{\mathbf{g}} |\mathbf{g}|^2 |C_s(\mathbf{g})|^2$$
- Phase II: The orbital coefficients are transformed from Fourier space to real space. This operation requires N_s three-dimensional fast Fourier transforms (FFTs).
 - Phase III: The real-space coefficients are squared and summed to generate the density $n(\mathbf{r})$.
 - Phase IV: The real-space density $n(\mathbf{r})$ is used to evaluate the exchange-correlation functional and its functional derivatives with respect to the density. Note that $E_{\text{xc}}[n]$ is generally evaluated on a regular mesh, hence, the functional derivatives are replaced by ordinary derivatives at the mesh points.
 - Phase V: The density is Fourier transformed to reciprocal space, and the coefficients $\tilde{n}(\mathbf{g})$ are used to evaluate the Hartree and purely local part of the pseudopotential energy using the formulas

$$E_H = \frac{1}{V} \sum_{\mathbf{g} \neq (0,0,0)} \frac{2\pi}{|\mathbf{g}|^2} |\tilde{n}(\mathbf{g})|^2$$

$$E_{\text{loc}} = \frac{1}{V} \sum_{I=1}^N \sum_{\mathbf{g}} \tilde{n}^*(\mathbf{g}) \tilde{v}_{\bar{l}}(\mathbf{g}) e^{-i\mathbf{g} \cdot \mathbf{R}_I}$$

and their derivatives and nuclear position derivatives, where $\tilde{v}_{\bar{l}}(\mathbf{g})$ is the Fourier transform of the potential $v_{\bar{l}}(\mathbf{r})$.

- Phase VI: The derivatives from Phase VI are Fourier transformed to real space and combined with the derivatives from Phase V. The combined functional

derivatives are multiplied against the real-space orbital coefficients to produce part of the orbital forces in real space.

7. Phase VII: The reciprocal-space orbital coefficients are used to evaluate the nonlocal pseudopotential energy and its derivatives.
8. Phase VIII: The forces from Phase VI are combined and are then transformed back into reciprocal space, an operation that requires N_s FFTs.
9. Phase IX: The nuclear–nuclear Coulomb repulsion energy and its position derivatives are evaluated using standard Ewald summation.
10. Phase X: The reciprocal space forces are combined with those from Phases I and VII to yield the total orbital forces. These, together with the nuclear forces, are fed into a numerical solver in order to advance the nuclear positions and reciprocal-space orbital coefficients to the next time step, and the process returns to Phase I. As part of this phase, the condition of orthogonality

$$\langle \psi_s | \psi_{s'} \rangle = \sum_{\mathbf{g}} C_s^*(\mathbf{g}) C_{s'}(\mathbf{g}) = \delta_{ss'}$$

is enforced as a holonomic constraint on the dynamics.

Parallelization

Two basic strategies for parallelization of *ab initio* molecular dynamics will be outlined. The first is a hybrid state/grid-level parallelization scheme useful on machines with a modest number of fast processors having large memory but with slow communication. This scheme does not require a parallel fast Fourier transform (FFT) and can be coded up relatively easily starting from an optimized serial code. The second scheme is a fine-grained parallelization approach based on parallelization of all operations and is useful for massively parallel architectures. The tradeoff of this scheme is its considerable increase in coding complexity. An intermediate scheme between these builds a parallel FFT into the hybrid scheme as a means of reducing the memory and some of the communication requirements. In all such schemes if the FFT used is a complex-to-complex FFT and the orbitals are real, then the states can be double packed into the FFT routine and transformed two at a time, which increases the overall efficiency of the algorithms to be presented below.

Hybrid scheme – Let `ncoef` represent the number of coefficients used to represent each Kohn–Sham orbital, and let `nstate` represent the number of orbitals (also called “states”). In a serial calculation, the coefficients are then stored in two arrays `a(ncoef, state)` and `b(ncoef, nstate)` holding the real and imaginary parts of the coefficients, respectively. Alternatively, complex data typing could be used for the coefficient array. Let `nproc` be the number of processors available for the calculation. In the hybrid parallel scheme, the coefficients are stored in one of two ways at each point in the calculation. The default storage mode is called “transposed” form in which the coefficient arrays are dimensioned as `a(ncoef/nproc, nstate)` and `b(ncoef/nproc, nstate)`, so that each processor has a portion of the orbitals for all of the states. At certain points in the calculation, the coefficients are transformed to “normal” form in which the arrays are dimensioned as `a(ncoef, nstate/nproc)` and `b(ncoef, nstate/nproc)`, so that each processor has a fraction of the orbitals but each of the orbitals is complete on the processor.

In the hybrid scheme, operations on the density, both in real and reciprocal spaces, are carried out in parallel. These terms include the Hartree and local pseudopotential energies, which are carried out on a spherical reciprocal-space grid, and the exchange-correlation energy, which is carried out on a rectangular real-space grid. The Hartree and local pseudopotential terms require arrays `gdens_a(ndens/nproc)` and `gdens_b(ndens/nproc)` that hold, on each processor, a portion of the real and imaginary reciprocal-space density coefficients $\tilde{n}(\mathbf{g})$. Here, `ndens` is the number of reciprocal-space density coefficients. The exchange-correlation energy makes use of an array `rdens(ngrid/nproc)` that holds, on each processor, a portion of the real-space density $n(\mathbf{r})$. Here, `ngrid` is the number of points on the rectangular grid.

Given this division of data over the processors, the algorithm proceeds in the following steps:

1. With the coefficients in transposed form, each processor calculates its contribution to the electronic kinetic energy and the corresponding forces on the coefficients it holds. A reduction is performed to obtain the total kinetic energy.

2. The coefficient arrays are transposed into normal form, and each processor must subsequently perform $0.5A * nstate / nproc$ three-dimensional serial FFTs on its subset of states to obtain the corresponding orbitals in real space. These orbitals are stored as `creal(ngrid, nstate/nproc)`. Each processor sums the square of this orbital over $nstate / nproc$ at each grid point.
3. Each processor performs a serial FFT on its portion of the density to obtain its contribution to the reciprocal-space density coefficients $\tilde{n}(\mathbf{g})$.
4. `Reduce_scatter` operations are used to sum each processor's contributions to the real and reciprocal-space densities and distribute `ngrid / nproc` and `ndens / nproc` real and reciprocal-space density values on each processor.
5. Each processor calculates its contribution to the Hartree and local pseudopotential energies, Kohn-Sham potential, and nuclear forces using its reciprocal-space density coefficients and exchange-correlation energies and Kohn-Sham potential using its real-space density coefficients.
6. As the full Kohn-Sham potential is needed on each processor, `Allgather` operators are used to collect the reciprocal and real-space potentials. The reciprocal-space potential is additionally transformed to real space by a single FFT.
7. With the coefficients in normal form, the Kohn-Sham potential contributions to the coefficient forces are computed via the product $V_{KS}(\mathbf{r})\psi_s(\mathbf{r})$. Each processor computes this product for the states it has.
8. Each processor transforms its coefficient force contributions $V_{KS}(\mathbf{r})\psi_s(\mathbf{r})$ back to reciprocal space by performing $0.5 * nstate / nproc$ serial FFTs.
9. With the coefficients in normal form, each processor calculates its contribution to the nonlocal pseudopotential energy, coefficient forces, and nuclear forces for its states.
10. Each processor adds its contributions to the nonlocal forces to those from Steps 9 and 1 to obtain the total coefficient forces in normal form. The energies and nuclear forces are reduced over processors.
11. The coefficients and coefficient forces are transformed back to transposed form, and the equations of motion are integrated with the coefficients in transposed form.
12. In order to enforce the orthogonality constraints, various partially integrated coefficient and coefficient velocity arrays are multiplied together in transposed form on each processor. In this way, each processor has a set of $N_s \times N_s$ matrices that are reduced over processors to obtain the corresponding $N_s \times N_s$ matrices needed to obtain the Lagrange multipliers. The Lagrange multiplier matrix is broadcast to all of the processors and each processor applies this matrix on its subset of the coefficient or coefficient velocity array.

Intermediate scheme – The storage requirements of this scheme are the same as those of the hybrid approach except that the coefficient arrays are only used in their transposed form. Since all FFTs are performed in parallel, a full grid is never required, which cuts down on the memory and scratch-space requirements. The key to this scheme is having a parallel FFT capable of achieving good load balance in the presence of the spherical truncation of the reciprocal-space coefficient and density grids.

This algorithm is carried out as follows:

1. With the coefficients in transposed form, each processor calculates its contribution to the electronic kinetic energy and the corresponding forces on the coefficients it holds. A reduction is performed to obtain the total kinetic energy.
2. A set of $0.5 * nstate$ three-dimensional parallel FFTs is performed in order to transform the coefficients to corresponding orbitals in real space. These orbitals are stored in an array with dimensions `creal(ngrid/nproc, nstate)`. Since each processor has a full set of state, the real-space orbitals can simply be squared so that each processor has the full density on its subset of `ngrid / nproc` grid points.
3. A parallel FFT is performed on the density to obtain the reciprocal-space density coefficients $\tilde{n}(\mathbf{g})$, which are also divided over the processors. Each processor will have `ndens / nproc` coefficients.
4. Each processor calculates its contribution to the Hartree and local pseudopotential energies, Kohn-Sham potential, and nuclear forces using its reciprocal-space density coefficients. Each processor

also calculates its contribution to the exchange-correlation energies and Kohn–Sham potential using its real-space density coefficients.

5. A parallel FFT is used to transform the reciprocal-space Kohn–Sham potential to real space.
6. With the coefficients in transposed form, the Kohn–Sham potential contributions to the coefficient forces are computed via the product $V_{KS}(\mathbf{r})\psi_s(\mathbf{r})$. Each processor computes this product at the grid points it has.
7. The coefficient force contributions $V_{KS}(\mathbf{r})\psi_s(\mathbf{r})$ on each processor are transformed back to reciprocal space via a set of $0.5 * nstate$ three-dimensional parallel FFTs.
8. With the coefficients in transposed form, each processor calculates the nonlocal pseudopotential energy, coefficient forces, and nuclear forces using its subset of reciprocal-space grid points.
9. Each processor adds its contributions to the non-local forces to those from Steps 8 and 1 to obtain the total coefficient forces in transposed form. The energies and nuclear forces are reduced over processors.
10. In order to enforce the orthogonality constraints, various partially integrated coefficient and coefficient velocity arrays are multiplied together in transposed form on each processor. In this way, each processor has a set of $N_s \times N_s$ matrices that are reduced over processors to obtain the corresponding $N_s \times N_s$ matrices needed to obtain the Lagrange multipliers. The Lagrange multiplier matrix is broadcast to all of the processors and each processor applies this matrix on its subset of the coefficient or coefficient velocity array.

3D parallel FFTs and fine-grained data decomposition – Any fine-grained parallelization scheme for Car–Parrinello molecular dynamics requires a scalable three-dimensional FFT and a data decomposition strategy that allows parallel operations to scale up to large numbers of processors. Much of this is true even for the intermediate scheme discussed above.

Starting with the 3D parallel FFT, when the full set of indices of the coefficients $C_s(\mathbf{g})$ are displayed, the array appears as $C_s(g_x, g_y, g_z)$, where the reciprocal-space points lie within a sphere of radius $\sqrt{2}E_{cut}$. A common approach for transforming this array

to real space is based on data transposes. First, a set of one-dimensional FFTs is computed to yield $C_s(g_x, g_y, g_z) \longrightarrow \tilde{C}_s(g_x, g_y, z)$. Since the data is dense in real space, this operation transforms the sphere into a cylinder. Next, a transpose is performed on the z index to parallelize it and collect complete planes of g_x and g_y along the cylindrical axis. Once this operation is complete, the remaining two one-dimensional FFTs can be performed. The first maps the cylinder onto a rectangular slab, and the final FFT transforms the slab into a dense real-space array $\psi_s(x, y, z)$.

Given this strategy for the 3D FFT, the optimal data decomposition scheme is based on dividing the state and density arrays into planes both in reciprocal space in and in real space. Briefly, it is useful to think of dividing the coefficient array into data objects represented as $G(s, p)$, where p indexes the (g_x, g_y) planes. The planes are optimally grouped in such a way that complete lines along the g_z axis are created. This grouping is important due to the spherical truncation of reciprocal space. This type of virtualization allows parallelization tools such as the Charm++ software to be employed as a way of mapping the data objects to the physical processors as discussed by Bohm et al. in [9]. The granularity of the object $G(s, p)$ is something that can be tuned for each given architecture.

Once the data decomposition is accomplished, the planes must be mapped to the physical processors. A simple map that allocates all planes of a state to the same processor, for example, would make all 3D FFT transpose operations local, resulting in good performance. However, such a mapping is not scalable because massively parallel architectures will have many more processors than states. Another extreme would map all planes of the same rank in all of the states to the same processor. Unfortunately, this causes the transposes to be highly nonlocal and this leads to a communication bottleneck. Thus, the optimal mapping is a compromise between these two extremes, mapping collections of planes in a state partition to the physical processors, where the size of these collections depends on the number of processors and communication bandwidth. This mapping then enables the parallel computation of overlap matrices obtained by summing objects with different state indices s and s' over reciprocal space.

This entry is focused on the parallelization of plane-wave based Car–Parrinello molecular dynamics.

However, other basis sets offer certain advantages over plane waves. These are localized real-space basis sets useful for chemical applications where the orbitals $\psi_s(\mathbf{r})$ can be easily transformed into a maximally spatially localized form. Future work will focus on developing parallelization strategies for *ab initio* molecular dynamics calculations with such basis sets.

Bibliographic Notes and Further Reading

As noted in the introduction, the Car–Parrinello method was introduced in Ref. [1] and is discussed in greater detail in a number of review articles [2, 3] and a recent book [4]. Further details on the algorithms presented in this entry and their implementation in the open-source package PINY_MD can be found in Refs. [5, 6]. A detailed discussion of the Charm++ runtime environment alluded to in the “Parallelization” section can be found in Ref. [7]. Finally, fine-grained algorithms leveraging the Charm++ runtime environment in the manner described in this article are described in more detail in Refs. [8, 9]. These massively parallel techniques have been implemented in the Charm++ based open-source *ab initio* molecular dynamics package OpenAtom [10].

Cedar Multiprocessor

PEN-CHUNG YEW

University of Minnesota at Twin-Cities, Minneapolis, MN, USA

Definition

The Cedar multiprocessor was designed and built at the Center for Supercomputing Research and Development (CSR) in the University of Illinois at Urbana-Champaign (UIUC) in 1980s. The project brought together a group of researchers in computer architecture, parallelizing compilers, parallel algorithms/applications, and operating system, to develop a scalable, hierarchical, shared-memory multiprocessor. It was the largest machine building effort in academia since ILLIAC-IV. The machine became operational in 1989 and decommissioned in 1994. Some pieces of the boards are still displayed in the Department of Computer Science at UIUC.

Discussion

Introduction

The Cedar multiprocessor was the first scalable, cluster-based, hierarchical shared-memory multiprocessor of its kind in 1980s. It was designed and built at the

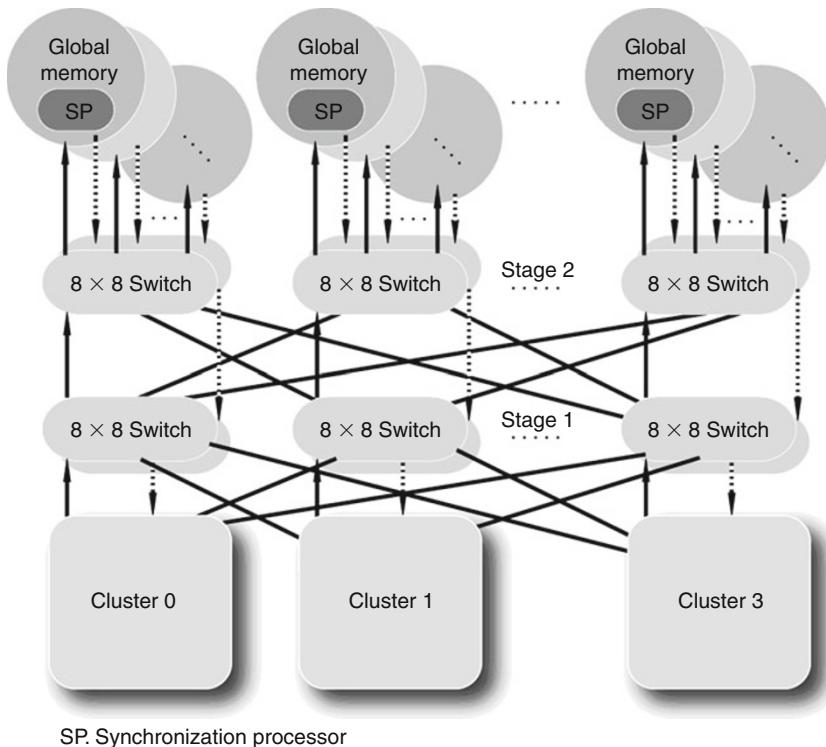

Center for Supercomputing Research and Development (CSRD) in the University of Illinois at Urbana-Champaign (UIUC). The project succeeded in building a complete scalable shared-memory multiprocessor system with a working 4-cluster (32-processor) hardware prototype [9], a parallelizing compiler for Cedar Fortran [2, 3, 8], and an operating system, called Xylem, for scalable multiprocessor [5]. Real application programs were ported and run on Cedar [6, 7] with performance studies presented in [9]. The Cedar project was started in 1984 and the prototype became functional in 1989.

Cedar had many features that later used extensively in large-scale multiprocessor systems, such as software-managed cache memory to avoid very expensive cache coherence hardware support; vector data prefetching to cluster memories for hiding long memory latency; parallelizing compiler techniques that take sequential applications and extract task-level parallelism from their loop structures; language extensions that include memory attributes of the data variables to allow programmers and compilers to manage data locality more easily; and parallel dense/sparse

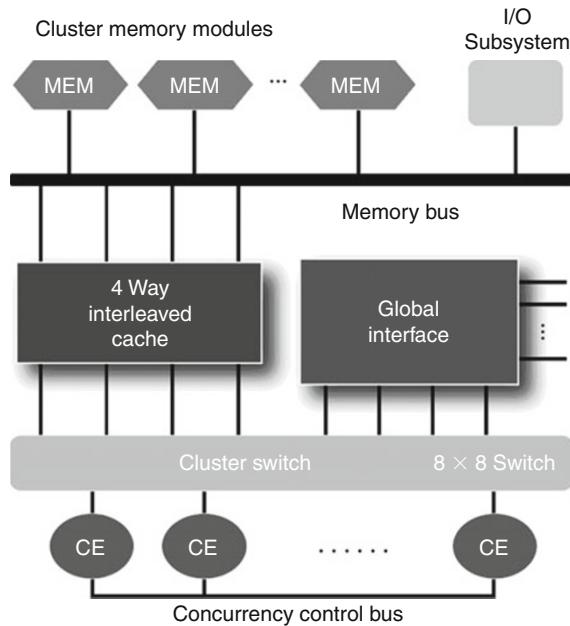

matrix algorithms that could speed up the most time consuming part of many linear systems in large-scale scientific applications.

Machine Organization of Cedar

The organization of Cedar consists of multiple *clusters* of processors connected through two high-bandwidth single-directional *global interconnection networks* (GINs) to a globally shared memory system (GSM) (see Fig. 1). One GIN provides memory requests from *clusters* to the GSM. The other GIN provides data and responses from GSM back to *clusters*. In the Cedar prototype built at CSRD, an Alliant FX/8 system was used as a cluster (See Fig. 2). Some hardware components in FX/8, such as the crossbar switch and the interface between the shared cache and the crossbar switch, were modified to accommodate additional ports for the *global network interface* (GNI). GNI provides pathways from a *cluster* to GIN. Each GNI board also has a software-controlled *vector prefetching unit* (VPU) that is very similar to the DMA in later IBM's Cell Broadband Engine.

Cedar Multiprocessor. Fig. 1 Cedar machine organization

Cedar Multiprocessor. Fig. 2 Cedar cluster

Cedar Cluster: In each Alliant system, there are eight processors, called *computational elements* (CEs). Those eight CEs are connected to a four-way interleaved shared cache through an 8×8 crossbar switch, and four ports to GNI that provide access to GIN and GSM (see Fig. 2). On the other side of the shared cache is a high-speed shared bus that is connected to multiple cluster memory modules and interactive processors (IPs). IPs handle input/output and network functions.

Each CE is a pipelined implementation of Motorola 68020 instruction set architecture, one of the most popular high-performance microprocessors in 1980s. The 68020 ISA was augmented with vector instructions. The vector unit includes both 64-bit floating-point and 32-bit integer operations. It also has eight 32-word vector registers. Each vector instruction could have one memory- and one register-operand to balance the use of registers and the requirement of memory bandwidth. The clock cycle time was 170 ns, but each CE has a peak performance of 11.8 Mflops for a multiply-and-add 64-bit floating-point vector instruction. It was a very high-performance microprocessor at that time, and was implemented on one printed-circuit board.

There is a *concurrency control bus* (CCB) that connects all eight CEs to provide synchronization and

coordination of all CEs. Concurrency control instructions include fast *fork*, *join*, and *fetch-and-increment* type of synchronization operations. For example, a single *concurrent start* instruction broadcast on CCB will spread the iterations and initiate the execution of a concurrent loop among all eight CEs simultaneously. Loop iterations are *self-scheduled* among CEs by fetch-and-incrementing a loop counter shared by all CEs. CCB also supports a *cascade synchronization* that enforces an ordered execution among CEs in the same cluster for a concurrent loop that requires a sequential ordering for a particular portion of the loop execution.

Memory Hierarchy: The 4 GB physical memory address space of Cedar is divided into two equal halves between the cluster memory and the GSM. There are 64 MB of GSM and 64 MB of cluster memory in each cluster on the Cedar prototype. It also supports a virtual memory system with a 4 KB page size. GSM could be directly addressed and shared by all clusters, but *cluster memory* is only addressable by the CEs within each cluster. Data coherence among multiple copies of data in different cluster memories is maintained explicitly through software by either programmer or the compiler. The peak GSM bandwidth is 768 MB/s and 24 MB/s per CE. The GSM is double-word interleaved, and aligned among all global memory modules. There is a *synchronization processor* in each GSM module that could execute each atomic Cedar synchronization instruction issued from a CE and staged at GNI.

Data Prefetching: It was observed early in the Cedar design phase that scientific application programs have very poor cache locality due to their vector operations. To compensate for the long access latency to GSM and to overcome the limitation of two outstanding memory requests per CE in the Alliant microarchitectural design, vector data prefetching is needed. The large GIN bandwidth is ideal for supporting such data prefetching.

To avoid major changes to Alliant's instruction set architecture (ISA) by introducing additional data prefetching instructions into its ISA, and also to avoid major alterations to CE's control and data paths of including a *data prefetching unit* (PFU) inside its CE, it was decided to build the PFU on the GIN board. Prefetched data is stored in a 512-word (each word is 8-byte) prefetch buffer inside PFU to avoid polluting the shared data cache and to allow data reuse. A CE will stage a prefetch operation at PFU by providing it with

the length, the stride, and the mask of the vector data to be prefetched. The prefetching operation could then be *fired* by providing the physical address of the first word of the vector. Prefetching operation could be overlapped with other computations or cluster memory operations.

When a page boundary is crossed during a data prefetching operation, the PFU will be suspended until the CE provides the starting address of the new page. In the absence of page crossing, PFU will prefetch 512 words without pausing into its prefetch buffer. Due to hardware limitation, only one prefetch buffer is implemented in each PFU. The prefetch buffer will thus be invalidated with another prefetch operation. Prefetched data could return from GSM out of order because of potential network and memory contentions. A *presence* bit per data word in the prefetch buffer allows the CE to both access the data without waiting for the completion of the prefetch instruction, and to access the prefetch data in the same order as requested. It was later proved from experiments that PFU is extremely useful in improving memory performance for scientific applications.

Data prefetching was later incorporated extensively into high-performance microprocessors that prefetch data from main memory into the last-level cache memory. Sophisticated compiler techniques that could insert prefetching instructions into user programs at compiler time or runtime have been developed and used extensively. Cache performance has shown significant improvement with the help of data prefetching.

Global Interconnection Network (GIN): The Cedar network is a multi-stage shuffle-exchange network as shown in Fig. 1. It is constructed with 8×8 crossbar switches with 64-bit wide data paths and some control signals for network flow control. As there are only 32-processors on the Cedar prototype, there are only two stages needed for each direction of GIN between clusters and GSM, i.e., it only need two clock cycles to go from GNI to one of the 32 GSM modules if there is no network contention. Hence, it provides a very low latency and high-bandwidth communication path to GSM from a CE. There is one GIN in each direction between clusters and GSM as mentioned above. To cut down possible signal noises and to maintain high reliability, all data signals between stages are implemented using differential signals. GIN is packet-switched and self-routed. Routing is based on a tag-controlled scheme

proposed in [11] for multi-stage shuffle-exchange networks. There is a unique path between each pair of GIN input and output ports. A two-word queue is provided at each input and output port of the 8×8 crossbar switch. Flow control between network stages is implemented to prevent buffer overflow and maintain low network contention. The total network bandwidth is 768 MB/s, and 24 MB/s each network port to match the bandwidth of GSM and CE. Hence, the requests and data flow from a CE to a GSM module and back to the CE. It forms a circular pipeline with balanced bandwidth that could support high-performance vector operations.

Memory-Based Synchronization: Given packet-switched multi-stage interconnection networks in Cedar, instead of a shared bus, it is very difficult to implement *atomic (indivisible)* synchronization operations such as a *test-and-set* or a *fetch-and-add* operation efficiently on the system interconnect. *Lock* and *unlock* operations are two low-level synchronization operations that will require multiple passes through GINs and GSM to implement a higher-level synchronization such as *fetch-and-add*, a very frequent synchronization operation in parallel applications that could be used to implement *barrier synchronizations* and *self-scheduling* for parallel loops.

Cedar implements a sophisticated set of synchronization operations [14]. They are very useful in supporting parallel loop execution that requires frequent fine-grained data synchronization between loop iterations that have cross-iteration data dependences, so called *doacross* loops [13]. Cedar synchronization instructions are basically *test-and-operate* operations, where *test* is any relational operation on 32-bit data (e.g., \leq) and *operate* could be a *read*, *write*, *add*, *subtract*, or *logical* operation on 32-bit data. These Cedar synchronization operations are also staged and controlled in a GNI board by each CE. There is also a *synchronization unit* at each GSM module that executes these atomic operations at GSM. It is a very efficient and effective way of implementing atomic global synchronization operations right at GSM.

Hardware Performance Monitoring System: It was determined at the Cedar design time that performance tuning and monitoring on a large-scale multiprocessor requires extensive support starting at the lowest hardware level. Important and critical system signals in all major system components that include GIN

and GSM must be made observable. To minimize the amount of hardware changes needed on Alliant clusters, it was decided to use external monitoring hardware to collect time-stamped event traces and histograms of various hardware signals. This allows the hardware performance monitoring system to evolve over time without having to make major hardware changes on the Cedar prototype. The Cedar hardware event tracers can each collect 1M events and the histogrammers have 64K 32-bit counters. These hardware tracers could be cascaded to capture more events. The triggering and stopping signals or events could come from special library calls in application programs, or some hardware signals such as a *GSM request* to indicate a shared cache miss. Software tools are built to support starting and stopping of tracers, off-loading data from the tracers and counters for extensive performance analysis.

Xylem Operating System

Xylem operating system [5] provides support for parallel execution of application programs on Cedar. It is based on the notion that a parallel user program is a flow graph of executable nodes. New system calls are added to allow Unix processes to create and control multiple tasks. It basically links the four separate operating systems in Alliant clusters into one Cedar operating system. Xylem provides virtual memory, scheduling and file system services for Cedar.

The Xylem scheduler schedules those tasks instead of the Unix scheduler. A Xylem task corresponds to one or more executions of each node in the program flowgraph. Support of multiprocessing in Xylem basically includes *create_task*, *delete_task*, *start_task*, *end_task*, and *wait_task*. The reason for separating *create_task* and *start_task* is because task creation is a very expensive operation, while starting a task is a relatively faster operation. Separating these two operations allow more efficient management of tasks, same for separating *delete_task* and *end_task* operations. For example, helper tasks could be created in the beginning of a process then later started when parallel loops are being executed. These helper tasks could be put back to the idle state without being deleted and recreated later.

There is no parent-child relationship between the *creator task* and the *created task* though. Either task could wait for, start or delete the other task. A task could delete itself if it is the last task in the process. *End_task*

marks the task idle and stops execution. *Wait_task* (*tasknum*) blocks the execution of the calling task until the task specified by *tasknum* enters an idle state. A task enters an idle state when it calls *end_task*. Hence, the waiting task will be unblocked when the task it is waiting for (identified by *tasknum*) ends execution.

Memory management of Xylem is based on a paging system. It has the notion of global memory pages and cluster memory pages, and provides kernels to allow a task to control its own memory environment or that of any other task in the process. They include kernels to allocate and de-allocate pages for any task in the process; change the attributes of pages; make copies and share pages with any other task in the process; and unmap pages from any task in the process. The attributes of a page include execute/no-execute, read-write/no-read-write, local/global/global-cached, and shared/private-copy/private-new/private.

Programming Cedar

A parallel program can be written using Cedar Fortran, a parallel dialect of the Fortran language, and Fortran 77 on Cedar. Cedar Fortran supports all key features of the Cedar system described above. Those Cedar features include its memory hierarchy, the data prefetching capability from GSM, the Cedar synchronization operations, and the concurrency control features on CCB. These features are supported through a language extension to Fortran 77. Programs written in Fortran 77 could be restructured by a *parallelizing restructurer*, and translated into parallel programs in Cedar Fortran. They are then fed into a backend compiler, mostly an enhanced and modified Alliant compiler, to produce Cedar executables. The *parallelizing restructurer* was based on the *KAP restructurer* [10], a product of *Kuck and Associates (KAI)*.

Cedar Fortran has many features common to the ANSI Technical Committee X3H5 standard for parallel Fortran whose basis was PCF Fortran developed by the Parallel Computing Forum (PCF). The main features encompass parallel loops, vector operations that include vector reduction operations and a WHERE statement that could mask vector assignment as in Fortran-90, declaration of *visibility* (or *accessibility*) of data, and post/wait synchronization.

Several variations of parallel loops that take into account the loop structure and the Cedar organization

are included in Cedar Fortran. There are basically two types of parallel loops: *doall* loops and *doacross* loops. A *doacross* loop is an *ordered* parallel loop whose loop iterations start sequentially as in its original sequential order. It uses *cascade synchronization* on CCB to enforce such sequential order on parts of its loop body (see Fig. 4). A *doall* loop is an *unordered* parallel loop that enforces no order among the iterations of its loop. However, a *barrier synchronization* is needed at the end of the loop.

The syntactic form of all variations of these two parallel loops is shown in Fig. 3.

There are three variations of the parallel loops: *cluster* loops, *spread* loops, and *cross-cluster* loops, denoted with prefixes C, S, X, respectively in the concurrent loop syntax shown in Fig. 3. CDOALL and CDOACROSS loops require *all* CEs in a *cluster* to join in the execution of the parallel loops. SDOALL and SDOACROSS loops cause a single CE from each cluster to join the execution of the parallel loops. It is not necessarily the best way to execute a parallel loop, but if each loop iteration has a large working set that could fill the cluster memory, such a scheduling will be very effective. Another common situation is to have a CDOALL loop nested inside an SDOALL loop. It could engage all CEs in a cluster. An XDOALL loop will require *all* CEs in *all* clusters to execute the loop body.

Local declaration of data variables in a CDOALL and XDOALL will be *visible* only to a single CE, while visible

```
{C/S/X}{DOALL/DOACROSS} index = start, end [,increment]
[local declarations of data variables]
[Preamble/Loop]
Loop Body
[Endloop/Postamble] (only SDO or XDO)

END {C/S/X}{DOALL/DOACROSS}
```

Cedar Multiprocessor. Fig. 3 Concurrent loop syntax

```
CDOACROSS j = 1, m
A(j) = B(j) + C(j)
call wait (1,1)
D(j) = E(j) + D(j-1)
call advance (1)

END DOACROSS
```

Cedar Multiprocessor. Fig. 4 An example DOACROSS loop with cascade synchronization

to *all* CEs in a *single cluster* if in an SDOALL. The statements in the *preamble* of a loop are executed *only once* by each CE when it first joins the execution of the loop and prior to the execution of loop body. The statements in the *postamble* of a loop are executed *only once* after all CEs complete the execution of the loop. Postamble is only available in SDOALL and XDOALL.

By default, data declared outside of a loop in a Cedar Fortran program are *visible* to *all* CEs in a *single* cluster. However, it provides statements to explicitly declare variables outside of a loop to be visible to *all* CEs in *all* clusters (see Fig. 5).

The GLOBAL and PROCESS COMMON statements in Fig. 5 declare that the data are visible to all CEs in all clusters. A single copy of the data exists in global memory. All CEs in all clusters could access the data, but it is the programmer's responsibility to maintain coherence if multiple copies of the data are kept in separate cluster memories. The CLUSTER and COMMON statements declare that the data are visible to all CEs inside a *single* cluster. A separate copy of the data is kept in the cluster memory of each cluster that participates in the execution of the program.

Implementation of Cedar Fortran on Cedar: All parallel loops in Cedar Fortran are self-scheduled. Iterations in a CDOALL or CDOACROSS loop are dispatched by CCB inside each cluster. CCB also provides *cascade synchronization* for a CDOACROSS loop through *wait* and *advance* calls in the loop as shown in Fig. 4. The execution of SDOALL and XDOALL are supported by the Cedar Fortran runtime library. The library starts a requested number of *helper tasks* by calling Xylem kernels in the beginning of the program execution. They remain idle until a SDOALL or XDOALL starts. The helper tasks begin to compete for loop iterations using self-scheduling.

Subroutine-level tasking is also supported in the Cedar Fortran runtime library. It allows a new thread of execution to be started for running a subroutine. In the

```
GLOBAL var [,var]
CLUSTER var [,var]
PROCESS COMMON /name/ var [,var]
COMMON /name/ var [,var]
```

Cedar Multiprocessor. Fig. 5 Variable declaration statements in Cedar Fortran

mean time, the main thread of execution continues following the subroutine call. The thread execution ends when the subroutine returns. The new thread of execution could be through one of the idle helper tasks or through the creation of a new task.

It also supports vector prefetching by generating prefetch instructions before a vector register load instruction. It could reduce the latency and overhead of loading vector data from GSM. The Cedar synchronization instructions are used primarily in the runtime library. They have been proven to be useful in controlling loop self-scheduling. They are also available to a Fortran programmer through runtime library routines.

Parallelizing Restructurer: There was a huge volume of research work on parallelizing scientific application programs written in Fortran before Cedar was built [14]. Hence, there were many sophisticated program analysis and parallelization techniques available through a very advanced parallelizing restructurer based on the *KAP restructurer* for Cedar [2, 3]. The parallelizing restructurer could convert a sequential program written in FORTRAN 77 into a parallel program in Cedar Fortran that takes advantage of all unique features in Cedar. Through this conversion and restructuring process, not only loop-level parallelism is exposed and extracted, but

also data locality is enhanced through advance techniques such as strip-mining, data globalization, and privatization [2, 4].

Performance measurements have been done extensively on Cedar [6, 7, 9]. Given the complexity of Cedar architecture, parallelizing restructurer, OS, and the programs themselves, it is very difficult to isolate the individual effects at all levels that influence the final performance of each program. The performance results shown in Fig. 6 are the most thorough measurements presented in [9]. A suite of scientific application benchmark programs called Perfect Benchmark [1] were used to measure Cedar performance. It was a collection of Fortran programs that span a wide spectrum of scientific and engineering applications from quantum chromodynamics (QCD) to analog circuit simulation (SPICE).

The table in Fig. 6 lists the performance improvement over the serial execution time of each individual program. The second column shows the performance improvement using KAP-based parallelizing restructurer. The results show that despite the most advance parallelizing restructurer at that time, the performance improvement overall is still quite limited. Hence, each benchmark program was analyzed and parallelized

Program	Complied by Kap/Cedar time (Improvement)	Auto, transforms time (Improvement)	W/o Cedar Synchronization time (% slowdown)	W/o prefetch time (% slowdown)	MFLOPS (YMP-8/Cedar)
ADM	689 (1.2)	73 (10.8)	81 (11%)	83 (2%)	6.9 (3.4)
ARC2D	218 (13.5)	141 (20.8)	141 (0%)	157 (11%)	13.1 (34.2)

Cedar Multiprocessor. Fig. 6 Cedar performance improvement for Perfect Benchmarks [9]

manually. The techniques are limited to those that could be implemented in an *automated* parallelizing restructurer. The third column under an *automatable transformation* shows the performance improvement that could be achieved if those programs are restructured by a more intelligent parallelizing restructurer.

It is quite clear that there was still a lot of potential in improving the performance of parallelizing restructurer because *manually* parallelized programs show substantial improvement in overall performance. However, through another decade of research in more advanced techniques of parallelizing restructurer since the publication of [2–4, 13], the consensus seems to be pointing to a direction that programmers must be given more tools and control to parallelize and write their own parallel code instead of relying totally on a parallelizing restructurer to convert a sequential version of their code automatically into a parallel form, and expect to have a performance improvement equals to that of the parallel code implemented by the programmers themselves.

The fourth column in the table of Fig. 6 shows the performance improvement using Cedar synchronization instructions. The fifth column shows the impact of vector prefetching on overall performance. The improvement from vector prefetching was not as significant as those obtained in later studies in other literatures because the Cedar backend compiler was not using sophisticated algorithms to place those prefetching instructions, and the number of prefetching buffers is too small.

Definition

The Cell Broadband Engine is a processor that conforms to the Cell Broadband Engine Architecture (CBEA). The CBEA is a heterogeneous architecture defined jointly by Sony, Toshiba, and IBM that extends the Power architecture with “Memory flow control” and “Synergistic processor units.”

CBEA compliant processors are used in a variety of systems, most notably the PlayStation 3 (now PS3) from Sony Computer Entertainment, the IBM QS20, QS21, and QS22 server blades, Regza-Cell Televisions from Toshiba, single processor PCI-express accelerator boards, rackmount servers, and a variety of custom systems including the Roadrunner supercomputer at Los

Alamos National Laboratory that was the first to achieve petaflop level performance on the Linpack benchmark and was ranked as the world's #1 supercomputer from June 2008 to November 2009.

Discussion

Note: In what follows a system or chip that has multiple differing cores sharing memory is referred to as heterogeneous and a system that contains multiple differing computational elements but that does not provide shared memory between these elements is referred to as hybrid.

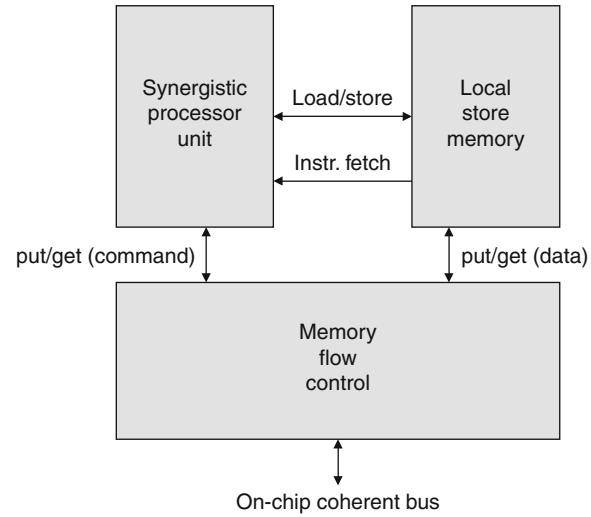

Cell Broadband Engine

The Cell Broadband Engine Architecture (CBEA) defines a heterogeneous architecture for shared-memory multi-core processors and systems. Heterogeneity allows a higher degree of efficiency and/or improved performance compared to conventional homogeneous shared-memory multi-core processors by allowing cores to gain efficiency through specialization.

The CBEA extends the Power architecture and processors that conform to the CBEA architecture are also fully Power architecture compliant. Besides the Power cores CBEA adds a new type of core: the Synergistic Processor Element (SPE). The SPE derives its efficiency and performance from the following key attributes:

- A per-SPE local store for code and data
- Asynchronous transfers between the local store and global shared memory
- A single-mode architecture
- A large register file
- A SIMD-only instruction set architecture
- Instructions to improve or avoid branches
- Mechanisms for fast communication and synchronization

Whereas a (traditional) CISC processor defines instructions that transform main memory locations directly and RISC processors transform only data in registers and therefore must first load operands into registers, the SPEs stage code and data from main memory to the local store, and the SPEs RISC core called the Synergistic Processor Unit (SPU) (Fig. 1). The SPU operates on local store the way a conventional RISC processor operates on memory, i.e., by loading data from the local store into registers before it is transformed. Similarly,

Cell Broadband Engine Processor. Fig. 1 Internal organization of the SPE

results are produced in registers, and must be staged through the local store on its way to main memory. The motivation for this organization is that while a large enough register file allows a sufficient number of operations to be simultaneously executing to effectively hide latencies to a store closely coupled to the core, a much larger store or buffer is required to effectively hide the latencies to main memory that, taking multi-core arbitration into account, can approach a thousand cycles. In all the current implementations of the SPE the local store is 256 kB which is an order of magnitude smaller than the size of a typical per-core on-chip cache for similarly performing processors. SPEs can be effective with an on-chip store that is this small because data can be packed as it is transferred to the local store and, because the SPE is organized to maximally utilize the available memory bandwidth, data in the local store is allowed to be replaced at a higher rate than is typical for a hardware cache.

In order to optimize main memory bandwidth, a sufficient number of main memory accesses (*put* and *get*) must be simultaneously executable and data access must be nonspeculative. The latter is achieved by having software issue *put* and *get* commands rather than having hardware cache pre-fetch or speculation responsible for bringing multiple sets of data on to the chip simultaneously. To allow maximum flexibility in how *put* and *get* commands are executed, without adding hardware

complexity, *put* and *get* semantics defines these operations as asynchronous to the execution of the SPU. The unit responsible for executing these commands is the Memory Flow Control unit (MFC). The MFC supports three mechanisms to issue commands.

Any unit in the system with the appropriate memory access privileges can issue an MFC command by writing to or reading from memory-mapped command registers.

The SPU can issue MFC commands by reading or writing to a set of channels that provide a direct interface to the MFC for its associated SPU.

Finally, *put-list* and *get-list* commands instruct the MFC to execute a list of *put* and *get* commands from the local store. This can be particularly effective if a substantial amount of noncontiguous data needs to be gathered into the local store or distributed back to main memory.

put and *get* commands are issued with a tag that allows groups of these commands to be associated in a tag group. Synchronization between the MFC and the SPU or the rest of the system is achieved by checking on the completion status of a tag group or set of tag groups. The SPU can avoid busy waiting by checking on the completion status with a blocking MFC channel read operation. Put and get commands adhere to the Power addressing model for main memory and specify effective addresses for main (shared) memory that are translated to real addresses according to the page and segment tables maintained by the operating system. While the local store, like the register file, is considered private, access to shared memory follows the normal Power architecture coherence rules.

The design goals of supporting both a relatively large local store and high single-thread performance imply that bringing data from the local store to a register file is a multi-cycle operation (six cycles in current SPE implementations). In order to support efficient execution for programs that randomly access data in the local store a typical loop may be unrolled four to eight times. Supporting this without creating a lot of register spills requires a large register file. Thus the SPU was architected to provide a 128-entry general-purpose register file. Further efficiency is gained by using a single register file for all data types including bit, byte, half-word and word unsigned integers, and word and double-word floating point. All of these data types are SIMD with a width that equates to 128 bits. The unified register file

allows for a rich set of operations to be encoded in a 32-bit instruction, including some performance critical operations that specify three sources and an independent target including select (conditional assignment) and multiply-add.

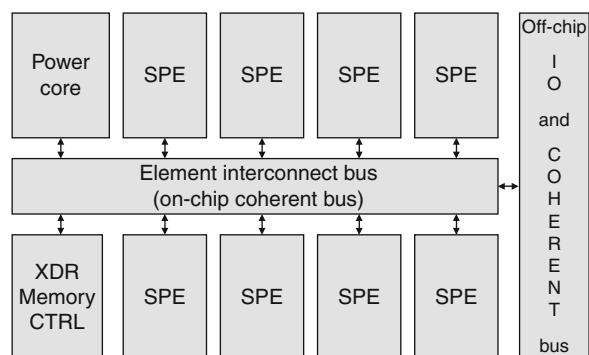

The abovementioned select instruction can quite often be used to design branchless routines. A second architectural mechanism that is provided to limit branch penalties is a branch hint instruction that provides advance notice that an upcoming branch is predicted taken and also specifies its target so that the code can be pre-fetched by the hardware and the branch penalty avoided.

The Cell Broadband Engine and PowerXCell8i processors combine eight SPEs, a Power core and high-bandwidth memory controllers, and a configurable off-chip coherence fabric onto a single chip. On-chip the cores and controllers are interconnected with a high-bandwidth coherent fabric. While physically organized as a set of ring buses for data transfers, the intent of this interconnect fabric is to allow all but those programs most finely tuned for performance to ignore its bandwidth or connectivity limitations and only consider bandwidth to memory and I/O, and bandwidth in and out of each unit (Fig. 2).

Cell B.E.-Based Systems

Cell Broadband Engine processors have been used in a wide variety of systems. Each system is reviewed briefly.

1. Sony PlayStation 3. This is perhaps the best-known use of the Cell B.E. processor. In PlayStation 3

Cell Broadband Engine Processor. Fig. 2 Organization of the Cell Broadband Engine and PowerXCell8i

the Cell B.E. processor is configured with a high-bandwidth I/O interface to connect to the RSX graphics processor. A second I/O interface connects the Cell B.E. to a SouthBridge which provides the connectivity to optical BluRay, HDD, and other storage and provides network connectivity. In the PlayStation 3 application, seven of the eight synergistic processors are used. This benefits the manufacturing efficiency of the processor.

2. Numerous PlayStation 3-based clusters. These range from virtual grids of PlayStations such as the grid used for the “Folding at Home” application that first delivered Petascale performance, to numerous clusters of PlayStations running the Linux operating system that are connected with Ethernet switches used for applications from astronomy to cryptography.
3. IBM QS20, QS21, and QS22 server blades. In these blades two Cell processors are used connected with a high-bandwidth coherent interface. Each of the Cell processors is also connected to a bridge chip that provides an interface to PCI-express, Ethernet, as well as other interfaces. The QS22 uses a version of the 65nm Cell processor with added double-precision floating-point capability that also supports larger (DDR2) memory capacities.
4. Cell-based PCI-express cards (multiple vendors). These PCI-express cards have a single Cell B.E. or PowerXCell8i processor and PCI-express bridge. The cards are intended for use as accelerators in workstations.
5. The “Roadrunner” supercomputer at Los Alamos. This supercomputer consists of a cluster of more than 3,000 Dual Dual-Core Opteron-based IBM server blades clustered together with an InfiniBand network. Each Opteron blade is PCI-express connected to two QS22 server blades, i.e., one PowerXCell8i processor per Opteron Core on each blade. This supercomputer, installed at Los Alamos in 2008, was the first to deliver a sustained Petaflop on the Linpack benchmark used to rank supercomputers (top500.org). Roadrunner was nearly three times more efficient than the next supercomputer to reach a sustained Petaflop.
6. The QPACE supercomputer developed by a European University consortium in collaboration with IBM leverages the PowerXCell8i processor in combination with an FPGA that combines the I/O

bridge and network switching functions. This configuration allows the system to achieve the very low communication latencies that are critical to Quantum Chromo Dynamics calculations. QPACE is a watercooled system, and the efficiency of water-cooling in combination with the efficiency of the PowerXCell8i processor made this system top the green500 list (green500.org) in November 2009 (Figs. 3–5).

In addition to the systems discussed above, the Cell B.E. and PowerXCell8i processors have been used in Televisions (Toshiba Regza-Cell), dual-Cell-processor 1U servers, experimental blade servers that combine FPGAs and Cell processors, and a variety of custom systems used as subsystems in medical systems and in aerospace and defense applications.

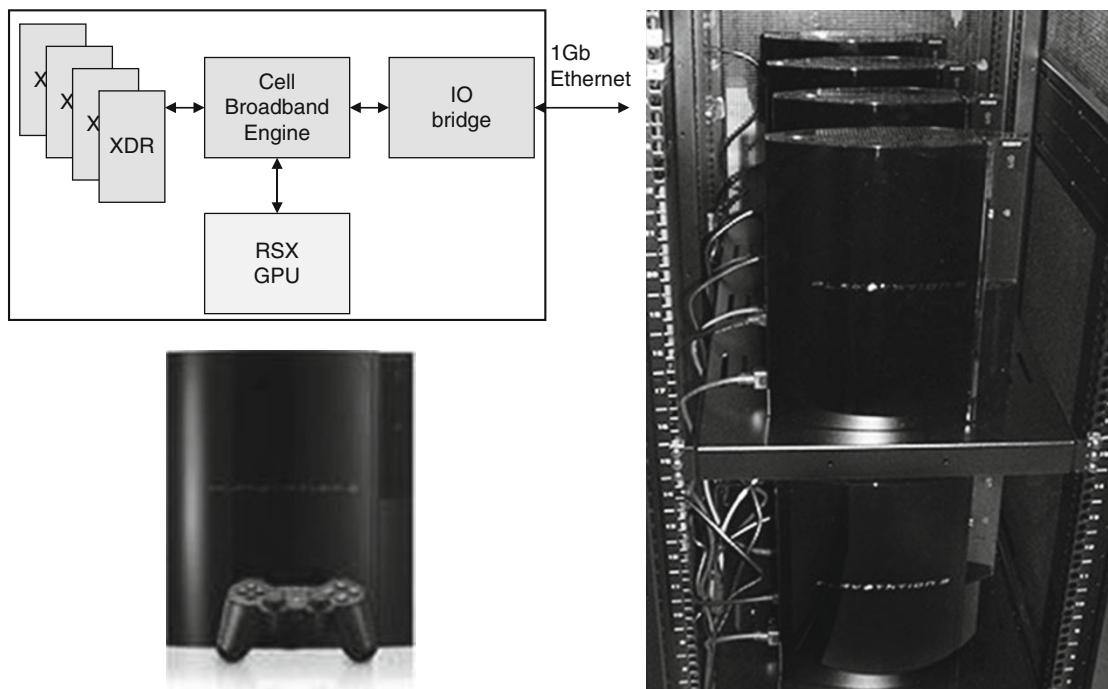

Programming Cell

The CBEA reflects the view that aspects of programs that are critical to their performance should be brought under software control for best performance and efficiency. Critical to application performance and efficiency are:

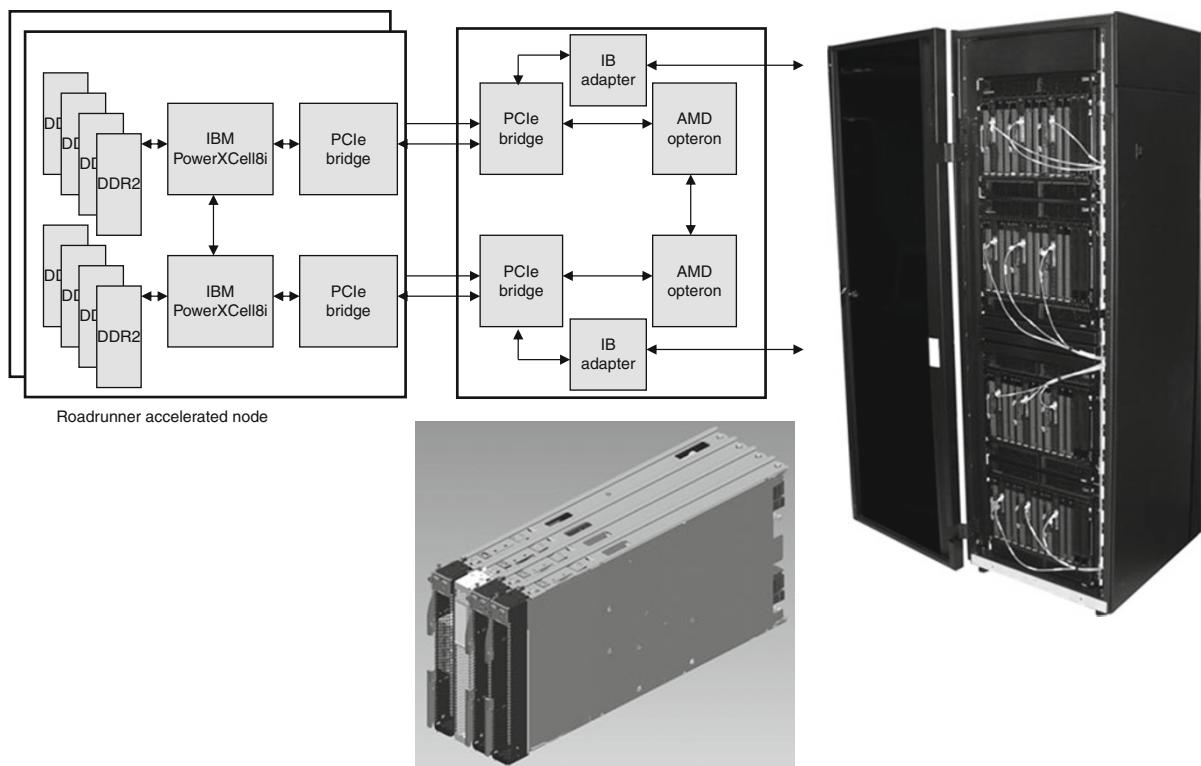

- Thread concurrency (i.e., ability to run parts of the code simultaneously on shared data)
- Data-level concurrency (i.e., ability to apply operations to multiple data simultaneously)
- Data locality and predictability (i.e., ability to predict what data will be needed next)
- Control flow predictability (i.e., ability to predict what code will be needed next)

The threading model for the Cell processor is similar to that of a conventional multi-core processor in that main memory is coherently shared between SPEs and Power cores.

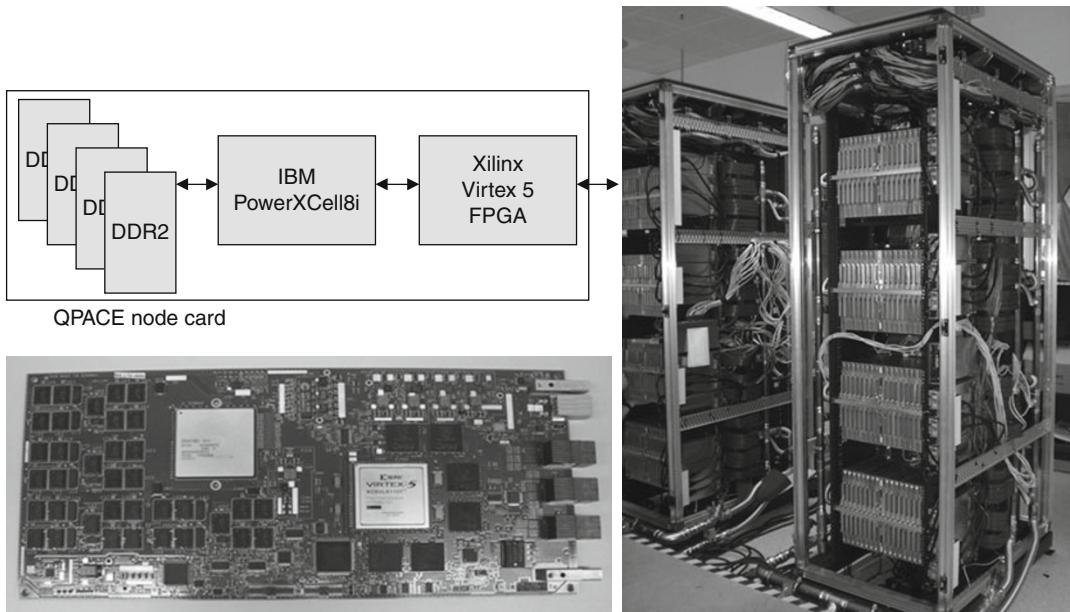

The effective addresses used by the application threads to reference shared memory are translated on the SPEs in the same way, and based on the same segment and page tables that govern translation on the Power cores. Threads can obtain locks in a consistent manner on the Power cores and on the SPEs. To this end the SPE supports atomic “get line and reserve” and “store line conditional” commands that mirror the Power core’s atomic load word and reserve and store word conditional operations. An important practical

Cell Broadband Engine Processor. Fig. 3 PlayStation 3 (configuration and system/cluster picture)

Cell Broadband Engine Processor. Fig. 4 Roadrunner (system configuration and picture)

Cell Broadband Engine Processor. Fig. 5 QPACE (card and system configuration and picture)

difference between a thread that runs on the Power core and one that runs on an SPE is that the context on the SPE is large and includes the 128 general-purpose registers, the 256 kB local store, and the state of the MFC. Therefore, unless an ABI is used that supports cooperative multitasking (i.e., switching threads only when there is minimal state in the SPE), doing a thread switch is an expensive operation. SPE threads therefore are preferentially run to completion and when a thread requires an operating system service it is generally preferable to service this with code on another processor than to interrupt and context switch the SPE. In the Linux operating system for Cell, SPE threads are therefore first created as Power threads that initialize and start the SPEs and then remain available to service operating system functions on behalf of the SPE threads they started. Note that while a context switch on an SPE is expensive, once re-initialized, the local store is back in the same state where the process was interrupted, unlike a cache which typically suffers a significant number of misses right after a thread switch. Because the local store is much larger than a typical register file and part of the state of the SPE, a (preemptive) context switch on an SPE is quite expensive. It is therefore best to think of the SPE as a single-mode or batch-mode resource. If the time to gather the inputs for a computation into the

local store leaves the SPE idle for a substantial amount of time, then double-buffering of tasks within the same user process can be an effective method to improve SPE utilization.

The SPU provides a SIMD instruction set that is similar to the instruction sets of other media-enhanced processors and therefore data-level concurrency is handled in much the same way. Languages such as OpenCL provide language support for vector data types allowing portable code to be constructed that leverages the SIMD operations. Vectorizing compilers for Cell provide an additional path toward leveraging the performance provided by the SIMD units while retaining source code portability. The use of standard libraries, the implementation of which uses the SIMD instructions provided by Cell directly, provides a third path toward leveraging the SIMD capabilities of Cell and other processors without sacrificing portability. While compilers for the Cell B.E. adhere to the language standards and thus also accept scalar data types, performance on scalar applications can suffer performance penalties for aligning the data in the SIMD registers.

The handling of data locality predictability and the use of the local store is the most distinguishing characteristic of the Cell Broadband Engine. It is possible to use the local store as a software-managed cache for code

and data with runtime support and thus remove the burden of dealing with locality from both the programmer and the compiler. While this provides a path toward code portability of standard multithreaded languages, doing so generally results in poor performance due to the overheads associated with software tag checks on loads and stores (the penalties associated with issuing the MFC commands on a cache miss are insignificant in comparison to the memory latency penalties incurred on a miss). On certain types of codes, data pre-fetching commands generated by the compiler can be effective. If the code is deeply vectorized then the local store can be treated by the compiler as essentially a large vector register file and if the vectors are sufficiently long this can lead to efficient compiler-generated pre-fetching and gathering of data. Streaming languages, where a set of kernels is applied to data that is streamed from and back to global memory can also be efficiently supported. Also, if the code is written in a functional or task-oriented style which allows operands of a piece of work to be identified prior to execution then again compiler-generated pre-fetching of data can be highly effective. Finally, languages that explicitly express data locality and/or privacy can be effectively compiled to leverage the local store. It is not uncommon for compilers or applications to employ multiple techniques, e.g., the use of a software data cache for hard to prefetch data in combination with block pre-fetching of vector data.

Because the local store stores code as well as data, software must also take care of bringing code into the local store. Unlike the software data cache, a software instruction cache generally operates efficiently and explicitly dealing with pre-fetching code to the local store can be considered a second-order optimization step for most applications. That said, there are cases, such as hard-real-time applications, where explicit control over code locality is beneficial. As noted earlier, the Cell B.E. provides branch hint instructions that allow compilers to leverage information about preferred branch directions.

Cell Processor Performance

Cell Broadband Engine processors occupy a middle ground between CPUs and GPUs. On properly structured applications, an SPU is often an order of magnitude more efficient than a high-end CPU. This can be seen by comparing the performance of the Cell B.E.

or PowerXCell8i to that of dual core processors that require a similar amount of power and chip area in the same semiconductor technology. For an application to benefit from the Cell B.E. architecture it is most important that it be possible to structure the application such that the majority of the data can be pre-fetched into the local store prior to program execution. The SIMD-width on the Cell B.E. is similar to that of CPUs of its generation and thus the degree of data parallelism is not a big distinguishing factor between Cell B.E. and CPUs. GPUs are optimized for streaming applications and with a higher degree of data parallelism can be more efficient than Cell B.E. on those applications.

Cellular Automata

MATTHEW SOTTILE
Galois, Inc., Portland, OR, USA

Definition

A cellular automaton is a computational system defined as a collection of cells that change state in parallel based on a transition rule applied to each cell and a finite number of their neighbors. A cellular automaton can be treated as a graph in which vertices correspond to cells and edges connect adjacent cells to define their neighborhood. Cellular automata are well suited to parallel implementation using a Single Program, Multiple Data (SPMD) model of computation. They have historically been used to study a variety of problems in the biological, physical, and computing sciences.

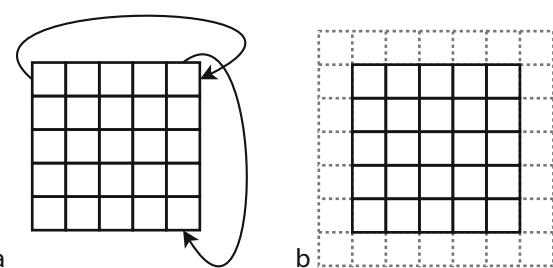

Discussion

Definition of Cellular Automata

Cellular automata (CA) are a class of highly parallel computational systems based on a transition function applied to elements of a grid of cells. They were first introduced in the 1940s by John von Neumann as an effort to model self-reproducing biological systems in a framework based on mathematical logic. The system is evolved in time by applying this transition function to all cells in parallel to generate the state of the system at time t based on the state from time $t-1$. Three properties are common amongst different CA algorithms:

1. A grid of cells is defined such that for each cell there exists a finite neighborhood of cells that influence its state change. This neighborhood is frequently defined to be other cells that are spatially adjacent. The topology of the grid of cells determines the neighbors of each cell.
2. A fixed set of state values are possible for each cell. These can be as simple as boolean true/false values, all the way up to real numbers. Most common examples are restricted to either booleans or a small set of integer values.
3. A state transition rule that evolves the state of a cell to a new state based on its current value and that of its neighbors.

Cells are positioned at the nodes of a regular grid, commonly based on rectangular, triangular, or hexagonal cells. The grid of cells may be finite or unbounded in size. When finite grids are employed, the model must account for the boundaries of the grid (Fig. 1). The most common approaches taken are to either impose a toroidal or cylindrical topology to the space in which all or some edges wrap around, or adopt a fixed value for all

Cellular Automata. Fig. 1 Common boundary types.
(a) Toroidal, (b) planar with fixed values off grid

off-grid cells to represent an appropriate boundary condition. Finite grids are easiest to model computationally, as unbounded grids will require a potentially large and endlessly growing amount of memory to represent all cells containing important state values.

1D Grids

In a simple 1D CA, the grid is represented as an array of cells. The neighborhood of a cell is the set of cells that are spatially adjacent within some finite radius. For example, in Fig. 2 a single cell is highlighted with a neighborhood of radius 1, which includes one cell on each side.

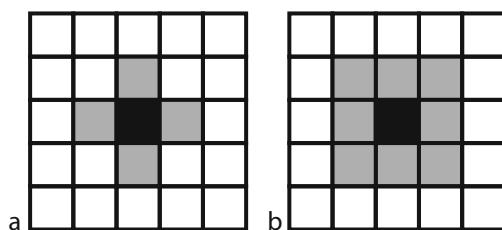

2D Grids

In a 2D CA, there are different ways in which a neighborhood can be defined. The most common are the von Neumann and Moore neighborhoods as shown in Fig. 3. For each cell, the eight neighbor cells are considered due to either sharing a common face or corner. The von Neumann neighborhood includes only those cells that share a face, while the Moore neighborhood also includes those sharing a corner.

When considering 2D systems, the transition rule computation bears a strong similarity to stencil-based computations common in programs that solve systems of partial differential equations. For example, a simple stencil computation involves averaging all values in the neighborhood of each point in a rectangular grid and replacing the value of the point at the center with the result. In the example of Conway's game of life introduced later in this entry, there is a similar computation for the transition rule, in which the number of cells that

Cellular Automata. Fig. 2 1D neighborhood of radius 1

Cellular Automata. Fig. 3 2D neighborhoods. (a) von Neumann (b) Moore

are in the “on” state in the neighborhood of a cell is used to determine the state of the central cell. In both cases there is a neighborhood of cells where a reduction operation (such as +) is applied to their state to compute a single value from which the new state of the central cell is computed.

Common Cellular Automata

1D Boolean Automata

The simplest cellular automata are one-dimensional boolean systems. In these, the grid is an array of boolean values. The smallest neighborhood is that in which a cell is influenced only by its two adjacent neighbors. The state transition rule for a cell c_i is defined as

$$c_i^{t+1} = R(c_i^t, c_{i-1}^t, c_{i+1}^t).$$

Wolfram Rule Scheme

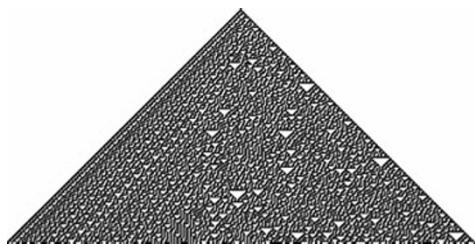

Wolfram [12] defined a concise scheme for naming 1D cellular automata that is based on a binary encoding of the output value for a rule over a family of possible inputs. The most common scheme is applied to systems in which a cell is updated based only on the values of itself and its two nearest neighbors. For any cell there are only eight possible inputs to the transition rule R : 000, 001, 010, 011, 100, 101, 110, and 111. For each of these inputs, R produces a single bit. Therefore, if each 3-bit input is assigned a position in an 8-bit number and set that bit to either 0 or 1 based on the output of R for the corresponding 3-bit input state, an 8-bit number can be created that uniquely identifies the rule R .

For example, a common example rule is number 30, which in binary is written as 00011110. This means that the input states 000, 101, 110, and 111 map to 0, and the inputs 001, 010, 011, and 100 map to 1. It is common to see these rules represented visually as in Fig. 4. The result of this rule is shown in Fig. 5.

This numbering scheme can be extended to 1D cellular automata with larger neighborhoods. For example, a CA with a neighborhood of five cells (two on each side of the central cell) would have $2^5 = 32$ possible input states; so each rule could be summarized with a single

Cellular Automata. Fig. 4 Rule 30 transition rule. Black is 1, white is 0

Cellular Automata. Fig. 5 A sequence of time steps for the 1D rule 30 automaton, starting from the top row with a single cell turned on

Cellular Automata. Fig. 6 A three color 1D automaton representing rule 1635 with initial conditions 101

32-bit number. The 1D scheme can also be extended to include cells that have more than two possible states. Extensions to these larger state spaces yield example rules that result in very complex dynamics as they evolve. For example, rule 1635 in Fig. 6 shows the evolution of the system starting from an initial condition of 101 centered on the first row.

2D Boolean Automata

In 1970, Martin Gardner introduced a cellular automaton invented by John Conway [8] on 2D grids with boolean-valued cells that is known as the *game of life*. For each cell, the game of life transition rule considers all cells in the 8-cell Moore neighborhood. Cells that contain a true value are considered to be “alive,” while those that are false are “dead.” The rule is easily stated as follows, where c_t is the current state of the cell at time step t , and N is the number of cells in its neighborhood that are alive:

- If c_t is alive:
 - If $N < 2$ then c_{t+1} is set to dead.
 - If $N > 3$ then c_{t+1} is set to dead.
 - If $N = 2$ or $N = 3$ then c_{t+1} is set to alive.
- If c_t is dead and $N = 3$, c_{t+1} is set to alive.

This rule yields very interesting dynamic behavior as it evolves. Many different types of structures have been discovered, ranging from those that are static and stable, those that repeat through a fixed sequence of states, and persistent structures that move and produce new structures. Figure 7a shows a typical configuration of the space after a number of time steps from a random initial state. A number of interesting structures that appear commonly are also shown, such as the self-propagating glider (Fig. 7b), oscillating blinker (Fig. 7d), and a configuration that rapidly stabilizes and ceases to change (Fig. 7c).

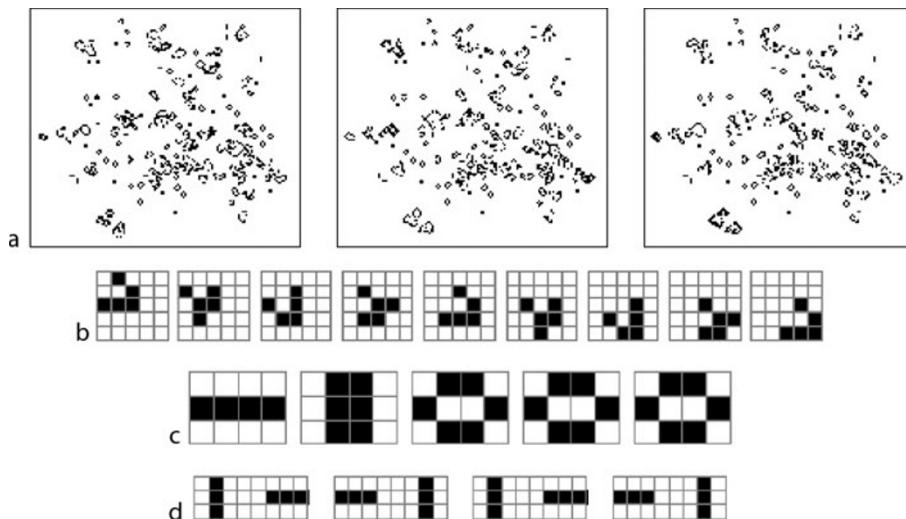

Lattice Gas Automata

Cellular automata have a history of being employed for modeling physical systems in the context of statistical mechanics, where the macroscopic behavior of the system is dictated primarily by microscopic interactions with a small spatial extent. The Ising model used in solid state physics is an example of non-automata systems that share this characteristic of local dynamics leading to a global behavior that mimics real physical systems.

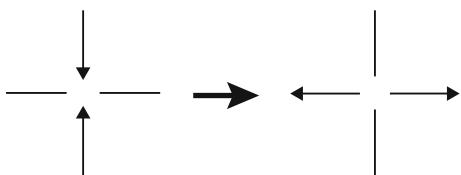

In the 1970s, cellular automata became a topic of interest in the physics community for modeling fluid systems based on the observation that macroscopic behavior of fluids is determined by the microscopic behavior of a large ensemble of fluid particles. Instead of considering cells as containing generic boolean values, one could encode more information in each cell to represent entities such as interacting particles. Two important foundational cellular automata systems are described here that laid the basis for later models of modern relevance such as the Lattice Boltzmann Method (LBM). The suitability of CA-based algorithms to parallelization is a primary reason for current interest in LBM methods for physical simulation.

HPP Lattice Gas

One of the earliest systems that gained attention was the HPP automaton of Hardy, Pomeau and de Pazzis [9]. In the simple single fluid version of this system, each cell contains a 4-bit value. Each bit in this value corresponds to a vector relating the cell to its immediately adjacent neighbors (up, down, left, and right). A bit being on corresponds to a particle coming from the neighbor into the cell, and a bit being off corresponds to the absence of a particle arriving from the neighbor.

Cellular Automata. Fig. 7 Plots showing behavior observed while evolving the game of life CA. (a) Game of life over three time steps; (b) two full periods of the glider; (c) feature that stabilizes after three steps; (d) two features that repeat every two steps

Cellular Automata. Fig. 8 A sample HPP collision rule

The transition rule for the HPP automaton was constructed to represent conservation of momentum in a physical system. For example, if a cell had a particle arriving from above and from the left, but none from the right or from below, then after a time step the cell should produce a particle that leaves to the right and to the bottom. Similarly, if a particle arrives from the left and from the right, but from neither the top or bottom, then two particles should exit from the top and bottom. In both of these cases, the momentum of the system does not change. This simple rule models the physical properties of a system based on simple collision rules. This is illustrated in Fig. 8 for a collision of two particles entering a cell facing each other. If the cell encoded the entry state as the binary value 1010 where the bits correspond in order to North, East, South, and West, then the exit state for this diagram would be defined as 0101.

The rules for the system are simple to generate by taking advantage of rotation invariant properties of the system – the conservation laws underlying a collision

rule do not change if they are transformed by a simple rotation. For example, in the cell illustrated here, rotation of the state by 90° corresponds to a circular shift of the input and output bit encodings by one. As such, a small set of rules need to be explicitly defined and the remainder can be computed by applying rotations. The same shortcut can be applied to generating the table of transition rules for more sophisticated lattice gas systems due to the rotational invariance of the underlying physics of the system.

From a computational perspective, this type of rule set was appealing for digital implementation because it could easily be encoded purely based on boolean operators. This differed from traditional methods for studying fluid systems in which systems of partial differential equations needed to be solved using floating point arithmetic.

FHP Rules

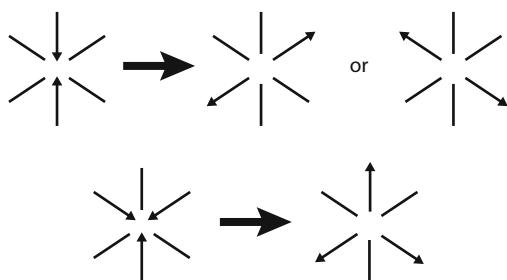

The HPP system, while intuitively appealing, lacks properties that are necessary for modeling realistic physical systems – for example, the HPP system does not exhibit isotropic behavior. The details related to the physical basis of these algorithms are beyond the scope of this entry, but are discussed at length by Doolen [5], Wolf-Gladrow [4], and Rivet [10]. A CA inspired by the early HPP automaton was created by Frisch, Hasslacher,

and Pomeau [7], leading to the family of FHP lattice gas methods.

The primary advance of these new methods made over prior lattice gas techniques was that it was possible to derive a rigorous relationship between the FHP cellular automaton and more common models for fluid flow based on Navier–Stokes methods requiring the solution of systems of partial differential equations. Refinements of the FHP model, and subsequent models based on it, are largely focused on improving the correspondence of the CA-based algorithms to the physical systems that they model and better match accepted traditional numerical methods.

In the 2D FHP automaton, instead of a neighborhood based on four neighbors, the system is defined using a neighborhood of six cells arranged in a hexagonal grid with triangular cells. This change in the underlying topology of the grid of cells was critical to improving the physical accuracy of the system while maintaining a computationally simple CA-based model. The exact same logic is applied in constructing the transition rules in this case as for the HPP case – the rules must obey conservation laws. The first instance of the automaton was based on this simple extension of HPP, in which the rules for transitions were intended to model collisions in which the state represented only particles arriving at a cell. Two example rules are shown in Fig. 9, one that has two possible outcomes (each with equal probability), and one that is deterministic. In both cases, the starting state indicates the particles entering a cell, and the exit state(s) show the particles leaving the cell after colliding.

Later revisions of the model added a bit to the state of each cell corresponding to a “rest particle” – a particle that, absent any additional particle arriving from

Cellular Automata. Fig. 9 Two examples of FHP collision rules

any neighbor, remained in the same position. Multiple variants of the FHP-based rule set appeared in the literature during the 1980s and 1990s. These introduced richer rule sets with more collision rules, with the effect of producing models that corresponded to different viscosity coefficients [4]. Further developments added the ability to model multiple fluids interacting, additional forces influencing the flow, and so on.

Modeling realistic fluid systems required models to expand to three dimensions. To produce a model with correct isotropy, d'Humières, Lallemand and Frisch [3] employed a four-dimensional structure known as the *face centered hyper-cubic*, or FCHC, lattice. The three-dimensional lattice necessary for building a lattice gas is based on a dimension reducing procedure that projects FCHC into three-dimensional space. Given this embedded lattice, a set of collision rules that obey the appropriate physical conservation laws can be defined much like those for FHP in two dimensions.

Lattice gas methods were successful in demonstrating that, with careful selection of transition rules, realistic fluid behavior could be modeled with cellular automata. The lattice Boltzmann method (LBM) is a derivative of these early CA-based fluid models that remains in use for physical modeling problems today. In the LBM, a similar grid of cells is employed, but the advancement of their state is based on continuous valued function evaluation instead of a boolean state machine.

Self-organized Criticality: Forest Fire Model

In 1992, a model was proposed by Drossel and Schwabl [6] to model forest fire behavior that built upon a previous model proposed by Bak, Chen, and Tang [1]. This model is one of a number of similar systems that are used to study questions in statistical physics, such as phase transitions and their critical points. A related system is the sandpile model, in which a model is constructed of a growing pile of sand that periodically experiences avalanches of different sizes.

As a cellular automaton, the forest fire model is interesting because it is an automaton in which the rules for updating a cell are probabilistic. The lattice gas models above include rules that are also probabilistic, but unlike the forest fire system, the lattice gas probabilities are fixed to ensure accurate correspondence with the physical system being modeled. Forest fire parameters are intended to be changed to study the response

of the overall system to their variation. Two probability parameters are required: p and f , both of which are real numbers between 0 and 1. The update rule for a cell is defined as:

- A cell that is burning becomes empty (burned out).
- A cell will start burning if one or more neighbor cells are burning.
- A cell will ignite with probability f regardless of how many neighbors are burning.
- A cell that is empty turns into a non-burning cell with probability p .

The third and fourth rules are the probabilistic parts of the update algorithm. The third rule states that cells can spontaneously combust without requiring burning neighbors to ignite them. The fourth rule states that a burned region will eventually grow back as a healthy, non-burning cell. All four rules correspond to an intuitive notion for how a real forest functions. Trees can be ignited by their neighbors; events can cause trees to start burning in a non-burning region (such as by lightning or humans), and over time, burned regions will eventually grow back.

This model differs from basic cellular automata due to the requirement that for each cell update there may be a required sampling of a pseudorandom number source to determine whether or not spontaneous ignition or new tree growth occurs. This has implications for parallel implementation because it requires the ability to generate pseudorandom numbers in a parallel setting.

Universality in Cellular Automata

Cellular automata are not only useful for modeling physical phenomena. They have also been used to study computability theory. It has been shown that cellular automata exist that exhibit the property of computational universality. This is a concept that arises in computability theory and is based on the notion of Turing-completeness. Simply stated, a system that exhibits Turing-completeness is able to perform any calculation by following a simple set of rules on input data. In essence, given a carefully constructed input, the execution of the automaton will perform a computation (such as arithmetic) that has been “programmed into” the input data. This may be accomplished by finding an encoding of an existing universal computing system

within the system which is to be shown as capable of universal computation.

For example, the simple one-dimensional Rule 110 automaton was shown by Cook [2] to be capable of universal computation. He accomplished this by identifying structures known as “spaceships” that are self-perpetuating and could be configured to interact. These interactions could be used then to encode an existing computational system in the evolving state of the Rule 110 system. The input data and program to execute would then be encoded in a linear form to serve as the initial state of the automaton. A similar approach was taken to show that the game of life could also emulate any Turing machine or other universal computing system. Using self-perpetuating structures, their generators, and structures that react with them, one can construct traditional logic gates and connect them together to form structures equivalent to a traditional digital computer.

As Cook points out, a consequence of this is that it is formally undecidable to predict certain behaviors, such as reaching periodic states or a specific configuration of bits. The property of universality does not imply that encoding of a system like a digital computer inside a CA would be at all efficient – the CA implementation would be very slow relative to a real digital computer.

Parallel Implementation

Cellular automata fit well with parallel implementations due to the high degree of parallelism present in the update rules that define them. Each cell is updated in parallel with all others, and the evolution of the system proceeds by repeatedly applying the rule to update the entire set of cells.

The primary consideration for parallel implementation of a cellular automaton is the dependencies imposed by the update rule. Parallel implementation of any sequential algorithm often starts with an analysis of the dependencies within the program, both in terms of control and data. In a CA implementation, there exists a data dependency between time steps due to the need for state data from time step t to generate the state for time $t + 1$.

For this discussion, consider the simple 1D boolean cellular automaton. To determine the value of the i th cell at step t of the evolution of the system, the update rule requires the value of the cell itself and its neighbors ($i - 1$

and $i + 1$) at step $t - 1$. This dependency has two effects that determine how the algorithm can be implemented in parallel.

1. Given that the previous step $t - 1$ is not changed at all and can be treated as read-only, all cell values for step t can be updated in parallel.
2. An in-place update of the cells is not correct, as any given cell i from step $t - 1$ is in the dependency set of multiple cells. If an in-place update occurred, then it is possible that the value from step $t - 1$ would be destructively overwritten and lost, disrupting the update for any other cell that requires its step $t - 1$ value. A simple double-buffering scheme can be used to overcome this issue for parallel implementations.

In more sophisticated systems such as those discussed earlier, the number of dependencies that each cell has between time steps grows with the size of its neighborhood. The game of life rule states that each cell requires the state of nine cells to advance – the state of the cell itself and that of its eight neighbors. The 3D FCHC lattice gas has 24 channels per node to influence the transition rule leading to a large number of dependencies per cell.

Hardware Suitability

Historically cellular automata were of interest on massively parallel processing (MPP) systems in which a very large number of simple processing elements were available. Each processing element was assigned a small region of the set of cells (often a spatially contiguous patch), and iterated over the elements that it was responsible for to apply the update rule. A limited amount of synchronization would be required to ensure that each processing element worked on the same update step.

In the 1990s, there was a research effort at MIT to build the CAM8 [11], a parallel architecture designed specifically for executing cellular automata. Machines specialized for CA models could achieve performance comparable to conventional parallel systems of the era, including the Thinking Machines CM-2 and Cray X-MP. The notable architectural features of the CAM8 were the processing nodes based on DRAM for storing cell state data, SRAM for storing a lookup table holding the transition rules for a CA, and a mesh-based

interconnection network connecting processing nodes together for exchanging data. The machine could be programmed for different CA rules, and was demonstrated on examples from fluid dynamics (lattice gases), statistical physics (diffusion limited aggregation), image processing, and large-scale logic simulation.

Another approach that has been taken to hardware implementation of CAs is the use of Field Programmable Gate Arrays (FPGAs) to encode the boolean transition rule logic directly in hardware. More recently, hardware present in accelerator-based systems such as General Purpose Graphics Processing Units (GPGPU) presents a similar feature set as the traditional MPPs. These devices present the programmer with the ability to execute a large number of small parallel threads that operate on large volumes of data. Each thread in a GPU is very similar to the basic processing elements from a traditional MPP. The appeal of these modern accelerators is that they can achieve performance comparable to traditional supercomputers on small, specialized programs like cellular automata that are based on a single small computation run in parallel on a large data set.

Chaco

BRUCE HENDRICKSON
Sandia National Laboratories, Albuquerque, NM, USA

Definition

Chaco was the first modern graph partitioning code developed for parallel computing applications. Although developed in the early 1990s, the code continues to be widely used today.

Discussion

Chaco is a software package that implements a variety of graph partitioning techniques to support parallel applications. Graph partitioning is a widely used abstraction for dividing work amongst the processors of a parallel machine in such a way that each processor has about the same amount of work to do, but the amount of interprocessor communication is kept small. Chaco is a serial code, intended to be used as a preprocessing step to set up a parallel application. Chaco takes in a graph which describes the data dependencies in a computation and outputs a description of how the computation should be partitioned amongst the processors of a parallel machine.

Chaco was developed by Bruce Hendrickson and Rob Leland at Sandia National Laboratories. It provides implementations of a variety of graph partitioning algorithms. Chaco provided an advance over the prior state of the art in a number of areas [4].

- Although multilevel partitioning was simultaneously co-invented by several groups [2, 3, 5], the implementation in Chaco led to the embrace of this approach as the best balance between speed and quality for many practical problems. In parallel computing, this remains the dominant approach to partitioning problems.
- All the algorithms in Chaco support graphs with weights on both edges and vertices.
- Chaco provides a suite of partitioning algorithms including spectral, geometric and multilevel approaches.
- Chaco supports the coupling of global methods (e.g., spectral or geometric partitioning) with local

refinement provided by an implementation of the Fiduccia-Mattheyses (FM) implementation.

- Chaco provides a robust yet efficient algorithm for computing Laplacian eigenvectors which can be used for spectral partitioning or for other algorithms.
- Chaco supports generalized spectral, combinatorial, and multilevel algorithms that partition into more than two parts at each level of recursion.
- Chaco has several approaches that consider the topology of the target parallel computer during the partitioning process.

Synonyms

Cascade high productivity language

Definition

Chapel is a parallel programming language that emerged from Cray Inc.'s participation in the High Productivity Computing Systems (HPCS) program sponsored by the Defense Advanced Research Projects Agency (DARPA). The name Chapel derives from the phrase "Cascade High Productivity Language," where "Cascade" is the project name for the Cray HPCS effort. The HPCS program was launched with the goal of raising user productivity on large-scale parallel systems by a factor of ten. Chapel was designed to help with this challenge by vastly improving the programmability of parallel architectures while matching or beating the performance, portability, and robustness of previous parallel programming models.

Discussion

History

The Chapel language got its start in 2002 during the first phase of Cray Inc.'s participation in the DARPA HPCS program. While exploring candidate system design concepts to improve user productivity, the technical leaders of the Cray Cascade project decided that one component of their software solution would be to pursue the development of an innovative parallel programming language. Cray first reported their interest in pursuing a new language to the HPCS mission partners in January 2003. The language was named Chapel later that year, stemming loosely from the phrase "Cascade High Productivity Language." The early phases of Chapel development were a joint effort between Cray Inc. and their

academic partners at Caltech/JPL (Jet Propulsion Laboratory).

The second phase of the HPCS program, from summer 2003 through 2006, saw a great deal of work in the specification and early implementation of Chapel. Chapel's initial design was spearheaded by David Callahan, Brad Chamberlain, and Hans Zima. This group published an early description of their design in a paper entitled "The Cascade High Productivity Language" [1]. Implementation of a Chapel compiler began in the winter of 2003, initially led by Brad Chamberlain and John Plevyak (who also played an important role in the language's early design). In late 2004, a rough draft of the language specification was completed. Around this same time, Steve Deitz joined the implementation effort, who would go on to become one of Chapel's most influential long-term contributors. This group established the primary themes and concepts that set the overall direction for the Chapel language. The motivation and vision of Chapel during this time was captured in an article entitled "Parallel Programmability and the Chapel Language" [4], which provided a wish list of sorts for productive parallel languages and evaluated how well or poorly existing languages and Chapel met the criteria.

By the summer of 2006, the HPCS program was transitioning into its third phase and the Chapel team's composition had changed dramatically, as several of the original members moved on to other pursuits and several new contributors joined the project. Of the original core team, only Brad Chamberlain and Steve Deitz remained and they would go on to lead the design and implementation of Chapel for the majority of phase III of HPCS (ongoing at the time of this writing).

The transition to phase III also marked a point when the implementation began to gain significant traction due to some important changes that were made to the language and compiler design based on experience gained during phase II. In the spring of 2006, the first multi-threaded task-parallel programs began running on a single node. By the summer of 2007, the first task-parallel programs were running across multiple nodes with distributed memory. And by the fall of 2008, the first multi-node data-parallel programs were being demonstrated.

During this time period, releases of Chapel also began taking place, approximately every 6 months. The

very first release was made available in December 2006 on a request-only basis. The first release to the general public occurred in November 2008. And in April 2009, the Chapel project more officially became an open-source project by migrating the hosting of its code repository to SourceForge.

Believing that a language cannot thrive and become adopted if it is controlled by a single company, the Chapel team has often stated its belief that as Chapel grows in its capabilities and popularity, it should gradually be turned over to the broader community as an open, consortium-driven language. Over time, an increasing number of external collaborations have been established with members of academia, computing centers, and industry, representing a step in this direction.

At the time of this writing, Chapel remains an active and evolving project. The team's current emphasis is on expanding Chapel's support for user-defined distributions, improving performance of key idioms, supporting users, and seeking out strategic collaborations.

Influences

Rather than extending an existing language, Chapel was designed from first principles. It was decided that starting from scratch was important to avoid inheriting features from previous languages that were not well suited to large-scale parallel programming. Examples include pointer/array equivalence in C and common blocks in Fortran. Moreover, Chapel's design team believed that the challenging part of learning any language is learning its semantics, not its syntax. To that end, embedding new semantics in an established syntax can often cause more confusion than benefit. To this end, Chapel was designed from a blank slate. That said, Chapel's design does contain many concepts and influences from previous languages, most notably ZPL, High Performance Fortran (HPF), and the Tera/Cray MTA extensions to C and Fortran, reflecting the backgrounds of the original design team. Chapel utilizes a partitioned global namespace for convenience and scalability, similar to traditional PGAS languages like UPC, Co-Array Fortran, and Titanium; yet it departs from those languages in other ways, most notably by supporting more dynamic models of execution and parallelism. Other notable influences include CLU, ML, NESL, Java, C#, C/C++, Fortran, Modula, and Ada.

Themes

Chapel's design is typically described as being motivated by five major themes: (1) support for general parallel programming, (2) support for global-view abstractions, (3) a multiresolution language design, (4) support for programmer control over locality and affinity, and (5) a narrowing of the gap between mainstream and HPC programming models. This section provides an overview of these themes.

General Parallel Programming

Chapel's desire to support general programming stems from the observation that while programs and parallel architectures both typically contain many types of parallelism at several levels, programmers typically need to use a mix of distinct programming models to express all levels/types of software parallelism and to target all available varieties of hardware parallelism. In contrast, Chapel aims to support multiple levels of hardware and software parallelism using a unified set of concepts for expressing parallelism and locality. To this end, Chapel programs support parallelism at the function, loop, statement, and expression levels. Chapel language concepts support data parallelism, task parallelism, concurrent programming, and the ability to compose these different styles within a single program naturally. Chapel programs can be executed on desktop multicore computers, commodity clusters, and large-scale systems developed by Cray Inc. or other vendors.

Global-View Abstractions

Chapel is described as supporting global-view abstractions for data and for control flow. In the tradition of ZPL and High Performance Fortran, Chapel supports the ability to declare and operate on large arrays in a holistic manner even though they may be implemented by storing their elements within the distributed memories of many distinct nodes. Chapel's designers felt that many of the most significant challenges to parallel programmability stem from the typical requirement that programmers write codes in a cooperating executable or Single Program, Multiple Data (SPMD) programming model. Such models require the user to manually manage many tedious details including data ownership, local-to-global index transformations, communication, and synchronization. This overhead often clutters a program's text, obscuring its intent and making the code

difficult to maintain and modify. In contrast, languages that support a global view of data such as ZPL, HPF, and Chapel shift this burden away from the typical user and onto the compiler, runtime libraries, and data distribution authors. The result is a user code that is cleaner and easier to understand, arguably without a significant impact on performance.

Chapel departs from the single-threaded logical execution models of ZPL and HPF by also providing a global view of control flow. Chapel's authors define this as a programming model in which a program's entry point is executed by a single logical task, and then additional parallelism is introduced over the course of the program through explicit language constructs such as parallel loops and the creation of new tasks. Supporting a global view for control flow and data structures makes parallel programming more like traditional programming by removing the requirement that users must write programs that are complicated by details related to running multiple copies of the program in concert as in the SPMD model.

A Multiresolution Design

Another departure from ZPL and HPF is that those languages provide high-level data-parallel abstractions without providing a means of abandoning those abstractions in order to program closer to the machine in a more explicit manner. Chapel's design team felt it was important for users to have such control in order to program as close to the machine as their algorithm requires, whether for reasons of performance or expressiveness. To this end, Chapel's features are designed in a layered manner so that when high-level abstractions like its global-view arrays are inappropriate, the programmer can drop down to lower-level features and control things more explicitly. As an example of this, Chapel's global-view arrays and data-parallel features are implemented in terms of its lower-level task-parallel and locality features for creating distinct tasks and mapping them to a machine's processors. The result is that users can write different parts of their program using different levels of abstraction as appropriate for that phase of the computation.

Locality and Affinity

The placement of data and tasks on large-scale machines is crucial for performance and scalability due to the

latencies incurred by communicating with other processors over a network. For this reason, performance-minded programmers typically need to control where data is stored on a large-scale system and where the tasks accessing that data will execute relative to the data. As multicore processors grow in the number and variety of compute resources, such control over locality is likely to become increasingly important for desktop programming as well. To this end, Chapel provides concepts that permit programmers to reason about the compute resources that they are targeting and to indicate where data and tasks should be located relative to those compute resources.

Narrowing the Gap Between Mainstream and HPC Languages

Chapel's designers believe there to be a wide gap between programming languages that are being used in education and mainstream computing such as Java, C#, Matlab, Perl, and Python and those being used by the High Performance Computing community: Fortran, C, and C++ in combination with MPI and OpenMP (and in some circles, Co-Array Fortran and UPC – Unified Parallel C). It was believed that this gap should be bridged in order to take advantage of productivity improvements in modern language design while also being able to better utilize the skills of the emerging workforce. The challenge was to design a language that would not alienate traditional HPC programmers who were perhaps most comfortable in Fortran or C. An example of such a design decision was to have Chapel support object-oriented programming since it is a staple of most modern languages and programmers, yet to make the use of objects optional so that Fortran and C programmers would not need to change their way of thinking about program and data structure design. Another example was to make Chapel an imperative, block-structured language, since the languages that have been most broadly adopted by both the mainstream and HPC communities have been imperative rather than functional or declarative in nature.

Language Features

Data Parallelism

Chapel's highest-level concepts are those relating to data parallelism. The central concept for data-parallel programming in Chapel is the domain, which is a first-class

language concept for representing an index set, potentially distributed between multiple processors. Domains are an extension of the region concept in ZPL. They are used in Chapel to represent iteration spaces and to declare arrays. A domain's indices can be Cartesian tuples of integers, representing dense or sparse index sets on a regular grid. They may also be arbitrary values, providing the capability for storing arbitrary sets or key/value mappings. Chapel also supports the notion of an unstructured domain in which the index values are anonymous, providing support for irregular, pointer-based data structures.

The following code declares three Chapel domains:

```
const D: domain(2) = [1..n, 1..n] ,
  DDiag: sparse subdomain(D)
    = [i in 1..n] (i,i),
  Employees: domain(string)
    = readNamesFromFile(infile);
```

In these declarations, *D* represents a regular 2-dimensional $n \times n$ index set; *DDiag* represents the sparse subset of indices from *D* describing its main diagonal; and *Employees* is a set of strings representing the names of a group of employees.

Chapel arrays are defined in terms of domains and represent a mapping from the domain's indices to a set of variables. The following declarations declare a pair of arrays for each of the domains above:

```
var A, B: [D] real,
  X, Y: [DDiag] complex,
  Age, SSN: [Employees] int;
```

The first declaration defines two arrays *A* and *B* over domain *D*, creating two $n \times n$ arrays of real floating point values. The second creates sparse arrays *X* and *Y* that store complex values along the main diagonal of *D*. The third declaration creates two arrays of integers representing the employees' ages and social security numbers.

Chapel users can express data parallelism using forall loops over domains or arrays. As an example, the following loops express parallel iterations over the indices and elements of some of the previously declared domains and arrays.

```
forall a in A do
  a += 1.0;

forall (i,j) in D do
  A(i,j) = B(i,j) + 1.0i * X(i,j);
```

```
forall person in Employees do
  if (Age(person) < 18) then
    SSN = 0;
```

Scalar functions and operators can be promoted in Chapel by calling them with array arguments. Such promotions also result in data-parallel execution, equivalent to the forall loops above. For example, each of the following whole-array statements will be computed in parallel in an element-wise manner:

```
A = B + 1.0i * X;
B = sin(A);
Age += 1;
```

In addition to the use cases described above, domains are used in Chapel to perform set intersections, to slice arrays and refer to subarrays, to perform tensor or elementwise iterations, and to dynamically resize arrays. Chapel also supports reduction and scan operators (including user-defined variations) for efficiently computing common collective operations in parallel. In summary, domains provide a very rich support for parallel operations on a rich set of potentially distributed data aggregates.

Locales

Chapel's primary concept for referring to machine resources is called the locale. A locale in Chapel is an abstract type, which represents a unit of the target architecture that can be used for reasoning about locality. Locales support the ability to execute tasks and to store variables, but the specific definition of the locale for a given architecture is defined by a Chapel compiler. In practice, an SMP node or multicore processor is often defined to be the locale for a system composed of commodity processors.

Chapel programmers specify the number of locales that they wish to use on the executable's command line. The Chapel program requests the appropriate resources from the target architecture and then spawns the user's code onto those resources for execution. Within the Chapel program's source text, the set of execution locales can be referred to symbolically using a built-in array of locale values named *Locales*. Like any other Chapel array, *Locales* can be sliced, indexed, or reshaped to organize the locales in any manner that suits the program. For example, the following statements create customized views of the locale set. The first divides the locales into two disjoint sets while the

second reshapes the locales into a 2-dimensional virtual grid of nodes:

```
// given: const Locales:
[0..#numLocales] locale;

const localeSetA = Locales[0..#localesInSetA],
    localeSetB = Locales[localesInSetA..];
const compGrid
    = Locales.reshape[1..2,numLocales/2];
```

Distributions

As mentioned previously, a domain's indices may be distributed between the computational resources on which a Chapel program is running. This is done by specifying a domain map as part of the domain's declaration, which defines a mapping from the domain's index set to a target locale set. Since domains are used to define iteration spaces and arrays, this also implies a distribution of the computations and data structures that are expressed in terms of that domain. Chapel's domain maps are more than simply a mapping of indices to locales, however. They also define how each locale should store its local domain indices and array elements, as well as how operations such as iteration, random access, slicing, and communication are defined on the domains and arrays. To this end, Chapel domain maps can be thought of as recipes for implementing parallel, distributed data aggregates in Chapel. The domain map's functional interface is targeted by the Chapel compiler as it rewrites a user's global-view array operations down to the per-node computations that implement the overall algorithm.

A well-formed domain map does not affect the semantics of a Chapel program, only its implementation and performance. In this way, Chapel programmers can tune their program's implementation simply by changing the domain declarations, leaving the bulk of the computation and looping untouched. For example, the previous declaration of domain D could be changed as follows to specify that it should be distributed using an instance of the Block distribution:

```
const D: domain(2) dmapped MyBlock
    = [1..n, 1..n];
```

However, none of the loops or operations written previously on D , A , or B would have to change.

Advanced users can write their own domain maps in Chapel and thereby create their own implementations

of parallel, distributed data structures. While Chapel provides a standard library of domain maps, a major research goal of the language is to implement these standard distributions using the same mechanism that an end-user would rather than by embedding semantic knowledge of the distributions into the compiler and runtime as ZPL and HPF did.

Task Parallelism

As mentioned previously, Chapel's data-parallel features are implemented in terms of its lower-level task-parallel features. The most basic task-parallel construct in Chapel is the begin statement, which creates a new task while allowing the original task to continue executing. For example, the following code starts a new task to compute an FFT while the original task goes on to compute a Jacobi iteration:

```
begin FFT(A);
Jacobi(B);
```

Inter-task coordination in Chapel is expressed in a data-centric way using special variables called synchronization variables. In addition to storing a traditional data value, these variables also maintain a logical full/empty state. Reads to synchronization variables block until the variable is full and leave the variable empty. Conversely, writes block until the variable is empty and leave it full. Variations on these default semantics are provided via method calls on the variable. This leads to the very natural expression of inter-task coordination. Consider, for example, the elegance of the following bounded buffer producer/consumer pattern:

```
var buffer: [0..#buffsize] sync int;

begin { // producer
    for i in 0..n do
        buffer[i%buffsize] = ...;
}
{ // consumer
    for j in 0..n do
        ...buffer[j%buffsize]...;
}
```

Because each element in the bounded buffer is declared as a synchronized integer variable, the consumer will not read an element from the buffer until the producer has written to it, marking its state as full. Similarly, the producer will not overwrite values in the buffer until the consumer's reads have reset the state to empty.

In addition to these basic task creation and synchronization primitives, Chapel supports additional constructs to create and synchronize tasks in structured ways that support common task-parallel patterns.

Locality Control

While domain maps provide a high-level way of mapping iteration spaces and arrays to the target architecture, Chapel also provides a low-level mechanism for controlling locality called the on-clause. Any Chapel statement may be prefixed by an on-clause that indicates the locale on which that statement should execute. On-clauses can take an expression of locale type as their argument, which specifies that the statement should be executed on the specified locale. They may also take any other variable expression, in which case the statement will execute on the locale that stores that variable. For example, the following modification to an earlier example will execute the FFT on Locale #1 while executing the Jacobi iteration on the locale that owns element i,j of B:

```
on Locales[1] do begin FFT(A);
on B(i,j) do Jacobi(B);
```

Base Language

Chapel's base language was designed to support productive parallel programming, the ability to achieve high performance, and the features deemed necessary for supporting user-defined distributions effectively. In addition to a fairly standard set of types, operators, expressions, and statements, the base language supports the following features:

- A rich compile-time language: Chapel supports the ability to define functions that are evaluated at compile time, including functions that return types. Users may also indicate conditionals that should be folded at compile time as well as loops that should be statically unrolled.
- Static-type inference: Chapel supports a static-type inference scheme in which specifications can be omitted in most declaration settings, causing the compiler to infer the types from context. For example, a variable declaration may omit the variable's type as long as it is initialized, in which case the compiler infers its type from the initializing expression. This supports exploratory programming as in scripting languages without the runtime overhead of

dynamic typing. It also supports generic programming and code reuse.

- Iterators: Chapel's iterators are functions that yield multiple values over their lifetime (as in CLU or Ruby) rather than returning a single time. These iterators can be used to control serial and parallel loops.
- Configuration variables: Chapel's configuration variables are symbols whose default values can be overridden on the command line of the compiler or executable using argument parsing that is implemented automatically by the compiler.
- Tuples: These support the ability to group values together in a lightweight manner, for example, to return multiple values from a function or to represent multidimensional array indices using a single variable.

Future Directions

At the time of this writing, the Chapel language is still evolving based on user feedback, code studies, and the implementation effort. Some notable areas where additional work is expected in the future include:

- Support for heterogeneity: Heterogeneous systems are becoming increasingly common, especially those with heterogeneous processor types such as traditional CPUs paired with accelerators such as graphics processing units (GPUs). To support such systems, it is anticipated that Chapel's locale concept will need to be refined to expose architectural substructures in abstract and/or concrete terms.
- Transactional memory: Chapel has plans to support an atomic block for expressing transactional computations against memory, yet software transactional memory (STM) is an active research area in general, and becomes even trickier in the distributed memory context of Chapel programs.
- Exceptions: One of Chapel's most notable omissions is support for exception- and/or error-handling mechanisms to deal with software failures in a robust way, and perhaps also to be resilient to hardware failures. This is an area where the original Chapel team felt unqualified to make a reasonable proposal and intended to fill in that lack over time.

In addition to the above areas, future design and implementation work is expected to take place in the areas of task teams, dynamic load balancing, garbage

collection, parallel I/O, language interoperability, and tool support.

Bibliographic Notes and Further Reading

The two main academic papers providing an overview of Chapel's approach are also two of the earliest: "The Cascade High Productivity Language" [1] and "Parallel Programmability and the Chapel Language" [4]. While the language has continued to evolve since these papers were published, the overall motivations and concepts are still very accurate. The first paper is interesting in that it provides an early look at the original team's design while the latter remains a good overview of the language's motivations and concepts. For the most accurate description of the language at any given time, the reader is referred to the Chapel Language Specification. This is an evolving document that is updated as the language and its implementation improve. At the time of this writing, the current version is 0.796 [9].

Other important early works describing specific language concepts include "An Approach to Data Distributions in Chapel" by Roxana Diaconescu and Hans Zima [13]. While the approach to user-defined distributions eventually taken by the Chapel team differs markedly from the concepts described in this paper [6], it remains an important look into the early design being pursued by the Caltech/JPL team. Another concept-related paper is "Global-view Abstractions for User-Defined Reductions and Scans" by Deitz, Callahan, Chamberlain, and Snyder, which explored concepts for user-defined reductions and scans in Chapel [12].

In the trade press, a good overview of Chapel in Q&A form entitled "Closing the Gap with the Chapel Language" was published in HPCWire in 2008 [14]. Another Q&A-based document is a position paper entitled "Multiresolution Languages for Portable yet Efficient Parallel Programming," which espouses the

use of multiresolution language design in efforts like Chapel [3].

For programmers interested in learning how to use Chapel, there is perhaps no better resource than the release itself, which is available as an open-source download from SourceForge [7]. The release is made available under the Berkeley Software Distribution (BSD) license and contains a portable implementation of the Chapel compiler along with documentation and example codes. Another resource is a tutorial document that walks through some of the HPC Challenge benchmarks, explaining how they can be coded in Chapel. While the language has evolved since the tutorial was last updated, it remains reasonably accurate and provides a gentle introduction to the language [5]. The Chapel team also presents tutorials to the community fairly often, and slide decks from these tutorials are archived at the Chapel Web site [8].

Many of the resources above, as well as other useful resources such as presentations and collaboration ideas, can be found at the Chapel project Web site hosted at Cray [8].

To read about Chapel's chief influences, the best resources are probably dissertations from the ZPL team [2, 11], the High Performance Fortran Handbook [15], and the Cray XMT Programming Environment User's Guide [10] (the Cray XMT is the current incarnation of the Tera/Cray MTA).

Charm++

LAXMIKANT V. KALÉ
University of Illinois at Urbana-Champaign, Urbana,
IL, USA

Definition

Charm++ is a C++-based parallel programming system that implements a *message-driven migratable objects* programming model, supported by an adaptive runtime system.

Discussion

Charm++ [1] is a parallel programming system developed at the University of Illinois at Urbana-Champaign. It is based on a message-driven migratable objects programming model, and consists of a C++-based parallel notation, an adaptive runtime system (RTS) that automates resource management, a collection of debugging and performance analysis tools, and an associated family of higher level languages. It has been used to program several highly scalable parallel applications.

Motivation and Design Philosophy

One of the main motivations behind Charm++ is the desire to create an optimal division of labor between the programmer and the system: that is, to design a programming system so that the programmers do what they can do best, while leaving to the “system” what it can automate best. It was observed that deciding what to do in parallel is relatively easy for the application developer to specify; conversely, it has been very difficult for a compiler (for example) to automatically parallelize a given sequential program. On the other hand, automating resource management – which subcomputation to carry out on what processor and which data to store on a particular processor – is something that the system may be able to do better than a human programmer, especially as the complexity of the resource management task increases. Another motivation is to emphasize the importance of data locality in the language, so that the programmer is made aware of the cost of non-local data references.

Programming Model in Abstract

In Charm++, computation is specified in terms of collections of objects that interact via asynchronous method invocations. Each object is called a *chare*. Chares are assigned to processors by an adaptive runtime system, with an optional override by the programmer. A chare is a special kind of C++ object. Its behavior is specified by a C++ class that is “special” only in the sense that it must have at least one method designated as an “entry” method. Designating a method as an entry method signifies that it can be invoked from a remote processor. The signatures of the entry methods (i.e., the type and structure of its parameters) are specified in a separate interface file, to allow the system to generate code for packing (i.e., serializing) and unpacking the parameters into messages. Other than the existence of

the interface files, a Charm++ program is written in a manner very similar to standard C++ programs, and thus will feel very familiar to C++ programmers.

The chares communicate via *asynchronous* method invocations. Such a method invocation does not return any value to the caller, and the caller continues with its own execution. Of course, the called chare may choose to send a value back by invoking an entry method upon the caller object. Each chare has a globally valid ID (its *proxy*), which can be passed around via method invocations. Note that the programmer refers to only the target chare by its global ID, and not by the processor on which it resides. Thus, in the baseline Charm++ model, the processor is not a part of the ontology of the programmer.

Chares can also create other chares. The creation of new chares is also asynchronous in that the caller does not wait until the new object is created. Programmers typically do not specify the processor on which the new chare is to be created; the system makes this decision at runtime. The number of chares may vary over time, and is typically much larger than the number of processors.

Message-Driven Scheduler

At any given time, there may be several pending method invocations for the chares on a processor. Therefore, the Charm++ runtime system employs a *user-level* scheduler (Fig. 1) on each processor. The scheduler is user-level in the sense that the operating system is not aware of it. Normal Charm++ methods are non-preemptive: once a method begins execution, it returns control to the scheduler only after it has completed execution. The scheduler works with a queue of pending entry

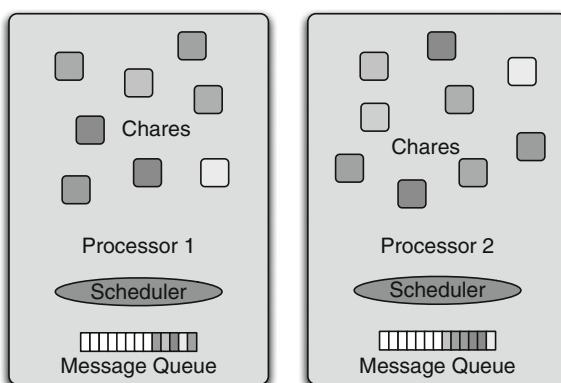

method invocations. Note that this queue may include asynchronous method invocations for chares located on this processor, as well as “seeds” for the creation of new chares. These seeds can be thought of as invocations of the constructor entry method. The scheduler repeatedly selects a message (i.e., a pending method invocation) from the queue, identifies the object targeted, creating an object if necessary, unpacks the parameters from the message if necessary, and then invokes the specified method with the parameters. Only when the method returns does it select the next message and repeats the process.

Chare-arrays and Iterative Computations

The model described so far, with its support for dynamic creation of work, is well-suited for expressing divide-and-conquer as well as divide-and-divide computations. The latter occur in state-space search. Charm++ (and its C-based precursor, Charm, and Chare Kernel [2]) were used in the late 1980s for implementing parallel Prolog [3] as well as several combinatorial search applications [4].

In principle, singleton chares could also be used to create the arbitrary networks of objects that are required to decompose data in Science and Engineering applications. For example, one can organize chares in a two-dimensional mesh network, and through some additional message passing, ensure that each chare knows the ID of its four neighboring chares. However, this method of creating a network of chares is quite cumbersome, as it requires extensive bookkeeping on the part of the programmer. Instead, Charm++ supports indexed collections of chares, called *chare-arrays*. A Charm++ computation may include multiple chare-arrays. Each chare-array is a collection of chares of the same type. Each chare is identified by an index that is unique within its collection. Thus, an individual chare belonging to a chare-array is completely identified by the ID of the chare-array and its own index within it. Common index structures include dense as well as sparse multidimensional arrays, but arbitrary indices such as strings or bit vectors are also possible. Elements in a chare-array may be created all at once, or can be inserted one at a time.

Method invocations can be broadcast to an entire chare-array, or a section of it. Reductions over chare-arrays are also supported, where each chare in a chare-array contributes a value, and all submitted values are combined via a commutative-associative operation. In

Charm++. Fig. 1 Message-driven scheduler

many other programming models, a reduction is a collective operation which blocks all callers. In contrast, reductions in Charm++ are non-blocking, that is, asynchronous. A `contribute` call simply deposits the value created by the calling chare into the system and returns to its caller. At some later point after all the values have been combined, the system delivers them to a user-specified callback. The callback, for example, could be a broadcast to an entry method of the same chare-array.

Charm++ does not allow generic global variables, but it does allow “specifically shared variables.” The simplest of these are read-only variables, which are initialized in the main chare’s constructor, and are treated as constants for the remainder of the program. The runtime system (RTS) ensures that a copy of each read-only variable is available on all physical processors.

Benefits of Message-driven Execution

The message-driven execution model confers several performance and/or productivity benefits.

Automatic and Adaptive Overlap of Computation and Communication

Since objects are scheduled based on the availability of messages, no single object can occupy the processor while waiting for some remote data. Instead, objects that have asynchronous method invocations (messages) waiting for them in the scheduler’s queue are allowed to execute. This leads to a natural overlap of communication and computation, without any extra work from the programmer. For example, a chare may send a message to a remote chare and wait for another message from it before continuing. The ensuing communication time, which would otherwise be an idle period, is naturally and automatically filled in (i.e., overlapped) by the scheduler with useful computation, that is, processing of another message from the scheduler’s queue for another chare.

Concurrent Composition

The ability to compose in parallel two individually parallel modules is referred to as concurrent composition. Consider two modules P and Q that are both ready to execute and have no direct dependencies among them. With other programming models (e.g., MPI) that

associate work directly with processors, one typically has two options. One may divide the set of processors so that a subset is executing one module (P) while the remaining processors execute the other (Q). Alternatively, one may sequentialize the modules, executing P first, followed by Q, on all processors. Neither alternative is efficient. Allowing the two modules to interleave the execution on all processors is often beneficial, but is hard to express even with wild-card receives, and it breaks abstraction boundaries between the modules in any case. With message driven execution, such interleaving happens naturally, allowing idle time in one module to be overlapped with computation in the other. Coupled with the ability of the adaptive runtime system to migrate communicating objects closer to each other, this adds up to strong support for concurrent composition, and thereby for increased modularity.

Prefetching Data and Code

Since the message driven scheduler can examine its queue, it knows what the next several objects scheduled to execute are and what methods they will be executing. This information can be used to asynchronously prefetch data for those objects, while the system executes the current object. This idea can be used by the Charm++ runtime system for increasing efficiency in various contexts, including on accelerators such as the Cell processor, for out-of-core execution and for prefetching data from DRAM to cache.

Capabilities of the Adaptive Runtime System Based on Migrability of Chares

Other capabilities of the runtime system arise from the ability to migrate chares across processors and the ability to place newly created chares on processors of its choice.

Supporting Task Parallelism with Seed Balancers

When a program calls for the creation of a singleton chare, the RTS simply creates a seed for it. This seed includes the constructor arguments and class information needed to create a new chare. Typically, these seeds are initially stored on the same processor where they are created, but they may be passed from processor to processor under the control of a runtime component called

the *seed balancer*. Different seed balancer strategies are provided by the RTS. For example, in one strategy, each processor monitors its neighbors' queues in addition to its own, and balances seeds between them as it sees fit. In another strategy, a processor that becomes idle requests work from a random donor – a work stealing strategy [5, 6]. Charm++ also includes strategies that balance priorities and workloads simultaneously, in order to give precedence to high-priority work over the entire system of processors.

Migration-based Load Balancers

Elements of chare-arrays can be migrated across processors, either explicitly by the programmer or by the runtime system. The Charm++ RTS leverages this capability to provide a suite of dynamic load balancing strategies. One class of such strategies is based on the *principle of persistence*, which is the empirical observation that in most science and engineering applications expressed in terms of their natural objects, computational loads and communication patterns tend to persist over time, even for dynamically evolving applications. Thus, the recent past is a reasonable predictor of the near future. Since the runtime system mediates communication and schedules computations, it can automatically instrument its execution so as to measure computational loads and communication patterns accurately. Load balancing strategies can use these measurements, or alternatively, any other mechanisms for predicting such patterns. Multiple load balancing strategies are available to choose from. The choice may depend on the machine context and applications, although one can always use the default strategy provided. Programmers can write their own strategy, either to specialize it to the specific needs of the application or in the hope of doing better than the provided strategies.

Dynamically Altering the Sets of Processors Used

A Charm++ program can be asked to change the set of processors it is using at runtime, without requiring any effort by the programmer. This can be useful to increasing utilization of a cluster running multiple jobs that arrive at unpredictable times. The RTS accomplishes this by migrating objects and adjusting its runtime data structures, such as spanning trees used in its collective

operations. Thus, a $1,024 \times 1,024 \times 1,024$ cube of data partitioned into $16 \times 16 \times 16$ array of chares, each holding $64 \times 64 \times 64$ data subcube, can be shrunk from 256 cores to (say) 247 cores without significantly losing efficiency. Of course, some cores will house 17 objects, instead of the 16 objects they did earlier.

Fault Tolerance

Charm++ provides multiple levels of support for fault tolerance, including alternative competing strategies. At a basic level, it supports automated application-level checkpointing by leveraging its ability to migrate objects. With this, it is possible to create a checkpoint of the program without requiring extra user code. More interestingly, it is also possible to use a checkpoint created on P processors to restart the computation on a different number of processors than P.

On appropriate machines and with job schedulers that permit it, Charm++ can also automatically detect and recover from faults. This requires that the job scheduler not kill a job if one of its nodes were to fail. At the time of this writing, these schemes are available on workstation clusters. The most basic strategy uses the checkpoint created on disk, as described above, to effect recovery. A second strategy avoids using disks for checkpointing, instead creating two checkpoints of each chare in the memory of two processors. It is suitable for those applications whose memory footprint at the point of checkpointing is relatively small compared with the available memory. Fortunately, many applications such as molecular dynamics and computational astronomy fall into this category. When it can be used, it is very fast, often accomplishing a checkpoint in less than a second and recovery in a few seconds. However, both strategies described above send *all* processors back to their checkpoints even when just one out of a million processors has failed. This wastes all the computation performed by processors that did not fail. As the number of processors increases and, consequently, the MTBF decreases, this will become an untenable recovery strategy. A third experimental strategy in Charm++ sends only the failed processor(s) to their checkpoints by using a message-logging scheme. It also leverages the over-decomposition and migratability of Charm++ objects to parallelize the restart process. That is, the

objects from failed processors are reincarnated on multiple other processors, where they re-execute, in parallel, from their checkpoints using the logged messages. Charm++ also provides a fourth *proactive* strategy to handle situations where a future fault can be predicted, say based on heat sensors, or estimates of increasing (corrected) cache errors. The runtime simply migrates objects away from such a processor and readjusts its runtime data structures.

Associated Tools

Several tools have been created to support the development and tuning of Charm++ applications. *LiveViz* allows one to inject messages into a running program and display attributes and images from a running simulation. *Projections* supports performance analysis and visualization, including live visualization, parallel on-line analysis, and log-based post-mortem analysis. *CharmDebug* is a parallel debugger that understands Charm++ constructs, and provides online access to runtime data structures. It also supports a sophisticated record-replay scheme and provisional message delivery for dealing with nondeterministic bugs. The communication required by these tools is integrated in the runtime system, leveraging the message-driven scheduler. No separate monitoring processes are necessary.

Code Example

[Figures 2](#) and [3](#) show fragments from a simple Charm++ example program to give a flavor of the programming model. The program is a simple Lennard-Jones molecular dynamics code. The computation is decomposed into a one-dimensional array of LJ objects, each holding a subset of atoms. The interface file ([Fig. 2](#)) describes

the main Charm-level entities, their types and signatures. The program has a read-only integer called numChares that holds the size of the LJ chare-array. In this particular program, the main chare is called Main and has only one method, namely, its constructor. The LJ class is declared as constituting a one-dimensional array of chares. It has two entry methods in addition to its constructor. Note the others [n] notation used to specify a parameter that is an array of size n, where n itself is another integer parameter. This allows the system to generate code to serialize the parameters into a message, when necessary. CkReductionMsg is a system-defined type which is used as a target of entry methods used in reductions.

Some important fragments from the C++ file that define the program itself are shown in [Fig. 3](#). Sequential code not important for understanding the program is omitted. The classes Main and LJ inherit from classes generated by a translator based on the interface file. The program execution consists of a number of time steps. In each time step, each processor sends its particles on a round-trip to visit all other chares. Whenever a packet of particles visits a chare via the passOn method, the chare calculates forces on each of the visiting (others) particles due to each of its own particles. Thus, when the particles return home after the round-trip, they have accumulated forces due to all the other particles in the system. A sequential call (integrate) then adds local forces to the accumulated forces and calculates new velocities and positions for each owned particle. At this point, to make sure the time step is truly finished for all chares, the program uses an “asynchronous reduction” via the contribute call. To emphasize the asynchronous nature of this call, the example makes

```
mainmodule ljdyn {
    readonly int numChares;
    ...
    mainchare Main {
        entry Main(CkArgMsg *m);
    };

    array [1D] LJ {
        entry LJ(void);
        entry void passOn(int home, int n, Particle others[n]);
        entry void startNextStep(CkReductionMsg *m);
    };
}
```

Charm++. Fig. 2 A simple molecular dynamics program: interface file

```

/*readonly*/ int numChares;

classMain : public CBase_Main {
    Main(CkArgMsg*m) {
        //Process command-line arguments
        ...
        numChares = atoi(m->argv[1]);
        ...
        CProxy_LJ arr = CProxy_LJ::ckNew(numChares);
    }
};

class LJ : public CBase_LJ {
    int timeStep, numParticles, next;
    Particle * myParticles;
    ...
    LJ() {
        ...
        myParticles = new Particle[numParticles];
        ... // initialize particle data
        next = (thisIndex + 1) % numChares;
        timeStep = 0;
        startNextStep((CkReductionMsg * )NULL);
    }

    void startNextStep(CkReductionMsg* m) {
        if (++timeStep > MAXSTEPS) {
            if (thisIndex == 0) { ckout << "Done\n" << endl; CkExit(); }
        } else
            thisProxy[next].passOn(thisIndex, numParticles, myParticles);
    }

    void passOn(int homeIndex, int n, Particle* others) {
        if (thisIndex != homeIndex) {
            interact(n, others); //add forces on "others" due to my particles
            thisProxy[next].passOn(homeIndex,n, others);
        } else { // particles are home, with accumulated forces
            CkCallback cb(CkIndex_LJ::startNextStep(NULL), thisProxy);
            contribute(cb); // asynchronous barrier
            integrate( n, others); // add forces and update positions
        }
    }

    void interact(int n, Particle* others){
        /* add forces on "others" due to my particles */
    }

    void integrate(int n, Particle* others){
        /*... apply forces, update positions... */
    }
};

```

Charm++.Fig. 3 A simple molecular dynamics program: fragments from the C++ file

the call before `integrate`. The `contribute` call simply deposits the contribution into the system and continues on to `integrate`. The `contribute` call specifies that after all the array elements of `LJ` have contributed, a callback will be made. In this case, the callback is

a broadcast to all the members of the chare-array at the entry-method `startNextStep`. Inherited variable `thisProxy` is a proxy to the entire chare-array. Similarly, `thisIndex` refers to the index of the calling chare in the chare-array to which it belongs.

Language Extensions and Features

The baseline programming model described so far is adequate to express all parallel interaction structures. However, for programming convenience, increased productivity and/or efficiency, Charm++ supports a few additional features. For example, individual entry methods can be marked as “threaded.” This results in the creation of a user-level, lightweight thread whenever the entry method is invoked. Unlike normal entry methods, which always complete their execution and return control to the scheduler before other entry methods are executed, threaded entry methods can block their execution; of course they do so without blocking the processor they are running on. In particular, they can wait for a “future,” wait until another entry method unblocks them, or make blocking method invocations. An entry method can be tagged as blocking (actually called a “sync” method), and such a method is capable of returning values, unlike normal methods that are asynchronous and therefore have a return type of `void`.

Often, threaded entry methods are used to describe the life cycle of a chare. Another notation within Charm++, called “structured dagger,” accomplishes the same effect without the need for a separate stack and associated memory for each user level thread and the, admittedly small, overhead associated with thread context switches. However, it requires that all dependencies on remote data be expressed in this notation within the text of an entry-method. In contrast, the thread of control may block waiting for remote data within functions called from a threaded entry method.

Charm++ as described so far does not bring in the notion of a “processor” in the programming model. However, some low-level constructs that refer to processors are also provided to programmers and especially to library writers. For example, when a chare is created, one can optionally specify which processor to create it on. Similarly, when a chare-array is created, one can specify its initial mapping to processors. One can create specialized chare-arrays, called *groups*, that have exactly one member on each processor, which are useful for implementing services such as load balancers.

Languages in the Charm Family

AMPI or Adaptive MPI is an implementation of the message passing interface standard on top of the

Charm++ runtime system. Each MPI process is implemented as a user level thread that is embedded inside a Charm++ object, as a threaded entry method. These objects can be migrated across processors, as is usual for Charm++ objects, thus bringing benefits of the Charm++ adaptive runtime system, such as dynamic load balancing and fault tolerance, to traditional MPI programs. Since there may be multiple MPI “processes” on each core, commensurate with the overdecomposition strategy of Charm++ applications, the MPI programs need to be modified in a mechanical, systematic fashion to avoid conflict among the global variables. Adaptive MPI provides tools for automating this process to some extent. As a result, a standard Adaptive MPI program is also a legal MPI program, but the converse is true only if the use of global variables has been handled via such modifications. In addition, Adaptive MPI provides primitives such as asynchronous collectives, which are not part of the MPI 2 standard. An asynchronous reduction, for example, carries out the communication associated with a reduction in the background while the main program continues on with its computation. A blocking call is then used to fetch the result of the reduction.

Two recent languages in the Charm++ family are multiphase shared arrays (MSA) and Charisma. These are part of the Charm++ strategy of creating a toolbox consisting of incomplete languages that capture some interaction modes elegantly and frameworks that capture the needs of specific domains or data structures, both backed up by complete languages such as Charm++ and AMPI. The compositionality afforded by message-driven execution ensures that modules written using multiple paradigms can be efficiently composed in a larger application.

MSA is designed to support disciplined use of shared address space. The computation consists of collections of threads and multiple user-defined data arrays, each partitioned into user-defined pages. Both entities are implemented as migratable objects (i.e., chares) available to the Charm++ runtime system. The threads can access the data in the arrays, but each array is in only one of a restrictive set of access modes at a time. *Read-only*, *exclusive-write*, and *accumulate* are examples of the access modes supported by MSA. At designated synchronization points,

a program may change the access modes of one or more arrays.

Charisma, another language implemented on top of Charm++, is designed to support computations that exhibit a static data flow pattern among a set of Charm++ objects. Such a pattern, where the flow of messages remains the same from iteration to iteration, even though the content and the length of messages may change, is extremely common in science and engineering applications. For such applications, Charisma provides a convenient syntax that captures the flow of values and control across multiple collections of objects clearly. In addition, Charisma provides a clean separation of sequential and parallel code that is convenient for collaborative application development involving parallel programmers and domain specialists.

Frameworks atop Charm++

In addition to its use as a language for implementing applications directly, Charm++ is seen as backend for higher level frameworks and languages described above. Its utility in this context arises because of the interoperability and runtime features it provides, which one can leverage to put together a new domain-specific framework relatively quickly. An example of such a framework is ParFUM, which is aimed at unstructured mesh applications. ParFUM allows developers of sequential codes based on such meshes to retarget them to parallel machines, with relatively few changes. It automates several commonly needed functions including the need to exchange boundary nodes (or boundary layers, in general) with neighboring objects. Once a code is ported to ParFUM, it can automatically benefit from other Charm++ features such as load balancing and fault tolerance.

Applications

Some of the highly scalable applications developed using Charm++ are in extensive use by scientists on national supercomputers. These include NAMD (for biomolecular simulations), OpenAtom (for electronic structure simulations), and ChaNGa (for astrophysical N-body simulations).

Origin and History

The Chare Kernel, a precursor of the Charm++ system, arose from the work on parallel Prolog at the University of Illinois in Urbana-Champaign in the late 1980s. The implementation mechanism required a collection of computational entities, one for each active clause (i.e., its activation record) of the underlying logic program. Each of these entities typically received multiple responses from its children in the proof tree, and they needed to create new nodes in the proof tree which had to fire new “tasks” for each of its active clauses. The implementation led to a message-driven scheduler and dynamic creation of the seeds of work. These entities were called *chares*, borrowing the term used by an earlier parallel functional-languages project, RediFlow. Chare Kernel essentially separated this implementation mechanism from its parallel Prolog context, into a C-based parallel programming paradigm of its own. Charm had similarities (in particular, its message-driven execution) with the earlier research on reworking of the Hewitt’s Actor framework by Agha and Yonezawa [7, 8]. However, its intellectual progenitors were in parallel logic and functional languages. With the increase in popularity of C++, Charm++ became the version of Charm for C++, which was a natural fit for its object-based abstraction. As many researchers in parallel logic programming shifted attention to scientific computations, indexed collections of migratable chares were developed in Charm++ to simplify addressing chares in mid-1990s. In the late 1990s, Adaptive MPI was developed in the context of applications being developed at the Center for Simulation of Advanced Rockets at Illinois. Charm++ continues to be developed and maintained from the University of Illinois, and its applications are in regular use at many supercomputers around the world.

Availability and Usage

Charm++ runs on most parallel machines available at the time this entry was written, including multicore desktops, clusters, and large-scale proprietary supercomputers, running Linux, Windows, and other operating systems. Charm++, its associated software tools and libraries can be downloaded in source code and binary forms from <http://charm.cs.illinois.edu> under a license that allows free use for noncommercial purposes.

Bibliographic Notes and Further Reading

One of the earliest papers on the Chare Kernel, the precursor of Charm++ was published in 1989 [9], followed by a more detailed description of the model and its load balancers [2, 10]. This work arose out of earlier work on parallel Prolog [3]. The C++ based version was described in an OOPSLA paper in 1993 [1] and was expanded upon in a book on parallel C++ in [11]. Early work on quantifying benefits of the programming model is summarized in a later paper [12].

Some of the early applications using Charm++ were in symbolic computing and, specifically, in parallel combinatorial search [4]. A scalable framework for supporting migratable arrays of chares is described in a paper [13], which is also useful for understanding the programming model. An early paper [14] describes support for migrating Chares for dynamic load balancing. Recent papers describe an overview of Charm++ [15] and its applications [16].

Checkpoint/Restart

- [Checkpointing](#)

Checkpointing

MARTIN SCHULZ

Lawrence Livermore National Laboratory, Livermore, CA, USA

Synonyms

[Checkpoint-recovery](#); [Checkpoint/Restart](#)

Definition

In the most general sense, Checkpointing refers to the ability to store the state of a computation in a way that

allows it to be continued at a later time without changing the computation's behavior. The preserved state is called the *Checkpoint* and the continuation is typically referred to as a *Restart*.

Checkpointing is most typically used to provide fault tolerance to applications. In this case, the state of the entire application is periodically saved to some kind of stable storage, e.g., disk, and can be retrieved in case the original application crashes due to a failure in the underlying system. The application is then restarted (or recovered) from the checkpoint that was created last and continued from that point on, thereby minimizing the time lost due to the failure.

Discussion

Checkpointing is a mechanism to store the state of a computation so that it can be retrieved at a later point in time and continued. The process of writing the computation's state is referred to as *Checkpointing*, the data written as the *Checkpoint*, and the continuation of the application as *Restart* or *Recovery*. The execution sequence between two checkpoints is referred to as a *Checkpointing Epoch* or just *Epoch*.

As discussed in section “► [Checkpointing Types](#)”, Checkpointing can be accomplished either at system level, transparently to the application (section “► [System-Level Checkpointing](#)”), or at application level, integrated into an application (section “► [Application-Level Checkpointing](#)”). While the first type is easier to apply for the end user, the latter one is typically more efficient.

While checkpointing is useful for any kind of computation, it plays a special role for parallel applications (section “► [Parallel Checkpointing](#)”), especially in the area of High-Performance Computing. With rising numbers of processors in each system, the overall system availability is decreasing, making reliable fault tolerance mechanisms, like checkpointing, essential. However, in order to apply checkpointing to parallel applications, the checkpointing software needs to be able to create globally consistent checkpoints across the entire application, which can be achieved using either coordinated (section “► [Coordinated Checkpointing](#)”) or uncoordinated (section “► [Uncoordinated Checkpointing](#)”) checkpointing protocols.

Independent of the type and the underlying system, checkpointing systems always require some kind

of storage to which the checkpoint can be saved, which is discussed in section “Checkpoint Storage Considerations”.

Checkpointing is most commonly associated with fault tolerance: It is used to periodically store the state of an application to some kind of stable storage, such that, after a hardware or operating system failure, an application can continue its execution from the last checkpoint, rather than having to start from scratch. The following entry will concentrate on this usage scenario, but will also discuss some alternate scenarios in section “Alternate Usage Scenarios”.

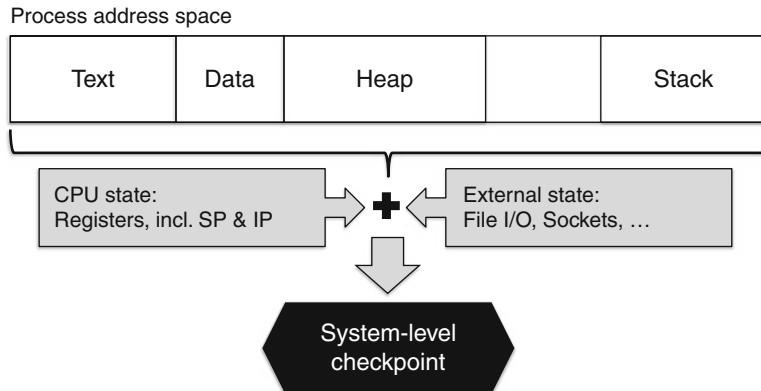

Checkpointing Types

Checkpointing can be implemented either at the system level, i.e., by the operating system or the system environment, or within the application itself.

System-Level Checkpointing

In system level checkpointing, the state of a computation is saved by an external entity, typically without the application's knowledge or support. Consequently, the complete process information has to be included in the checkpoint, as illustrated in Fig. 1. This includes not only the complete memory footprint including data segments, the heap, and all stacks, but also register and CPU state as well as open file and other resources. On restart, the complete memory footprint is restored, all file resources are made available to the process again, and then the register set is restored to its original state, including the program counter, allowing the application to continue at the same point where it had been interrupted for the checkpoint.

System-level checkpoint solutions can either be implemented inside the kernel as a kernel module or service, or at the user level. The former has the advantage that the checkpointer has full access to the target process as well as its resources. User-level checkpointers have to find other ways to gather this information, e.g., by intercepting all system calls. On the flip side, user-level schemes are typically more portable and easier to deploy, in particular in large-scale production environments with limited access for end users.

Checkpointing. Fig. 1 System-level checkpointing

Application-Level Checkpointing

The alternative to system-level checkpointing is to integrate the checkpointing capability into the actual application, which leads to application-level checkpointing solutions. In such systems, the application is augmented with the ability to write its own state into a checkpoint as well as to restart from it. While this requires explicit code inside the application and hence is no longer transparent, it gives the application the ability to decide when checkpoints should be taken (i.e., when it is a good time to write the state, e.g., when memory usage is low or no extra resources are used) and what should be contained in the checkpoint (Fig. 2). The latter enables applications to remove noncritical memory regions, e.g., temporary fields, from the checkpoint and hence reduce the checkpoint size.

To illustrate the latter point, let us consider a classical particle simulation in which the location and speed of a set of particles is updated at each iteration step based on the physical properties of the underlying system. The complete state of the computation can be represented by only the two arrays representing the coordinates and velocities of all particles in the simulation. If checkpoints are taken at iteration boundaries after the update of all arrays is complete, only these arrays need to be stored to continue the application at a later time. Any temporary array, e.g., used to compute forces between particles, as well as stack information does not need to be included. A system-level checkpoint, on the other hand, would not be able to determine which parts of the data are relevant and which are not and would have to store the entire memory segment.

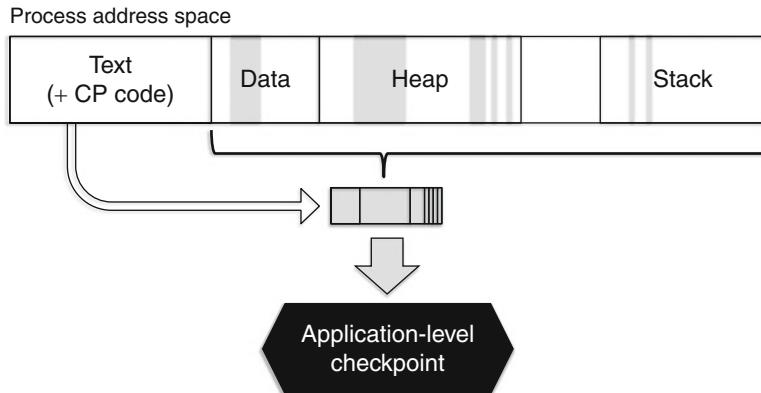

Application-level checkpointing is used in many high-performance computing applications, especially in simulation codes. They are part of the applications' base design and implemented by the programmer. Additionally, systems like SRS [1] provide toolboxes that allow users to implement application-level checkpoints in their codes on top of a simple and small API.

Trade-offs

Both approaches have distinct advantages and disadvantages. The key differences are summarized in Table 1. While system-level checkpoints provide full transparency to the user and require no special mechanism or consideration inside an application, this transparency is missing in application-level checkpointers. On the other hand, this transparency comes at the price of high implementation complexity for the checkpointing software. Not only must it be able to checkpoint the complete system state of an arbitrary process with arbitrary resources, but also has to do so at any time independent of the state the process is in.

In contrast to system-level checkpointers, application-level approaches can exploit application-specific information to optimize the checkpointing process. They are able to control the timing of the checkpoints and they can limit the data that is written to the checkpoint, which reduces the data that has to be saved and hence the size of the checkpoints.

Combining the advantages of both approaches by providing a transparent solution with the benefits of an application-level approach is still a topic of basic research. The main idea is, for each checkpoint inserted

Checkpointing. Fig. 2 Application-level checkpointing

Checkpointing. Table 1 Key differences between system- and application-level checkpointing

System-level checkpointing	Application-level checkpointing
Transparent	Integrated into the application
Implementation complexity high	Implementation complexity medium or low
System specific	Portable
Checkpoints taken at arbitrary times	Checkpoints taken at predefined locations
Full memory dump	Only save what is needed
Large checkpoint files	Checkpoint files only as large as needed

into the application (either by hand or by a compiler), to identify which variables need to be included in the checkpoint at that location, i.e., those variables that are in scope and that are actually used after the checkpoint location (and cannot be easily recomputed) [2, 3]. While this can eliminate the need to save some temporary arrays, current compiler analysis approaches are not powerful enough to achieve the same efficiency as manual approaches.

Parallel Checkpointing

Checkpointing is of special importance in parallel systems. The larger numbers of components used for a single computation naturally decreases the mean time between failures, making system faults more likely. Already today's largest systems consist of over 100,000

processing cores and systems with 1,000 to 10,000 cores are common in High-Performance Computing [4]; future architectures will have even more, as plans for machines with over a million cores have already been announced [5]. This scaling trend requires effective fault tolerance solutions for such parallel platforms and their applications.

However, checkpointing a parallel application cannot be implemented by simply replicating a sequential checkpointing mechanism to all tasks of a parallel application, since the individual checkpoints would not be coordinated and it would therefore not be possible to capture a complete snapshot of the application's state from which the computation can be restarted.

The solution of this problem depends on the type of system used. In the following, the entry discusses approaches for shared memory and message passing applications, the two dominant programming models for HPC (High-Performance Computing).

Checkpointing in Shared Memory Applications

Checkpointing for shared memory systems programmed using threads can be implemented very similar to a checkpointer for a sequential system. Since all state is shared, it is sufficient for a system-level checkpointer to suspend all threads before a checkpoint and then checkpoint the complete state of the process, including the separate call stacks and register files of all threads. No further coordination is necessary. On restart, the system has to recreate all threads that the original system had, including all resources like locks or semaphores held by the application before the

checkpoint, before loading the actual checkpoint into the context of all threads.

Application-level checkpointers typically use their knowledge about the code to insert checkpoints at locations in which only one thread is active and then can checkpoint the complete state as in a sequential program. Otherwise, a coordination between the threads and individual local checkpoints is necessary to ensure checkpoints with consistent global state (which is shared and accessible by all threads) and matching per thread call stacks (which are only accessible by the individual threads). An example for such a coordination protocol is given by Bronevetsky et al. [6], which ensures that all active threads are stopped at appropriate locations before taking a checkpoint.

Checkpointing in Message Passing Applications

The situation for message passing systems is more complicated since checkpoints from multiple processes, potentially running on different nodes, have to be taken. Therefore, a checkpointing mechanism needs to take into account which communication and interprocess dependencies exist before any checkpoint is actually committed to the system. In order to achieve this goal, an additional protocol is required that coordinates the checkpoints in one way or another.

[Figure 3](#) illustrates the two conflict scenarios that can occur without the proper coordination. All figures show the time lines of two processes P_0 and P_1 with time increasing from left to right and arrows indicating messages between the two processes. If local checkpoints are to be taken at arbitrary times and communication occurs between the individual instances of checkpoints, one of two scenarios can occur: A message is expected by a process after restart that will not be sent anymore because it was originally sent before the other sender's checkpoint ([Fig. 3a](#)); or a message should not be sent anymore after a restart since it is already been consumed by a receiver before its own checkpoint ([Fig. 3b](#)). The first type of scenario is typically referred to as a *late message*, while the second one is referred to as an *early message*.

Two main approaches exist to achieve proper checkpoint coordination between parallel processes to eliminate the conflicts caused by these two scenarios:

Coordinated Checkpointing protocols enforce a coordination at checkpoint time and hence avoid the problem before it occurs, while *Uncoordinated Checkpointing* protocols allow checkpoints at arbitrary points, but then use additional mechanisms to eliminate inconsistencies if they should occur.

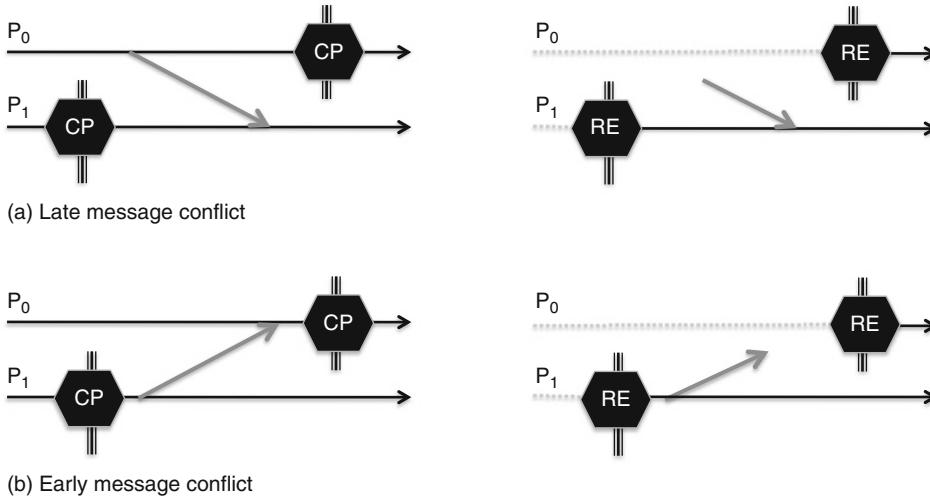

Coordinated Checkpointing

The first variant, coordinated checkpointing, controls the system in a way that all local checkpoints are taken at a point that avoids such inconsistencies. However, avoiding late messages in a general scheme without any application knowledge or global state is hard since a receiver can never know whether another process has already sent a message or not when it decides to take a checkpoint. Luckily, tracking and dealing with late message is straightforward: They can simply be buffered on the receiving task and stored at the receiver. During the restart, they are then replayed from the checkpoint instead of received from the network.

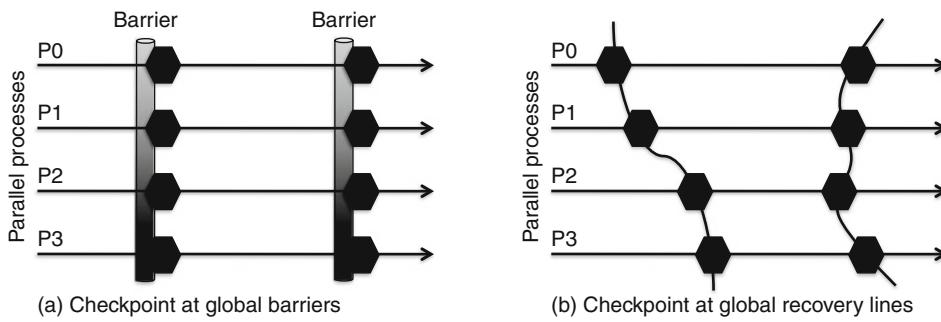

Early messages, on the other hand, are more difficult to handle. Not only do they require a global operation to avoid messages not being sent on restart, but they also require a deterministic execution after a restart to ensure that the same message content would have been sent in the early message, since the receiver has already consumed the message before the checkpoint and hence its contents is now part of the checkpointed state.

Due to these problems, most coordinated checkpointing schemes are designed in a way that prevents the occurrence of early messages. In the simplest case, as illustrated in [Fig. 4a](#), checkpoints are taking at global synchronization points, e.g., at barrier operations. This ensures that all tasks are at the same point in their executions and that no early messages can occur in the system. However, this solution is limited to codes that have natural points for global synchronization.

In the more general case, which is applicable to any irregular application, the system aims at forming a globally consistent cut through the program, which is not traversed by an early message ([Fig. 4b](#)). An algorithm for this has been introduced by Chandy and Lamport [7]. In this approach, the system forces a local checkpoint as soon as it receives a message from a process that has already started a checkpoint, but before the message is consumed. This prevents any process from receiving a message sent from a future checkpointing

Checkpointing. Fig. 3 Message conflicts caused by uncoordinated checkpoints (checkpoint shown left, restart shown right)

Checkpointing. Fig. 4 Consistency lines in coordinated checkpointing systems

epoch, since such messages would have triggered the automatic checkpoint.

The main restriction of this approach is that it dictates when local checkpoints have to be taken. This limits possible optimizations of the checkpoint location and reduces the flexibility when such a mechanism is intended to be used in an application-level scheme. Some research projects [8] have their proposed alternate solutions allowing early messages and adding the necessary information to remove their effects to the checkpoint.

Uncoordinated Checkpointing

A second approach to parallel checkpointing is the use of an uncoordinated checkpointing system. In such systems, local checkpoints are taken at arbitrary times, but then the system deploys additional mechanisms

to correct for inconsistent messages. The technique most used for this purpose is message logging. In this approach, all messages in an epoch are logged (together with the results of all nondeterministic operations and library calls) and stored together with the checkpoint. During restart, this complete message log is then used to recreate the complete global state of the application by replaying all messages and nondeterministic events that occurred between taking the individual local checkpoints.

In contrast to coordinated checkpointing, this approach requires less complexity during the initial application run since both the checkpoints and the message logging are purely local operation; no global coordination has to be executed. On the other hand, the restart of an application is significantly more complex since the shared state has to be recreated at that time. An

additional drawback is that for some applications, the message logs can be of significant size putting further pressure on the storage system.

Checkpoint Storage Considerations

Any checkpointing solution, independent of the design decisions discussed above, requires that each generated checkpoint has to be written to a storage location outside the current process, so that the computation can be restarted once the original process terminates. In the case of checkpointing for fault tolerance, this storage must also be able to survive the crash of the application or the underlying system.

Checkpoint Storage Locations

Therefore, the most common storage scenario is that checkpoints are written to disk, preferably to a remote server, since this allows the user to retrieve the checkpoint even if the initial system the application had been executed on becomes inaccessible or suffers a complete data loss. In case of a parallel checkpoint, the storage location has to receive checkpoints from all processes in the target application. While this is typically not a problem for small systems, it can lead to significant bottlenecks on systems with large numbers of nodes. In such cases, checkpoints are typically written to a parallel file system like lustre, GPFS, or PVFS, since those are designed to handle concurrent writes from a large number of processes.

Diskless Checkpointing

However, even with the use of a parallel file system, the I/O required for frequent checkpoints can be large and can, for growing numbers of nodes, start dominating the execution cost. Alternatively, checkpoints can also be stored in the memory of remote nodes, but within the cluster itself, which is referred to as *Diskless Checkpointing* and has, e.g., been demonstrated by Silvia et al. [9], Planck et al. [10], and Zheng et al. [11].

Such systems often distribute the state of a single node on multiple remote nodes using error correcting codes, such that the failure of one of the machines containing the checkpoint does not lead to the loss of the checkpoint. Diskless checkpointing eliminates the need for any I/O to a central storage facility outside the cluster and therefore reduces the time needed to store a

checkpoint. However, during the recovery, a more complex protocol is required to identify the remote storage locations of the last checkpoint and to reassemble it for a proper restart. Further, the application remains vulnerable to a failure of the entire cluster, e.g., caused by power loss. Some checkpoint solutions, like SCR [12], therefore provide mechanisms to combine in memory and on disk checkpoints by adaptively choosing the appropriate location based on the application's fault tolerance needs.

Incremental Checkpointing

A different aspect to optimizing storage are techniques to reduce the size of the checkpoints. Of particular interest for several research projects is thereby incremental checkpointing [13, 14]. In this approach, each checkpoint only stores the difference between itself and the previous checkpoint. In scenarios with frequent checkpoints or slowly evolving application, this has the potential to reduce the checkpoint storage requirements, and with that also the time it takes to store the checkpoint, significantly. On the downside, though, this approach requires the system to keep all previous checkpoints around, since these may be needed to recreate the most recent state.

Alternate Usage Scenarios

The usage scenario commonly associated with checkpointing is to provide transparent fault tolerance to the application that is being checkpointed. However, the idea of checkpointing, using the same techniques, can also be applied in different scenarios. Some of them are described in the following:

Time Sharing of Large-Scale Resources

In order to allow a fair scheduling for all users, large-scale compute centers often impose a limit on the total execution time of a single job. Large-scale applications, in particular simulation codes, however, often require significantly longer overall execution times than those dictated by these artificial limits.

In order to execute longer running jobs, they can take a checkpoint at the end of their time slot and then store this checkpoint on stable storage. When the application is granted access to a partition again, it can then read this checkpoint file and continue its execution.

This way several partition allocations, potentially even from the different machines, can be chained together.

Such checkpointing is typically implemented with the individual applications using an application-level approach. This reduces the amount of data that has to be stored and also allows for more flexibility during restart.

Migration

Similar to the above is the idea of process migration: A process is stored, removed from the system, and then either immediately or later restored, but in this case on a different node. [Figure 5](#) illustrates this further. The ability to migrate checkpoints is straightforward as long as the source and target architectures are identical, i.e., the checkpoint can be transferred and restarted without conversion.

In heterogeneous environments, however, this can be more complex. In this case, the checkpoint either needs to be stored in an architecture-independent format or the checkpoint needs to be converted from one architecture to the next. This has many implications, including the problem that heap address cannot be maintained anymore across checkpoint/restart sequences. Consequently, this option typically requires an application-level checkpointing approach or imposes limits on the applications, e.g., by only allowing a subset of a program language to be used.

Migration systems that use some kind of checkpointing exist at various granularities. For example, the Condor scheduling system [15, 16] applies it to complete jobs to achieve a better utilization of compute clusters for high-throughput computing, while systems like Charm++ [17, 18] have the ability to apply it to fine grain

parallelism and use it to checkpoint individual threads or active objects in a large-scale system to achieve load balancing.

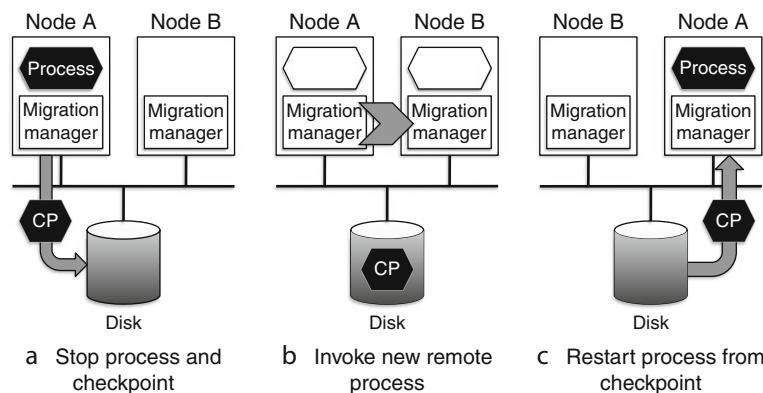

Virtual Machine Checkpointing

Virtual machines that allow the execution or emulation of an entire system on top of a (potentially different) host system have become commonplace. These systems typically allow the state of the virtual machine, which is often contained in a single file within the host system, to be saved such that the virtual machine can be interrupted and later continued. This functionality represents a system-level checkpointing, which is completely transparent. However, the target of the checkpointing is no longer a single process or computation, but rather the complete virtualized operating system image.

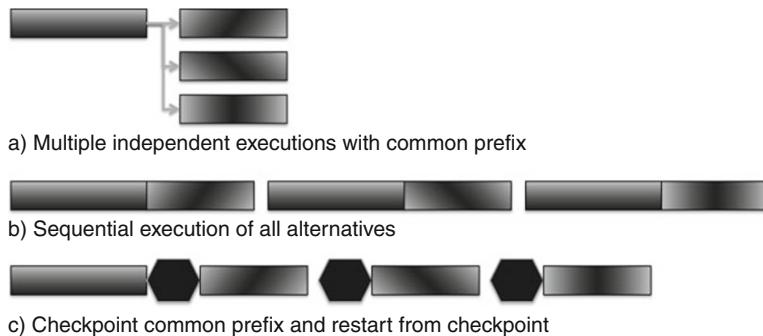

Exploration of Alternate Executions

Checkpointing systems can also improve the explore alternate execution sequences if those require a common prefix. Such scenarios can be found, e.g., in parameters studies of simulations (in which the common prefix is a warmup or initialization phase that should not be included in the actual parameter study) or in exhaustive search algorithms that require backtracking to intermediate execution points.

[Figure 6](#) illustrates this approach further: The top graphics ([Fig. 6a](#)) shows the conceptual execution with a common prefix and three alternate executions after the prefix. Without checkpointing, the complete run requires the execution of the application three times ([Fig. 6b](#)), repeating the common prefix. Using checkpointing it is possible, though, to execute the prefix

Checkpointing. [Fig. 5](#) Migrating a process using checkpointing

Checkpointing. Fig. 6 Investigating alternate executions

only once, checkpoint the state of the process, and then continue with the first execution. Once this is complete, the checkpoint can be restarted as many times as necessary to complete the remaining execution alternatives (Fig. 6c).

In contrast to traditional checkpointing, where checkpoints are written proactively and read only once, in this scenario, the application only writes a very limited set of checkpoints, but then reuses them several times.

Bibliographic Notes and Further Reading

Elnozahy et al. provide an in-depth overview of checkpoint/restart implementations [19]. Besides that, checkpointing solutions have been implemented on several platforms, typically in the form of system-level checkpointing, in some cases, like on IBM's BlueGene line, even as part of the standard operating system stack. Also some platform-independent solutions are commercially available, one example being Librato's Availability Services (Avs) [20] (a user-level implementation). Additionally, several academic projects offer system-level checkpoint/restart solutions, e.g., LibCkpt [21] (user-level), BLCR [22] (kernel-level), CoCheck [23] (user-level for MPI and PVM applications), or Condor [15, 16] (user-level, integrated with a cluster scheduling system). Message logging-based approaches have received special attention in the past few years due to their scaling promises. Examples for the latter are

in extensions to MVAPICH-2 by Bouteiller et al. [24] or the Optimistic Message Logging approach by Wang et al. [25].

Definition

Cilk (pronounced “silk”) is a linguistic and runtime technology for algorithmic multithreaded programming originally developed at MIT. The philosophy behind Cilk is that a programmer should concentrate on structuring her or his program to expose parallelism and exploit locality, leaving Cilk’s runtime system with the responsibility of scheduling the computation to run efficiently on a given platform. The Cilk runtime system takes care of details like load balancing, synchronization, and communication protocols. Cilk is algorithmic in that the runtime system guarantees efficient and predictable performance. Important milestones in Cilk technology include the original Cilk-1, which provided a provably efficient work-stealing runtime support but

little linguistic support; the later Cilk-5, which provided simple linguistic extensions for multithreading to ANSI C; the commercial Cilk++, which extended the Cilk model to C++ and introduced “reducer hyper-objects” as an efficient means for resolving races on nonlocal variables; and Intel Cilk Plus, which provided transparent interoperability with legacy C/C++ binary executables.

Discussion

Introduction

Cilk technology has developed and evolved over more than 15 years since its origin at MIT. Key releases of Cilk include Cilk-1 [11, 14, 53], Cilk-NOW [11, 18], Cilk-5 [38, 40, 76, 81], JCilk [29, 30, 59], Cilk++ [25, 50, 62], Intel Cilk Plus [51], and Cilk-M [60]. Section “► A Brief History of Cilk Technology” overviews the history of Cilk technology. Some of the Cilks were more runtime systems than full-blown parallel languages, but it is the simplicity of the more linguistically oriented Cilks – Cilk-5, JCilk, Cilk++, and Cilk Plus – which makes the technology compelling. This article will focus on Cilk++, whose linguistics are both full featured and simple.

Cilk++ is a *faithful* linguistic extension of the serial C++ programming language [80], which means that parallel code retains its serial semantics when run on one processor. The Cilk++ extensions to C++ consist of just three keywords, which can be understood from an example. Figure 1 shows a Cilk++ program adapted from http://en.wikibooks.org/wiki/Algorithm_implementation/Sorting/Quicksort, which implements the quicksort algorithm [26, Chap. 7]. Observe that the program would be an ordinary C++ program if the keywords `cilk_spawn` and `cilk_sync` were elided and `cilk_for` replaced by `for`. The program so modified is called the *serialization* of the Cilk++ program. (The term *serial elision* was used in earlier Cilks, because all the keywords could simply be elided.) One of the things that makes Cilk simple is that the serialization of a parallel code always provides a legal semantics for the parallel code that can execute on a single processor.

Parallel work is created when the keyword `cilk_spawn` precedes the invocation of a function.

The semantics of spawning differ from a C++ function (or method) call only in that the parent can continue to execute in parallel with the child, instead of waiting for the child to complete as is done in C++. The scheduler in the Cilk++ runtime system takes the responsibility of scheduling the spawned functions on the individual processor cores of the multicore computer.

A function cannot safely use the values returned by its children until it executes a `cilk_sync` statement. The `cilk_sync` statement is a local “barrier,” not a global one as, for example, is used in message-passing programming [82, 83]. In the quicksort example, a `cilk_sync` statement occurs on line 14 before the function returns to avoid the anomaly that would occur if the preceding calls to `qsort` were scheduled to run in parallel and did not complete before the return, thus leaving the vector to be sorted in an intermediate and inconsistent state.

In addition to explicit synchronization provided by the `cilk_sync` statement, every Cilk function syncs implicitly before it returns, thus ensuring that all of its children terminate before it does. Thus, for this example, the `cilk_sync` before the return is technically unnecessary.

Cilk++ provides faithful extensions of other C++ language features. It provides full support for C++ exceptions. When exceptions are thrown in parallel, the one that would occur first in a serial execution is the one that executes the `catch` block. Loops can be parallelized by simply replacing the keyword `for` with the keyword `cilk_for` keyword, which allows all iterations of the loop to operate in parallel. Within the main routine from Fig. 1, for example, the loop starting on line 26 fills the array in parallel with “random” numbers. In addition, Cilk++ includes a library for mutual-exclusion (mutex) locks. Locking tends to be used much less frequently than in other parallel environments, such as Pthreads [49], because all protocols for control synchronization are handled by the Cilk++ runtime system. Cilk++ also provides a powerful “hyperobject” library, which allows races on nonlocal variables to be mitigated without lock contention or restructuring of code. Cilk++ provides tool support in the form of the Cilscreen race detector, which guarantees to find race bugs in ostensibly deterministic code,

```

and the Cilkview scalability analyzer, which extrapolates speedups based on the algorithmic complexity measures of “work” and “span.”

The remainder of this article is organized as follows. Section “A Brief History of Cilk Technology” overviews the evolution of Cilk technology. Section “The Dag Model for Multithreading” provides a brief tutorial on the theory of parallelism. Section “►Runtime System” describes the performance guarantees of Cilk++’s “work-stealing” scheduler, illustrates the Cilkview scalability analyzer, and overviews how the scheduler operates. section “►Race Detection” briefly describes the Cilkscreen race-detection tool, and section “►Reducer Hyperobjects” explains Cilk++’s “hyperobject” technology. Finally, section “►Conclusion” provides some concluding remarks.

A Brief History of Cilk Technology

This section overviews the development of the Cilk technology starting from its origin at the MIT Laboratory for Computer Science under the direction of Professor Charles E. Leiserson. The four MIT Ph.D. theses [11, 38, 53, 76] contain more detailed descriptions of the foundation and early history of Cilk.

The Origins of Cilk

The first implementation of Cilk arose from three separate projects at MIT in 1993. The first project was theoretical work [15, 16] on scheduling multi-threaded applications. The second was StarTech [52, 55, 56], a parallel chess program built to run on the Thinking Machines Corporation’s Connection Machine Model CM-5 Supercomputer [63]. The third project

was PCM/Threaded-C [45], a C-based package for scheduling continuation-passing-style threads on the CM-5.

In April 1994 the three projects were combined and christened Cilk. (The name Cilk is not an acronym, but an allusion to nice threads (silk) and to the C programming language (hence Cilk and not Silk). One of Leiserson’s graduate students commented that Cilk is a language of the C ilk. When his graduate students held an acronym contest for Cilk, the winner was “Charles’s Idiotic Linguistic Kludge.”) The team began by implementing a new parallel chess program. Unlike StarTech, which intertwined the search code and the scheduler, the new chess program implemented its search completely on top of a general-purpose runtime system that incorporated a provably efficient work-stealing scheduler. At the end of June, the *Socrates chess program was entered into the 1994 ACM International Chess Championship, where, running on a 512-node CM-5, it finished third. The “Cilk-1” system [14] itself was released in September 1994. A notable branch of the Cilk-1 codebase was Cilk-NOW [11, 18], which provided an adaptively parallel and fault-tolerant network-of-workstations implementation.

Simple Linguistics

The Cilk-2 release in May 1995 [68] featured full type-checking, supported all of ANSI C in its C-language subset, and offered call-return semantics for writing multithreaded procedures. Thus, instead of having to “wire together” continuations, the programmer could simply insert the `spawn` keyword before a function call and execute a `sync` statement to ensure that all spawned subroutines had completed (as described with `cilk_spawn` and `cilk_sync` in section “Introduction”).

The runtime system was made more portable by replacing the general continuation-passing mechanism with a continuation mechanism based on Duff’s device [84]. The new continuation mechanism greatly simplified the runtime system, which allowed the base release to support several architectures other than the CM-5.

Cilk-3, which was released in October 1995, featured an implementation of “dag-consistent” distributed shared memory [12, 13, 41, 53]. With this addition of shared memory, Cilk could be applied to solve a much wider class of applications. Dag-consistency is a weak but

nonetheless useful consistency model, and its relaxed semantics allows for an efficient, low-overhead software implementation.

Optimization and Enhancement

With the Cilk-4 release in June 1996, the authors of Cilk changed their primary development platform from the distributed-memory CM-5 to the shared-memory Sun Microsystems SPARC SMP. The compiler and runtime system were completely reimplemented, eliminating continuation-passing as the basis of the scheduler, and instead embedding scheduling decisions directly into the compiled code. Instead of stealing children, as in the earlier Cilk releases, Cilk-4 adopted the “lazy-task-creation” strategy [70] of stealing parent continuations. The overhead to spawn a parallel thread in Cilk-4 was typically less than three times the cost of an ordinary C procedure call, and so Cilk-4 programs “scaled down” to run on one processor with nearly the efficiency of analogous C programs.

Cilk-4 provided two new language features to support speculative parallelism, so that applications such as computer chess [28] could be more easily programmed. The keyword `inlet` specified that an internal function could be invoked by a returning child to execute code on its parent’s frame. The keyword `abort` abruptly terminated subcomputations that had already been spawned. These mechanisms allowed a programmer to speculate that a subcomputation would be worthwhile to execute in parallel, but abort it efficiently if the subcomputation turned out to be superfluous.

For Cilk-5 [40], which was released in March 1997, the runtime system was rewritten to be more flexible and portable. Cilk-5.0 could use operating system threads as well as processes to implement the individual Cilk “workers” that schedule Cilk threads. The Cilk-5.2 release included a debugging tool called the Nondeterminator [23, 24, 35, 79], which allowed Cilk programmers to localize data-race bugs in their code. With the Cilk-5.3 release, Cilk graduated from research prototype to real-world tool intended to be used by programmers who are not necessarily parallel-processing experts. Many improvements were made to the runtime system to make it faster, more portable, and more maintainable, but the basic language has remained largely the same.

A Cilk for Java

Up to this point, the Cilk technology was grounded in the C programming language. JCilk [30, 59], however, marked an excursion into Java [8], largely to explore how exception mechanisms should interoperate with the Cilk **spawn** and **sync** primitives. Specifically, JCilk defined semantics for exceptions that are consistent with the existing semantics of Java’s `try` and `catch` constructs, but which handle concurrency in spawned methods. JCilk extends Java’s exception semantics to allow exceptions to be passed from a spawned method to its parent in a natural way that obviates the need for Cilk-5’s `inlet` and `abort` constructs. This extension is “faithful” in that it obeys Java’s ordinary serial semantics when executed on a single processor. When executed in parallel, however, an exception thrown by a JCilk computation signals its sibling computations to abort, which yields a clean semantics in which only a single exception from the enclosing `try` block is handled.

The Multicore Era

During most of the evolution of Cilk technology, a multiprocessor with n processors typically cost more than n times the cost of a single processor. Moreover, since clock frequency was increasing at about 30% per year, software vendors preferred to wait for more performance than refactor their codebases to support parallel processing. Thus, parallel computing, with or without Cilk, was very much a niche business. Around 2003, however, the trend of ever-increasing clock frequency hit a brick wall. Although the density of integrated circuits continued to double about every 18 months, the heat dissipated by transistor switching reached its physical limit. Vendors of microprocessor chips responded by placing multiple processing cores on a single chip, ushering in the era of multicore computing.

In September 2006, responding to the multicore trend, MIT spun out the Cilk technology to Cilk Arts, Inc., a venture-funded start-up founded by technical leaders Charles E. Leiserson and Matteo Frigo, together with Stephen Lewin-Berlin and Duncan C. McCallum. Although Cilk Arts licensed the historical Cilk codebase from MIT, it developed an entirely new codebase for a C++ product aptly named Cilk++ [25, 62], which was released in December 2008 for the Windows Visual Studio and Linux/gcc compilers.

Cilk++ improved upon the original MIT Cilk in several ways. The linguistic distinction between Cilk functions and C/C++ functions was lessened, allowing C++ “call-backs” to Cilk code, as long as the C++ code was compiled with the Cilk++ compiler. (This distinction was later removed altogether by Intel Cilk Plus.) The **spawn** and **sync** keywords were renamed `cilk_spawn` and `cilk_sync` to avoid naming conflicts. Loops were parallelized by simply replacing the keyword `for` with the keyword `cilk_for` keyword, which allows all iterations of the loop to operate in parallel. Cilk++ provided full support for C++ exceptions. Cilk++ also introduced “reducer hyperobjects” (see section “Reducer Hyperobjects”), which allow races on nonlocal variables to be mitigated without lock contention or restructuring of code.

The Cilk++ toolkit included the Cilkscreen race-detection tool which guarantees to find race bugs in ostensibly deterministic code. It also included the Cilkview scalability analyzer [47], a software tool for profiling, estimating scalability, and benchmarking multithreaded Cilk++ applications.

Cilk Arts was sold to Intel Corporation in July 2009, which continued developing the technology. In September 2010, Intel released its ICC compiler with Intel Cilk Plus [51]. The product included Cilk support for C and C++, and the runtime system provided transparent integration with legacy binary executables.

Research at MIT

Research on Cilk technology has also continued at MIT and includes the following contributions:

- An adaptive scheduler for multiple Cilk jobs that uses parallelism feedback to minimize wasted processor cycles while guaranteeing fairness among the jobs [3]
- The design of a work-stealing runtime-system, called CWSTM, that supports transactional memory, where transactions can contain both nested parallelism and nested transactions [2]
- A library for performing parallel sparse matrix-vector and matrix-transpose-vector multiplication using a novel matrix layout called **compressed sparse blocks** [21]
- The Helper library, which supports “helper” locks in which a thread that cannot acquire a lock, rather

than blocking, helps to complete the parallel work in the critical region protected by the lock [4]

- The Rabbit library for efficiently executing task graphs with arbitrary acyclic dependencies [5]
- A fast breadth-first search algorithm and method for analyzing nondeterministic Cilk programs that incorporate reducer hyperobjects [64]
- The research prototype Cilk-M, which uses memory mapping to solve the “cactus-stack problem,” an interoperability problem with legacy binary executables [60] (see also section “►Runtime System”)

Recognition

Over the years, Cilk technology has influenced many other non-Cilk concurrency platforms, including Sun Microsystems’ Fortress [6], University of Texas’s Hood [17], Java’s Fork/Join Framework [58], Microsoft’s Task Parallel Library (TPL) [61] and PPL [66], Intel’s Threading Building Blocks (TBB) [77], and IBM’s X10 [22].

Cilk technology has garnered many awards, including the following:

- First Prize in the 1998 *International Conference on Functional Programming*’s Programming Contest for Cilk Pousse, where Cilk was cited as “the superior programming tool of choice for discriminating hackers” [1]
- First Prize in the 2006 HPC Challenge Class 2 (Productivity) competition, where Cilk was cited for “Best Overall Productivity” [57]
- The 2008 award by ACM SIGPLAN for Most Influential 1998 PLDI Paper for [40]
- The 2009 award by the ACM *Symposium on Parallelism in Algorithms and Architectures* for Best Paper for [39]

In addition, the Cilk-based chess programs StarTech, *Socrates, and Cilkchess have won numerous prizes in international computer-chess competitions.

The Dag Model for Multithreading

The Cilk++ runtime system contains a provably efficient work-stealing scheduler [16, 40], which scales application performance linearly with processor cores, as long as the application exhibits sufficient parallelism (and the processor architecture provides sufficient memory bandwidth). Thus, to obtain good performance, the programmer needs to know what it means for his or

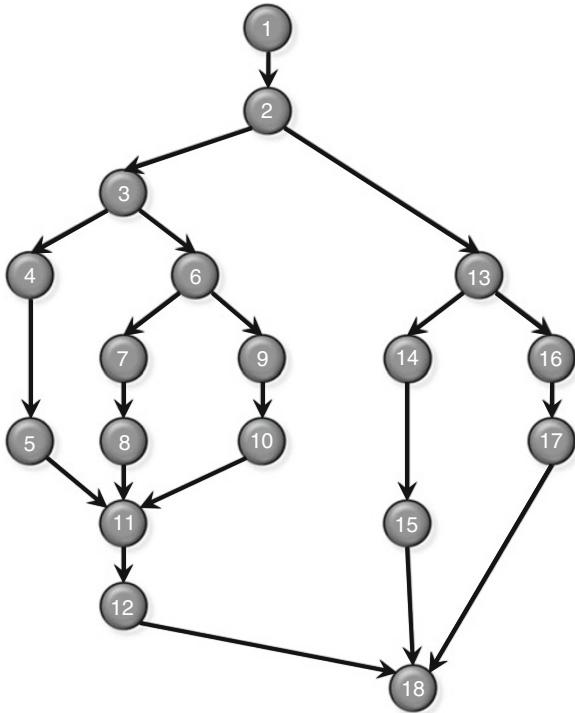

her application to exhibit sufficient parallelism. Before describing the Cilk++ runtime system, it is helpful to understand something about the theory of parallelism.

Many discussions of parallelism begin with Amdahl’s Law [7], originally proffered by Gene Amdahl in 1967. Amdahl made what amounts to the following observation. Suppose that 50% of a computation can be parallelized and 50% cannot. Then, even if the 50% that is parallel were run on an infinite number of processors, the total time is cut at most in half, leaving a speedup of at most 2. In general, if a fraction p of a computation can be run in parallel and the rest must run serially, Amdahl’s Law upper-bounds the speedup by $1/(1-p)$.

Although Amdahl’s Law provides some insight into parallelism, it does not *quantify* parallelism, and thus it does not provide a good understanding of what a concurrency platform such as Cilk++ should offer for multicore application performance. Fortunately, there is a simple theoretical model for parallel computing which provides a more general and precise quantification of parallelism that subsumes Amdahl’s Law. This “dag model of multithreading” [15, 16] provides a general and precise quantification of parallelism based on the theory developed by Graham [44]; Brent [19]; Eager, Zahorjan, and Lazowska [33]; and Blumofe and Leiserson [15, 16]. Tutorials on the dag model can be found in [26, Ch. 27] and [62].

The **dag model of multithreading** views the execution of a multithreaded program as a set of vertices called **strands** – sequences of serially executed instructions containing no parallel control – with graph edges indicating ordering dependencies between strands, as illustrated in Fig. 2. (The literature sometimes uses the term “Cilk thread” for “strand.”) A strand x **precedes** a strand y , denoted $x \prec y$, if x must complete before y can begin. If neither $x \prec y$ nor $y \prec x$, the strands are in **parallel**, denoted by $x \parallel y$. Figure 2, for example, has $1 \prec 2$, $6 \prec 8$, and $4 \parallel 9$. A strand can be as small as a single instruction, or it can represent a longer chain of serially executed instructions. A **maximal strand** is one that cannot be included in a longer strand. A maximal strand can be diced into a series of smaller strands in any manner that is convenient.

The dag model of multithreading can be interpreted in the context of the Cilk++ programming model. Normal serial execution of one strand after another creates a **serial edge** from the first strand to the next.

Cilk Fig. 2 A dag representation of a multithreaded execution. Each vertex is a strand. Edges represent ordering dependencies between instructions

A `cilk_spawn` of a function creates two dependency edges emanating from the instruction immediately before the `cilk_spawn`: the ***spawn edge*** goes to the strand containing the first instruction of the spawned function, and the ***continuation edge*** goes to the strand containing the first instruction after the spawned function. A `cilk_sync` creates a ***return edge*** from the strand containing the final instruction of each spawned function to the strand containing the instruction immediately after the `cilk_sync`. A `cilk_for` can be viewed as parallel divide-and-conquer recursion using `cilk_spawn` and `cilk_sync` over the iteration space.

The dag model admits two natural measures that allow parallelism to be defined precisely and provide important bounds on performance and speedup.

The Work Law

The first measure is ***work***, which is the total time spent in all the strands. Assuming for simplicity that it takes

unit time to execute a strand, the work for the example dag in Fig. 2 is 18.

A simple notation makes things more precise. Let T_P be the fastest possible execution time of the application on P processors. Since the work corresponds to the execution time on 1 processor, it is denoted by T_1 . One reason that work is an important measure is because it provides a lower bound on P -processor execution time:

$$T_P \geq T_1/P. \quad (1)$$

This ***Work Law*** holds, because in this simple theoretical model, each processor executes at most 1 instruction per unit time, and hence P processors can execute at most P instructions per unit time. Thus, with P processors, doing all the work requires at least T_1/P time.

One can interpret the Work Law Eq. (1) in terms of the ***speedup*** on P processors, which is just T_1/T_P . The speedup tells how much faster the application runs on P processors than on 1 processor. Rewriting the Work Law yields $T_1/T_P \leq P$, which is to say that the speedup on P processors can be at most P . If the application obtains speedup P (which is the best one can do in this simple theoretical model), the application exhibits ***linear speedup***. If the application obtains speedup greater than P (impossible in the model due to the Work Law, but possible in practice due to caching and other processor effects), the application exhibits ***superlinear speedup***.

The Span Law

The second measure is ***span***, which is the maximum time to execute along any path of dependencies in the dag. Assuming that it takes unit time to execute a strand, the span of the dag from Fig. 2 is 9, which corresponds to the path $1 \prec 2 \prec 3 \prec 6 \prec 7 \prec 8 \prec 11 \prec 12 \prec 18$. This path is sometimes called the ***critical path*** of the dag, and span is sometimes referred to in the literature as critical-path length. Since the span is the theoretically fastest time the dag could be executed on a computer with an infinite number of processors (assuming no overheads for communication, scheduling, etc.), it can be denoted by T_∞ . Like work, span also provides a bound on P -processor execution time:

$$T_P \geq T_\infty. \quad (2)$$

This ***Span Law*** arises for the simple reason that a finite number of processors cannot outperform an infinite number of processors, because the infinite-processor

machine could just ignore all but P of its processors and mimic a P -processor machine exactly.

Parallelism

The **parallelism** is defined as the ratio of work to span, or T_1/T_∞ . Parallelism can be viewed as the average amount of work along each step of the critical path. Moreover, perfect linear speedup cannot be obtained for any number of processors greater than the parallelism T_1/T_∞ . To see why, suppose that $P > T_1/T_\infty$, in which case the Span Law Eq. (2) implies that the speedup satisfies $T_1/T_P \leq T_1/T_\infty < P$. Since the speedup is strictly less than P , it cannot be perfect linear speedup. Another way to see that the parallelism bounds the speedup is to observe that, in the best case, the work is distributed evenly along the critical path, in which case the amount of work at each step is the parallelism. But, if the parallelism is less than P , there isn't enough work to keep P processors busy at every step.

As an example, the parallelism of the dag in Fig. 2 is $18/9 = 2$. Thus, executing it with more than two processors would be wasteful of cycles and yield diminishing returns, since the additional processors will be surely starved for work.

As a practical matter, many problems admit considerable parallelism. For example, matrix multiplication of 1000×1000 matrices is highly parallel, with a parallelism in the millions. Many problems on large irregular graphs, such as breadth-first search, generally exhibit parallelism on the order of thousands. Sparse-matrix algorithms can often exhibit parallelism in the hundreds.

Upper Bounds on Speedup

The Work and Span Laws engender two important upper bounds on speedup. The Work Law implies that the speedup on P processors can be at most P :

$$T_1/T_P \leq P. \quad (3)$$

The Span Law dictates that speedup cannot exceed parallelism:

$$T_1/T_P \leq T_1/T_\infty. \quad (4)$$

Runtime System

Although optimal multiprocessor scheduling is known to be NP-complete [42], Cilk++'s runtime system employs a “work-stealing” scheduler [16, 40] that

achieves provably tight bounds. An application with sufficient parallelism can rely on the Cilk++ runtime system to dynamically and automatically exploit an arbitrary number of available processor cores near optimally. Moreover, on a single core, typical Cilk++ programs run with negligible overhead (often 2% or less) when compared with its C++ serialization.

Performance Bounds

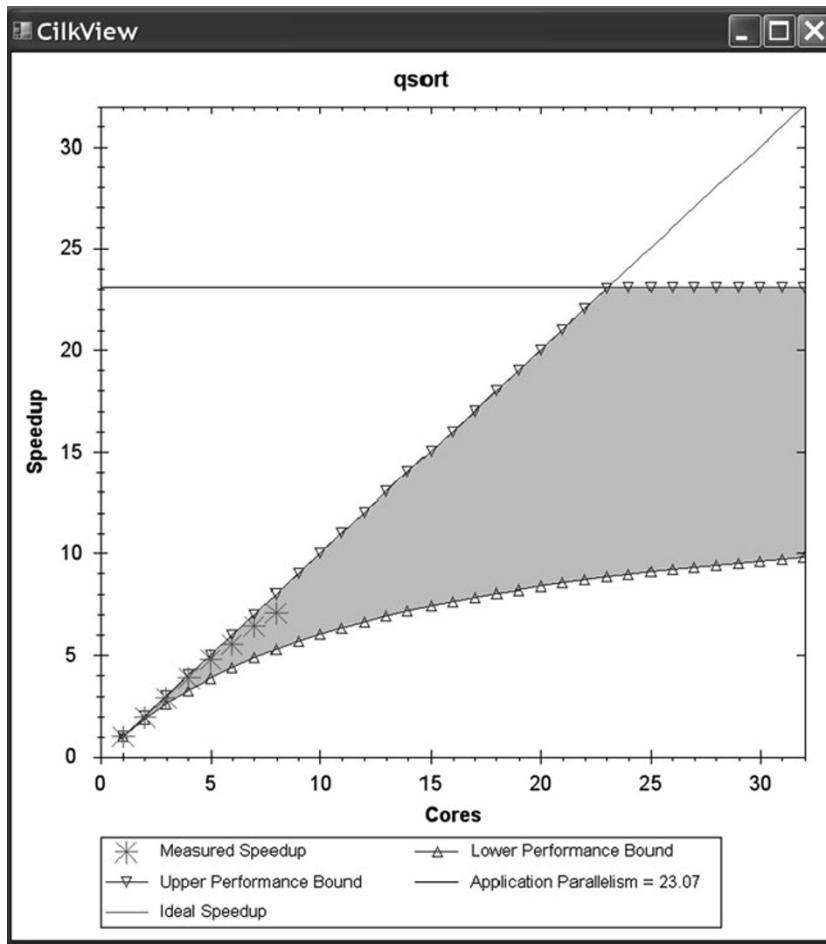

Specifically, for an application with T_1 work and T_∞ span running on a computer with P processors, the Cilk++ work-stealing scheduler achieves expected running time:

$$T_P \leq T_1/P + O(T_\infty). \quad (5)$$

If the parallelism T_1/T_∞ exceeds the number P of processors by a sufficient margin, this bound (proved in [16]), guarantees near-perfect linear speedup. To see why, assume that $T_1/T_\infty \gg P$, or equivalently, that $T_\infty \ll T_1/P$. Thus, in Inequality (5), the T_1/P term dominates the $O(T_\infty)$ term, and thus the running time is $T_P \approx T_1/P$, leading to a speedup of $T_1/T_P \approx P$.

The Cilkview scalability analyzer allows a programmer to determine the work and span of an application. Figure 3 shows the output of this tool running the quicksort program from Fig. 1 on 10 million numbers. The upper bound on speedup provided by the Work Law corresponds to the line of slope 1, and the upper bound provided by the Span Law corresponds to the horizontal line at 21.31. The performance analysis tool also provides an estimated lower bound on speedup – the lower curve in the figure – based on **burdened parallelism**, which takes into account the estimated cost of scheduling. Although quicksort seems naturally parallel, one can show that the expected parallelism for sorting n numbers is only $O(\lg n)$. Practical sorts with more parallelism exist, however. See [26, Chap. 27] for more details.

In addition to guaranteeing performance bounds, the Cilk++ runtime system also provides bounds on stack space. Specifically, on P processors, a Cilk++ program consumes at most P times the stack space of a single-processor execution. Specifically, let S_P denote the stack space required by a P -processor execution of a given Cilk++ application. Thus, S_1 is the stack space required by the C++ serialization of a Cilk++ program.

Cilk. Fig. 3 Parallelism profile of quicksort produced by the Cilkview scalability analyzer

The space guarantee of Cilk++’s work-stealing scheduler is

$$S_P \leq S_I P.$$

For specific applications, tighter bounds on space can be shown [12]. Work-stealing schedulers that provide better space bounds at the expense of higher communication are also known [10, 71].

To illustrate why a space bound is important, consider the following simple code fragment:

```
for (int i=0; i<1000*1000*1000; ++i) {
    cilk_spawn foo(i);
}
cilk_sync;
```

This code conceptually creates one billion invocations of `foo` that operate logically in parallel. Executing

on one processor, however, this Cilk++ code uses no more stack space than a serial C++ execution, that is, the call depth is of whichever invocation of `foo` requires the deepest stack. On two processors, it requires at most twice this space, and so on. This guarantee contrasts with the lack of a guarantee by more naive schedulers. For example, some schedulers would schedule this code fragment by creating a work queue of one billion tasks, one for each iteration of the subroutine `foo`, before executing even the first iteration, thus suffering exorbitant memory use.

Work Stealing

Cilk++’s work-stealing scheduler operates as follows. When the runtime system starts up, it allocates as many operating-system threads, called *workers*, as there are

processors (although the programmer can override this default decision). Each worker's stack operates like a work queue. When a subroutine is spawned, the subroutine's activation frame containing its local variables is pushed onto the bottom of the stack. When it returns, the frame is popped off the bottom. Thus, in the common case, Cilk++ operates just like C++ and imposes little overhead.

When a worker runs out of work, however, it becomes a *thief* and “steals” the top frame from another *victim* worker's stack. Thus, the stack is in fact a double-ended queue, with the worker operating on the bottom and thieves stealing from the top. This strategy has the great advantage that all communication and synchronization is incurred only when a worker runs out of work. If an application exhibits sufficient parallelism, one can prove mathematically [16, 40] that stealing is infrequent, and thus the cost of communication and synchronization to effect a steal is negligible.

The dynamic load-balancing capability provided by the Cilk++ runtime system adapts well in real-world multiprogrammed computing environments. If a worker becomes descheduled by the operating system (for example, because another application starts to run), the work of that worker can be stolen away by other workers. Thus, Cilk++ programs tend to “play nicely” with other jobs on the system.

Cilk++'s runtime system also makes Cilk++ programs *performance-composable*. Suppose that a programmer develops a parallel library in Cilk++. That library can be called not only from a serial program or the serial portion of a parallel program, it can be invoked multiple times in parallel and continue to exhibit good speedup. In contrast, some concurrency platforms constrain library code to run on a given number of processors, and if multiple instances of the library execute simultaneously, they end up thrashing as they compete for processor resources.

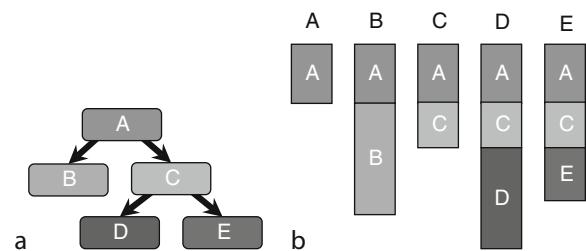

Stacks and Cactus Stacks

An execution of a serial Algol-like language, such as C [54] or C++ [80], can be viewed as a “walk” of an *invocation tree*, which dynamically unfolds during execution and relates function instances by the “calls” relation: If function instance A calls function instance B, then A is a *parent* of the *child* B in the invocation tree. Such serial languages admit a simple array-based stack for

allocating function activation frames. When a function is called, the stack pointer is advanced, and when the function returns, the original stack pointer is restored. This style of execution is space efficient, because all the children of a given function can use and reuse the same region of the stack. The compact linear-stack representation is possible only because in a serial language, a function has at most one extant child function at any time.

The notion of an invocation tree can be extended to include spawns, as well as calls, but unlike the serial walk of an invocation tree, a parallel execution unfolds the invocation tree more haphazardly and in parallel. Since multiple children of a function may exist simultaneously, a linear-stack data structure no longer suffices for storing activation frames. Instead, the tree of extant activation frames forms a *cactus stack* [46], as shown in Fig. 4. The implementation of cactus stacks is a well-understood problem for which low-overhead implementations exist [40, 43].

Although a work-stealing scheduler can guarantees bounds on both time and stack space [16, 40], implementations that meet these bounds – including Cilk-1, Cilk-5, and Cilk++ – suffer from interoperability problems with legacy (and third-party) serial binary executables that have been compiled to use a linear stack. (Although Fortress, Java Fork/Join Framework, TPL, and X10 employ work stealing, they do not suffer from the same interoperability problems, because they are

Cilk. Fig. 4 A cactus stack. (a) The invocation tree, where function A invokes B and C, and C invokes D and E. (b) The view of the stack by each of the five functions. In a serial execution, only one view is active at any given time, because only one function executes at a time. In a parallel execution, however, if some of the invocations are spawns, then multiple views may be active simultaneously

byte-code interpreted by a virtual-machine environment.) Transitioning from serial code (using a linear stack) to parallel code (using a cactus stack) is problematic, because the type of stack impacts the calling conventions used to allocate activation frames and pass arguments. The property of allowing arbitrary calling between parallel and serial code – including especially legacy (and third-party) serial binaries – is called ***serial-parallel reciprocity***, or ***SP-reciprocity*** for short.

SP-reciprocity is especially important if one wishes to multicore-enable legacy object-oriented environments by parallelizing an object’s member functions. For example, suppose that a function A allocates a new object x whose type has a member function `foo()`, which is parallelized. Now, suppose that A is linked with a legacy binary containing a function B, and A passes x to B, which proceeds to invoke `x.foo()`. Without SP-reciprocity, this simple callback does not work.

Cilk-5 and Cilk++ do not support SP-reciprocity. Cilk Plus supports SP-reciprocity by sacrificing the space bound Inequality (Eq. 4) and using multiple linear stacks to implement the cactus stack. Although no provable bound exists to date on the number of linear stacks needed, empirical studies indicate that $10P$ linear stacks suffice.

The research prototype Cilk-M [60] provides both SP-reciprocity and good theoretical bounds on time and space. Cilk-M uses thread-local memory mapping to implement cactus stacks. Benchmark results indicate that the performance of the prototype Cilk-M runtime system is comparable to the Cilk 5.4.6 system, and the consumption of stack space is modest.

Race Detection

The Cilk++ development environment includes a ***race detector***, called Cilkscreen, a powerful debugging tool that greatly simplifies the task of ensuring that a parallel application is correct. A ***data race*** [73] exists if logically parallel strands access the same shared location, the two strands hold no locks in common, and at least one of the strands writes to the location. A data race is usually a bug, because the program may exhibit unexpected, nondeterministic behavior depending on how the strands are scheduled. Serial code containing nonlocal variables is particularly prone to the introduction of data races when the code is parallelized.

As an example of a race bug, suppose that line 13 in Fig. 1 is replaced with the following line:

```
qsort(max(begin + 1, middle-1), end);
```

The resulting serial code is still correct, but the parallel code now contains a race bug, because the two subproblems overlap, which could cause an error during execution.

Race conditions have been studied extensively [24, 27, 31, 32, 34, 36, 48, 67, 69, 72, 74, 75, 78]. They are pernicious and occur nondeterministically. A program with a race bug may execute successfully millions of times during testing, only to raise its head after the application is shipped. Even after detecting a race bug, writing regression tests to ensure its continued absence is difficult.

The Cilkscreen race detector is based on provably good algorithms [9, 24, 35] developed originally for MIT Cilk. In a single serial execution on a test input for a deterministic program, Cilkscreen guarantees to report a race bug if the race bug is ***exposed***: that is, if two different schedulings of the parallel code would produce different results. Cilkscreen uses efficient data structures to track the series-parallel relationships of the executing application during a serial execution of the parallel code. As the application executes, Cilkscreen uses dynamic instrumentation [20, 65] to intercept every load and store executed at user level. Metadata in the Cilk++ binaries allows Cilkscreen to identify the parallel control constructs in the executing application precisely, track the series-parallel relationships of strands, and report races precisely. Additional metadata allows the race to be localized in the application source code.

Reducer Hyperobjects

Many serial programs use ***nonlocal variables***, which are variables that are bound outside of the scope of the function, method, or class in which they are used. If a variable is bound outside of all local scopes, it is a ***global variable***. Nonlocal variables have long been considered a problematic programming practice [85], but programmers often find them convenient to use, because they can be accessed at the leaves of a computation without the overhead and complexity of passing them as parameters through all the internal nodes. Thus, nonlocal variables have persisted in serial programming. In the world of parallel computing, nonlocal variables may inhibit

```

1  bool has_property(Node *);
2  std::list<Node *> output_list;
3  //...
4  void walk(Node *x)
5  {
6      if (x)
7      {
8          if (has_property(x))
9          {
10             output_list.push_back(x);
11         }
12         walk(x->left);
13         walk(x->right);
14     }
15 }
```

Cilk. Fig. 5 C++ code to create a list of all the nodes in a binary tree that satisfy a given property

```

1  bool has_property(Node *);
2  std::list<Node *> output_list;
3  // ...
4  void walk(Node *x)
5  {
6      if (x)
7      {
8          if (has_property(x))
9          {
10             output_list.push_back(x);
11         }
12         cilk_spawn walk(x->left);
13         walk(x->right);
14         cilk_sync;
15     }
16 }
```

Cilk. Fig. 6 A naive Cilk++ parallelization of the code in Fig. 5. This code has a data race in line 10

otherwise independent parts of a multithreaded program from operating in parallel, because they introduce races. This section describes Cilk++ reducer hyperobjects [39], which can mitigate races on nonlocal variables without creating lock contention or requiring code restructuring.

As an example of how a nonlocal variable can introduce a data race, consider the problem of walking a binary tree to make a list of those nodes that satisfy a given property. A C++ code to solve the problem is abstracted in Fig. 5. If the node x being visited is non-null, the code checks whether x has the desired property in line 8, and if so, it appends x to the list stored in the global variable `output_list` in line 10. Then, it recursively visits the left and right children of x in lines 12 and 13.

Figure 6 illustrates a straightforward parallelization of this code in Cilk++. In line 12 of the figure, the `walk` function is spawned recursively on the left child, while the parent continues on to execute an ordinary recursive call of `walk` in line 13. As the recursion unfolds, the running program generates a tree of parallel execution that follows the structure of the binary tree. Unfortunately, this naive parallelization contains a data race. Specifically, two parallel instantiations of `walk` may attempt to update the shared global variable `output_list` in parallel at line 10.

The traditional solution to fixing this kind of data race is to associate a mutual-exclusion lock (mutex) L with `output_list`, as is shown in Fig. 7. Before updating `output_list`, the mutex L is acquired in

```

1  bool has_property(Node *);
2  std::list<Node *> output_list;
3  mutex L;
4  // ...
5  void walk(Node *x)
6  {
7      if (x)
8      {
9          if (has_property(x))
10         {
11             L.lock();
12             output_list.push_back(x);
13             L.unlock();
14         }
15         cilk_spawnwalk(x->left);
16         walk(x->right);
17         cilk_sync;
18     }
19 }
```

Cilk. Fig. 7 Cilk++ code that solves the race condition using a mutex

line 11, and after the update, it is released in line 13. Although this code is now correct, the mutex may create a bottleneck in the computation. If there are many nodes that have the desired property, the contention on the mutex can destroy all the parallelism. For example, on one set of test inputs for a real-world tree-walking code that performs collision-detection of mechanical assemblies, lock contention actually degraded performance on 4 processors so that it was worse than running on a single processor. In addition, the locking solution has the problem that it jumbles up the order of list elements. That might be okay for some applications, but

other programs may depend on the order produced by the serial execution.

An alternative to locking is to restructure the code to accumulate the output lists in each subcomputation and concatenate them when the computations return. If one is careful, it is also possible to keep the order of elements in the list the same as in the serial execution. For the simple tree-walking code, code restructuring may suffice, but for many larger codes, disrupting the original logic can be time-consuming and tedious undertaking, and it may require expert skill, making it impractical for parallelizing large legacy codes.

Cilk++ provides a novel approach [39] to avoiding data races in code with nonlocal variables. A Cilk++ *reducer hyperobject* is a linguistic construct that allows many strands to coordinate in updating a shared variable or data structure independently by providing them different but coordinated views of the same object. The state of a hyperobject as seen by a strand of an execution is called the strand's "view" of the object at the time the strand is executing. A strand can access and change any of its view's state independently, without synchronizing with other strands. Throughout the execution of a strand, the strand's view of the reducer is private, thereby providing isolation from other strands. When two or more strands join, their different views are combined according to a system- or user-defined `reduce()` method. Thus, reducers preserve the advantages of parallelism without forcing

the programmer to restructure the logic of his or her program.

As an example, [Figure 8](#) shows how the tree-walking code from [Fig. 5](#) can be parallelized using a reducer. Line 3 declares `output_list` to be a reducer hyperobject for list appending. The `reducer_list_append` class implements a `reduce` function that concatenates two lists, but the programmer of the tree-walking code need not be aware of how this class is implemented. All the programmer does is identify the global variables as the appropriate type of reducer when they are declared. No logic needs to be restructured, and if the programmer fails to catch all the use instances, the compiler reports a type error.

This parallelization takes advantage of the fact that list appending is associative. That is, if a list L_1 is appended to a list L_2 and the result appended to L_3 , it is the same as if list L_1 were appended to the result of appending L_2 to L_3 . As the Cilk++ runtime system load-balances this computation over the available processors, it ensures that each branch of the recursive computation has access to a private view of the variable `output_list`, eliminating races on this global variable without requiring locks. When the branches synchronize, the private views are reduced (combined) by concatenating the lists, and Cilk++ carefully maintains the proper ordering so that the resulting list contains the identical elements in the same order as in a serial execution.

```

1 #include <reducer_list.h>
2 bool has_property(Node *);
3 cilk::hyperobject<cilk::reducer_list_append<Node*>>
    output_list;

4 // ...
5 void walk(Node *x)
6 {
7     if (x)
8     {
9         if (has_property(x))
10        {
11            output_list().push_back(x);
12        }
13        cilk_spawnwalk(x->left);
14        walk(x->right);
15        cilk_sync;
16    }
17 }
```

Cilk. Fig. 8 A Cilk++ parallelization of the code in [Fig. 5](#), which uses a reducer hyperobject to avoid data races

Conclusion

Multicore microprocessors are now commonplace, and Moore's Law is steadily increasing the pressure on software developers to multicore-enable their codebases. Cilk++ provides a simple but effective concurrency platform for multicore programming which leverages almost two decades of research on multithreaded programming. The Cilk++ model builds upon the sound theoretical framework of multithreaded dags, allowing parallelism to be quantified in terms of work and span. The Cilkscreen race detector allows race bugs to be detected and localized, and the Cilkview scalability analyzer allows the parallelism of an application to be quantitatively measured. Cilk++'s hyperobject library mitigates races on nonlocal variables. Although parallel programming will surely continue to evolve, Cilk++ today provides a full-featured suite of technology for multicore-enabling any compute-intensive application.

Acknowledgments

Thanks to the many students and postdocs who contributed to Cilk technology over the years. Space does not permit all to be listed. Thanks to the team at Cilk Arts and the new Cilk team at Intel. Special thanks to Matteo Frigo and Bradley C. Kuszmaul, who contributed mightily to developing and maintaining the MIT Cilk codebase. Many thanks to the DARPA and NSF sponsors of this research over the years.

Definition

A commodity cluster is a computing system comprising an integrated set of subsystems, each of which may be acquired commercially and is capable of independent and complete operation. The synthesis of the

commodity subsystems is achieved through the interconnection by one or more private networks that are themselves available from commercial sources. A commodity cluster incorporates a system software stack for resource management and application programming. Usually (but not always) such software is a mix of open source and proprietary components. Typically, a cluster is programmed through a message-passing application programming interface like MPI running on top of the operating system on each subsystem node.

Discussion

Introduction and Overview

A commodity cluster is a distributed computing system consisting of an integrated set of fully and independently operational and marketed computer subsystems (node) used together to perform a single application program or workload. These include compute nodes interconnected by a commercial network and possibly additional nodes configured for specific purposes such as login nodes, administrative nodes, and secondary storage managers. Each component is COTS (commercial off the shelf) and can be acquired separately on the open market. Clusters emerged in the mid-1990s to largely replace most other forms of high performance computing and now serve effectively in virtually every scientific user and commercial market sector. Except at the very top end where MPPs (Massively Parallel Processors) maintain a significant presence, clusters dominate high performance computing. This remarkable evolution is driven by a number of motivating factors, one of which is performance to cost achieved through the exploitation of economy of scale of mass marketed components harnessed en masse to deliver significant improvements in a multiple of operational properties through aggregation by integration. The major components then are the compute nodes, the interconnection network, the node operating system, the system management middleware, and the application programming interface. Clusters ride the continuous wave of technology advances to deliver ever increasing value per unit cost, exploiting progress in every technology class including microprocessors, memory, communication networks and switching, operating system software, and parallel numerical algorithms.

Motivation

The advent of the modern commodity cluster has been motivated by the opportunities it offers. Here are provided some of these that have been responsible for the rapid growth and ultimate domination of clusters in the domain of scalable computing.

Scalable Performance: Performance measured by throughput exhibits positive sensitivity to scale (number of cluster nodes) over broad range for many workloads and applications. Although narrower in range variation in performance measured in terms of response time can also be seen to scale with respect to the number of nodes employed.

Cost: A major driver for the use of clusters is the exploitation of economy of scale derived from mass market of the comprising node subsystems resulting in dramatic advantage in performance to cost with respect to custom parallel systems and low cost for implementation of parallel systems. This factor is driving the dominance of commodity clusters in the mid-range of the processing market and at the high end for major transaction processing and major scientific applications. It should be noted that there are custom cases for specific algorithms in which performance to cost is competitive with clusters.

Problem Size: Large applications require data sets larger than the capacity of single enterprise server mid-level systems. Clusters provide a quick and relatively inexpensive way of aggregating many boxes of memory, cluster nodes, to build systems containing large memory capacity. Where memory is the most expensive component of the system, the use of mass market memories is a cost effective way of achieving the largest possible memory system. These are distributed memory, not shared memory.

Mass Storage: Clusters make an excellent platform for building mass storage systems or applications that are based on secondary storage. The use of industry standards and low cost RAID disk systems attached to nodes of clusters is widely used, for example, by large on-demand search engines making up some of the largest systems in the world.

Early Technology Adoption: Rapid advances in microprocessor technology are most quickly captured by the mass-market products to exploit economy of scale and

achieve early return on investment. Cluster systems integrating such commodity subsystems serving as cluster nodes therefore can incorporate and are able to exploit.

Flexibility of Configuration: Because of the method by which clusters are constructed, using building blocks derived from already commercialized products and COTS (commercial off the shelf) interconnect networks, the end system deployment is highly flexible in its configuration and not limited by a few system offerings of vendors as is the case with custom MPPs. Number of nodes, topology, source of nodes, and many other attributes may be determined by the deploying institution and, indeed, can be modified over time, such as the addition of updated nodes or GPU accelerators. This further extends to the software stack that, if derived from open source components, can largely be defined, refined, and updated by the local site, again not restricted by vendor proprietary constraints.

Sum of the Parts: This notion reflects both the obvious attributes of the cluster itself but also more importantly the benefit of many contributing to a single class of systems, largely through open source framework even though commercial software targeting such framework also is of value.

Programming Model Commonality: A major feature of clusters is that they share the same distributed memory programming models with their custom MPP counterparts. Such application programming interfaces as PVM and MPI derived from the communicating sequential processing model are portable between the two classes of distributed memory system. Due to latency, bandwidth, and overhead considerations a commodity cluster of comparable size (number of nodes and memory capacity) to an MPP may deliver lower sustained performance than the MPP but will produce the same results.

Empowerment: This is the freedom many experience when working with clusters and has provided a strong impetus to acquiring skills and experimenting with such systems. The sense of empowerment is a consequence of the ability to implement and deploy clusters without constraints implicit with working with a particular vendor. Many young practitioners have been thus inspired with high school students finding ways to aggregate

surplus computing elements into locally implemented systems providing an important vehicle for education.

Coolness Factor: There is just something really cool about playing with clusters. Although a purely subjective factor, it nonetheless has driven much activity, especially among younger practitioners who react to many of the empowerment issues above but also to the attraction of open source software, unbounded performance opportunities, the sand box mindset that enables self-motivated experimentation, and a subtle attribute of the pieces of a cluster “talking” to each other on a cooperative basis to make something happen together. There is also a strong sense of community among contributors in the field, a basis for a sense of association that appeals to many people. Working with commodity clusters is fun!

Cluster System Architecture

Hardware Architecture

The hardware architecture of a cluster system is simple in concept, if not in the details of implementation. To first order, it consists of a set of compute nodes and an interconnection network at its core connected to secondary storage, an external local area network, and one or more administration terminals. One or more of the compute nodes are dedicated to serve as the master, host, or login node to handle user sessions.

The heart of the cluster is the COTS (commercial off the shelf) compute node. This subsystem is a fully operational stand-alone computer with the important attribute that it benefits from a market far greater than that of the cluster of which it is a part. The resulting economy of scale yields an exceptional performance to cost greatly in excess of alternative HPC strategies.

Each node is a fully functioning computer system in its own right. It incorporates as its major components:

- One or more multicore processor components that provides the primary computing capability of the node. By far, the most widely used processor family for clusters is the X86 architecture currently including the Intel Xeon (in multiple instantiations) and the AMD Opteron
- DRAM memory modules that provide the main storage of the node combined with a cache hierarchy supporting each of the processor cores

- Motherboard chip-set that provides all of the control features of the node, the intra-node communications, and the BIOS startup mechanisms for booting the system
- Network Interface Controller to connect the node to the cluster system private network
- Local disk storage for the node. Some nodes do not have this and are referred to as “diskless” or “stateless”
- Packaging, power, and cooling

A cluster is the integration of such nodes by means of a private system area network. The network consists of the NICs (described above) installed in the nodes, the switches that route packets, and the channels or cables connecting the switches to the nodes and to each other. The arrangement of the network components is described as the network topology, which for clusters is usually a tree (for smaller clusters) or a Clos network for larger clusters. Important network properties are its bandwidth and latency. Bandwidth establishes the amount of information that can be passed between all pairs of nodes simultaneously. Latency establishes the time it takes to move a packet between two nodes. The primary network types employed today in clusters is Ethernet in its myriad forms (primarily GigE) and the increasingly important Infiniband (IBA) network that provides lower overheads and shorter latencies.

Software Architecture

The cluster software structure matches that of the hardware architecture in integrating the functionality of the separate components in to a single operational system. The roles and responsibilities of cluster software range from the general managing of the individual hardware resources to providing programming environments for users and overall system administration. Typically every node supports its own operating system. Dominant among these is Linux. However, commercial versions of Unix such as Solaris, AIX, and HPUX are employed as well. Microsoft Windows is found on some clusters especially in the business community such as financial markets.

The programming environments at least for the scientific computing arena are based on the MPI

application programming interface, which is ubiquitous, stable, and portable. Application codes written in MPI (employing C, C++, or Fortran as the process language) are easily conveyed across systems of different scale (different number of nodes), different processor architectures, different network types and topologies, and even from clusters to MPPs with no or minimum changes for correctness of operation. Getting optimal performance from the different systems may require some code modifications. MPI describes communication patterns among processes on different nodes, the content of different messages, and their functionality as gather/scatter or collective operations. MPI has provided the first supercomputing common programming framework and is largely responsible for the success achieved by clusters today in industry and government sectors as well as academic research.

Additional software has been developed for system administration, workload scheduling, and initial installation and configuration.

History

The history of cluster computing has been driven by the opportunity to achieve rapid increase in one or more operational properties of a computer system through the aggregation and interoperability of replicated independent systems by means of interconnection networks. Such properties include but are not limited to throughput performance, total storage capacity, performance to cost, reliability, availability, and input/output communications rate. Indeed, the concept of clustering in its broadest sense as an abstraction predates computing altogether and has its antecedents in the genesis of human civilization in the domains of transportation, manufacturing, human enterprise (including military), and living environments (buildings and collections thereof). The motto of the USA found on every dollar bill, "E Pluribus Unum," is an emblem of clustering at least at a high level of abstraction. This general strategy of synthesis of existing systems to comprise much larger ensemble systems has been applied to computing systems since its second generation in the 1950s with SAGE and the IBM 7000 as its earliest exemplars. The modern commodity cluster emerged in the early to mid 1990s with the advent of critical enabling technologies derived from the previous decade with 1997

marking a milestone year of the first commodity cluster on the Top-500 list and the first Gordon Bell Prize awarded to a cluster based computation. Here is presented a brief history of clusters reflecting the diversity of ways they have been employed and the succession of enabling conditions that catalyzed their implementation, deployment, and use. For pedagogical purposes, this history is organized in four distinguishable periods: (1) prior to 1980, (2) 1980–1992, (3) 1993–2004, and (4) 2005 to present and probably beyond. The first was a period of exploration where some rudimentary forms of clustering were attempted and various incipient technologies were derived in their earliest forms that would one day become critical to successful cluster systems. The second period saw the first real clusters and the development of the enabling technologies, both hardware and software, that would ultimately in synthesis launch the cluster revolution as they matured. The third period introduced the classical period of clusters at a time when microprocessors were differentiated between those employed in workstations (NOW) and those used at the lowest cost personal computers or PCs (Beowulf) only to find this distinction to evaporate as microprocessor architectures converged. Equally important were the advances in network technologies, programming models, and middle ware. The final (fourth) ongoing period is witnessing the dominance of commodity clusters for scientific (STEM) and commercial high performance computing with the advent of new multicore processor sockets and GPU accelerators. Except for the highest end computing systems, clusters are likely to serve as the principal family of supercomputers across a broad range of uses and markets for the foreseeable future.

Exploratory Period: Before 1980

The earliest efforts to exploit the concept of clustering predated the true opportunities for improvement in performance-to-cost but addressed certain key niche requirements. It was also a period when some of the technologies that would eventually contribute to the wide spread uses of clusters were initially devised.

Perhaps the first example of a cluster of computers was the IBM SAGE computer system developed for the Department of Defense NORAD air defense system. Sage accepted radar information from a couple of dozen

sites using early wide area network technology and presented the strategic airspace status to operators using one of the first examples of digital video presentation displays. SAGE consisted of two CPUs connected, not to double the performance, but for reliability; if one failed, the other could immediately pick up the workload and continue the time critical processing of defense data. The SAGE CPUs were derived from the original MIT Whirlwind computer architecture but with extended word lengths and other features.

Many of the key technologies that would make up the primary components of later commodity clusters were first derived during this exploratory period. The microprocessor was first developed by Intel introduced in 1971 (4004) with the X86 family that has become the dominant CPU of commodity clusters marketed by 1978. The first local area network technology to be standardized, Ethernet, developed at Xerox PARC. The TCP protocol was also developed at this time. Together these two technologies established the foundations for networking and through their evolutionary descendants created the single most widely used network in clusters both integrating their constituent elements and their external input/output interfaces. Software technology also was developed at this time that would have long-term impact on clusters. Among these was the Unix operating system by Bell Labs that incorporated many of the service infrastructure capabilities that would be necessary for effective clustering. The programming languages Fortran and C, both widely used on clusters today were developed at this time. Finally, the fundamental model of computation that is used almost exclusively on clusters, Communicating Sequential Processes or CSP was formally described at this time upon which a number of future application programming interfaces for distributed memory systems including clusters would be based.

Enabling Period: 1980–1992

Throughout the enabling period, all of the technologies, both hardware and software, were developed that catalyzed the cluster explosion. The microprocessor evolved from the 16 bit to the 32 bit architectures with clock rates reaching 100 MHz. Local area network Ethernet technologies achieved 10 Mbps throughput with continuous improvements in bandwidth per cost as well as in switching and network interface controllers (NIC).

With Moore's Law, DRAM memory density continued its exponential growth with concomitant improvements in storage capacity per cost. Similar improvements were achieved in the arena of SCSI and EIDE disk storage.

Software advances were equally important during this period providing the initial basis for the first clusters. An advanced version of Unix, the DARPA sponsored BSD Unix from UC Berkeley, which included virtual memory, and network communications semantics was a key development that spurred many industry OS packages like Solaris from Sun Microsystems and the early open source Linux operating system that was to become a major software base for future clusters. Early implementations of programming tools based on the CSP model were developed both commercially and in academia including the influential PVM system jointly developed by Emory University and Oak Ridge National Laboratory. Originally targeted to early generation MPPs (Massively Parallel Processors), such application programming interfaces (API) were well suited for future clusters.

The use of local area networks (LAN), principally Ethernet, integrated working environments comprising distributed collections of workstations usually for personal use and shared resources such as printers, file servers, and external internet access. It was recognized by some that dependent on individual usage, many workstations lay idle for considerable periods and were potentially available for other purposes. Efforts were made to employ such aggregations of temporarily unused "workstation farms" for "cycle harvesting" by scheduling applications on unused workstations when available. Among many software packages developed for this purpose was Condor from the University of Wisconsin, still widely used today. Condor matches user job requirements with available system capabilities and schedules these pending jobs as suitable systems are made available.

Perhaps the earliest formal use of the term "cluster" occurred near the end of this period introduced by Digital Equipment Corporation (DEC) to relate to the development of a collection of VAX minicomputers interconnected by means of proprietary network hardware and software. The early Andromeda (M31) project at DEC explored this arena of opportunity followed by the VAXcluster product offerings. While the network

technology was custom, the cluster “nodes” were essentially off-the-shelf VAX computers (e.g., model 11/750) and therefore exhibited a critical property of future generation clusters to emerge a few years later.

By the end of the Enabling Period, essentially all technologies, system architectures, software frameworks, and methodologies had been developed, at least in experimental form or for ancillary purposes, which would lay the foundation for the initial forays into various forms of clusters and the eventual dominance of clusters as a principal means of achieving scalable systems.

Classical Period: 1993–2004

The emergence of the commodity cluster exploited the concepts of clustering, the aggregation of multiple like systems by means of interconnection techniques to form a super-system, and key enabling technologies to deliver a new and at the time unique capability measured in performance-to-cost. While clusters are pervasive today in scientific and commercial computing arenas, at the beginning of the classical period it was far from certain that clusters would be developed, let alone have any significant impact on high performance computing. At that time, “big iron,” the use of custom supercomputers, was ubiquitous with the cold war driving their development and much of their deployment. To many the cluster concept was counter intuitive and even counterproductive to the goals and methodology embodied by such machines as the CRI Cray YMP and the MasPar 2, both custom high-speed computer systems of the day. To some, the cluster paradigm was viewed as a threat to mainstream supercomputing and as it turned out, they were proved correct.

A number of early attempts at cluster implementation were conducted with two projects standing out as the pathfinders for what was to become the dominant form of scalable computing up until the present. These were the NOW (Network of Workstation) project at UC Berkeley and the Beowulf project at NASA (Goddard Space Flight Center and Jet Propulsion Laboratory). From the benefit of hindsight these system concepts were very similar but in the early to mid-1990s they were considered as quite distinct. NOW emphasized high-end workstations, high performance networks, and proprietary software. Beowulf emphasized low cost personal computers, mass market networks

(Ethernet), and the new trend in open source software including the Gnu editors and compilers and the Linux operating system. Both projects began in 1993, with significant systems deployed in 1994, and both had strong impact on the community, essentially defining the range of capabilities and techniques to be incorporated to this day. Among these was the choice between vendor and end user installations. At a time when there were few vendor offerings in the cluster market, most clusters were assembled and installed (both hardware and software) from component systems by the end user facility with early emphasis in the academic and government laboratory environments.

Another important advance was the development of the system area network (SAN) explicitly devised for interconnection networks in clusters. This was represented by Myrinet, a high speed low overhead network marketed in 1995 by Myricom initially for Sun workstations and later for general PCI connected nodes. Myrinet offered a superior performance lower latency and higher bandwidth interconnect to the competing Ethernet but at a higher cost. It was very successful in the emerging commercial marketplace but saw slower adoption by the cost sensitive Beowulf user community. Nevertheless, Myrinet narrowed the gap between commodity clusters and MPPs with their custom interconnects. Other commercial networks included Quadrics and SCI.

The Beowulf Project was initiated in 1993 at the NASA Goddard Space Flight Center in collaboration with the USRA Center for Excellence in Space Data and Information Systems (CESDIS) and the University of Maryland at College Park. The project was undertaken to explore the opportunity of employing mass market personal computer systems for science simulation and data analysis with a critical objective of low cost for dedicated user allocation. An initial set of performance and capacity requirements at a cost within \$50K (1994) hardware deployment. The first Beowulf system, Wiglaf, saw first life in the summer of 1994, and followed by Hrothgar (1995) and Hyglac (1996) all 16 nodes culminating in 1 Gigaflops sustained performance on a real world problem for under \$50K, a performance to cost gain of a factor of 20X–100X that of contemporary MPPs. All Beowulf systems of that time consisted of single microprocessor nodes, Intel X86 family microprocessors, Ethernet interconnect (10 Mbps followed

by 100 Mbps Fast Ethernet) with tree topology. These systems would grow to between 100 and 200 nodes, all still in their original “pizza box” or “tower” cases and usually stacked on shelves or sometimes inserted in racks. By 1997, a combined project of the California Institute of Technology and Los Alamos National Laboratory (LANL) won the first Gordon Bell Prize awarded to a cluster based computation. In the same year, the NOW project had the first cluster entry on the Top-500 List. The commodity cluster had been embraced by the mainstream HPC community. In 1999, *How to Build a Beowulf* by Sterling et al was published by MIT Press and represented the state of the art as it was then known providing a general methodology for realizing commodity clusters.

The most important advance in software for commodity cluster computing was the community-wide development and support for a general and widely accepted application programming interface, MPI (Message Passing Interface) that became the lingua franca for distributed memory system programming. The first MPI standard (MPI-1) was released in 1994 with the first implementations available as early as a year later. A critical factor in the success and early adoption of MPI by users and vendors alike was the MPICH library reference implementations that give early access and credible performance to appropriately crafted applications using the message-passing model. A more advanced but fully backward compatible MPI standard (MPI-2) was released in 1998 with implementations following. Within the scientific computing arena, MPI is ubiquitous on both commodity clusters and MPPs providing portability for users and stable target platforms and market for Independent Software Vendors.

During this period, advanced system software was developed to control cluster management. This middle layer of software such as PBS, the Maui scheduler, and the ROCKS deployment package was created out of a critical necessity for higher productivity of cluster installation, operation, and application. The do-it-yourself mentality while serving as a catalyst for initial exploration and application of clusters nonetheless suffered from inadequate methods and means of stable employment, expected of other commercial computer systems. This middleware went a long way in rectifying this shortcoming while providing both open source

and commercially maintained versions of the software for the widest usage.

As a commercial market for clusters emerged, vendors drove the next evolutionary step by developing and offering products better suited to clusters. Perhaps most importantly was the repackaging of the functional node in to a dense rack mountable unit that provided high density packaging, superior air cooling, superior reliability, improved performance and memory capacity, built in I/O and network ports, and both installed disk and diskless versions. Such nodes borrowed from a class of multiprocessor servers to provide multiple microprocessors in the same node sharing a common memory through cache coherence schemes (e.g., MESI). Offering alternative interconnection networks and different scale systems provided users with a wide space of choice and through mass market and economy of scale of these nodes excellent performance to cost. By 2004, commodity clusters comprised more than 50% of the Top-500 List of the world’s fastest computer systems.

Advanced Period: 2005 to Present (and Beyond)

In recent years, important changes in enabling technology have altered the form and function of commodity clusters. Prior to the advanced period that began in approximately 2005, performance gains were achieved primarily by technology advances driven in part by Moore’s law. Both clock rate and processor core complexity continued to increase at a steady predictable rate. This was augmented with improved high density packaging and corresponding increases in the number of nodes to yield performance gains of greater than 100X per decade. By the beginning of the current period essentially all of the processor architecture tricks had been exploited while limits on power consumption caused clock rates to flat-line around 2 GHz +/- 50%. At the same time, logic density continued to increase leading to multicore components providing multiple cores per socket. Initially MPI was thought to be sufficient to program multicore based commodity clusters but subtle changes in balance of communications resulting from these new system structures is suggesting that slowly alternative programming methods, perhaps augmenting rather than replacing MPI, such as Cilk, TBB, and

Concert, may be required to make best use of multicore based clusters.

A second important change is the recent interest in adapting special purpose graphical processor units (GPU) originally intended for the entertainment industry dependent on high-resolution and high-speed visualization for movie special effects and video games to more general purpose scientific computing application domain. This has resulted in the emergence of heterogeneous cluster architectures with individual nodes incorporating ancillary accelerators for speeding up, sometimes dramatically, aspects of the application workflow. This has challenged programming methodology once again with such supportive APIs as CUDA and the emerging OCL to assist programmers in exploiting these new devices.

A new system area network and community standard, Infiniband (IBA or IB), has emerged as the principal challenger to Ethernet and has largely replaced Myrinet as the high performance low latency and low overhead interconnection fabric. Today, Infiniband represents 36% of the installed base of systems on the Top-500 List surpassed only by Gigabit Ethernet at just over 50%. Early problems with initial IBA offerings slowed market penetration but that has largely been resolved and a mix of these two interconnect technologies may be anticipated with IB increasing its usage in the scientific cluster computing arena.

Commodity clusters now dominate high performance computing with greater than 80% of the HPC market overall. But at the highest end, MPPs dominate. This is due to the advantages of custom interconnect and packaging even though the basic multicore microprocessor and memory technologies employed in both are basically the same. Such MPP machines as the IBM Blue Gene/P and the Cray XT5 are optimized for the requirements of major computer centers where performance, power, size, and reliability are more important than normalized cost. With the reliance on increased number of cores for performance gain, custom MPPs are likely to find increased foothold at the highest realms of HPC replacing in dominance the commodity cluster.

A counter trend, however, is now asserting itself that is likely to increase cluster use even in some aspects of the very highest end of system performance, at least as measured in terms of throughput rather than strong

scaled (reduction in execution time) problems. Web search engines and internet accessed “Cloud Computing” that respond to very large remotely distributed user base calls for unprecedented scale in commodity clusters. This new market will have a dramatic albeit unpredictable effect on the future evolution of the commodity cluster. The only thing that is certain is that clusters will continue to serve the computing community in myriad ways as they evolve to serve diverse markets and user communities.

Cm* - The First Non-Uniform Memory Access Architecture

DANIEL P. SIEWIOREK¹, ED GEHRINGER²

¹Carnegie Mellon University, Pittsburgh, PA, USA

²North Carolina State University, Raleigh, NC, USA

Definition

The name Cm* derives from an architecture wherein each processor-memory pair was called a “computer module” that could be replicated any number of times, as denoted by the Klein star borrowed from set theory.

Discussion

Chronology

The Cm* architecture was described in the fall of 1973. It was designed to explore how microcomputers could be combined to form large digital systems. As the sixteen-processor multiprocessor C.mmp became operational at Carnegie Mellon University in the early 1970s and Digital Equipment Corporation introduced the LSI-11 (January 1975), the project became focused on building a modularly expandable multiprocessor for parallel processing research. The architecture was specified by March 1975, and the design was completed by the fall of 1975. A single-cluster system was operational by July

1976. A ten-processor, three cluster system and operation system were demonstrated in June 1978. All fifty processors in five clusters were operational by September 1979. The machine was used experimentally for applications until January 1986.

Cm* was one of the first large-scale general-purpose multiple-instruction/multiple-data (MIMD) processors [3]. Two complete operating systems – StarOS and Medusa – were developed along with a host of applications. Over a decade of experience representing more than 100 person-years of effort was accumulated in the emerging area of parallel processing. Cm* researchers explored issues ranging from programming parallel applications, to investigating interactions between the operating system and architecture, to developing an automated experimental environment that facilitated the construction of prototype applications [6].

Project Genesis: Historically, Cm* had its beginning in the register-transfer module (RTM) project [2]. RTMs are a module set for the systematic construction of digital systems at the register-transfer level. The successor to RTM project, and immediate forebear of Cm*, was the computer module (CM) project [2, 4], whose major objective was also the systematic construction of digital systems.

The prime assumption of the CM project was that a simple computer, a processor-memory pair, is an appropriate module for building large digital systems. Modular structures have several advantages, including reduced cost through faster system design, faster production, reduced inventories, and simplified maintenance. A second assumption of the CM project was that communication between modules should be at the level of a single memory reference. This allows fine-grained communication and supports the widest variety of interprocessor communication patterns.

Multiprocessors consist of many autonomous processors that address the same primary memory. In contrast, multicomputers are made up of autonomous computers communicating by means of messages through static or dynamic communication links. In particular, the Cm* architecture provides a continuum of memory sharing between processors ranging from no shared memory (multicomputer) to fully shared memory (multiprocessor).

Cm* - The First Non-Uniform Memory Access Architecture. **Table 1** Synchronization granularity and distributed computer structures

Grain size	Synchronization interval (instructions)	Distributed computer structure	Communication overhead (instructions)
Fine	1	Vector/array processor	1
Medium	10–100	Multiprocessor	1–10
Coarse	100–10,000	Multicomputer	100–10,000
Large	10,000–10 million	Network	10,000–10 million

One way of positioning a multiprocessor is to consider the synchronization granularity [7], or frequency of synchronization between tasks. Table 1 shows, for a variety of synchronization granularities, the best-suited distributed computer organization. Multiprocessor systems such as Cm* are more suitable for a medium grain of synchronization.

Multiprocessors and networks employ a variety of interconnection structures to couple processors with memory units. Among these are full interconnections, shared buses, multiple buses, crossbar switches, and multistage networks. See Siegel [8] for a complete discussion of this topic. The fully connected network couples each processor with each memory through a dedicated link. A shared bus is a single communication path to which both processors and memory are connected. Bus arbitration may either be done in a central arbiter or be distributed among the units. The bus bandwidth is divided between the processors and does not scale for large N .

A multiple shared bus is a set of shared buses connected by gateways or switches. The switches may be organized in many ways. The best-known topologies are crossbar switches and hierarchical switches. In crossbar switches, each processor and each memory unit is connected to a dedicated shared bus. Switches are used to connect the processor buses and memory buses into the form of a crossbar. In the 16-by-16 crosspoint switch of C.mmp, each switch connected a full bus of over 70 wires. Crosspoint switch complexity grows as N^2 where N is the number of processor/memories, and it does not scale for large N . With a hierarchical switch, a group of functional units is clustered around a single shared bus, and the clusters are interconnected with another shared bus. By repeating the process, a hierarchically organized multi-shared-bus is obtained. Bandwidth can be increased by adding another bus.

The number of bus connections grows approximately linearly with N .

Rather than have separate processors and memories, Cm* coupled processors and memories so that not all memory accesses encountered switch delays. Borrowing concepts from memory-mapped input/output, portions of the memory address space were assigned to local memory while the remainder of the address space could be mapped to any memory location in any other module – effectively turning Cm* into a software-managed hierarchical cache.

Two conceptually different operating systems were implemented for Cm*. Large portions of the operating-system kernels resided in firmware with operating-system calls triggered by accessing special memory addresses.

Cm* Architecture Evolution

Cm* is structured using processor-memory pairs called *computer modules* or Cm's (after the PMS notation of [1]). The memory local to a processor also serves as the shared memory in the system. Inherent in this structure is the assumption of program locality. The efficient use of the system depends on ensuring that most of the code and data referenced by a processor will be held local to that processor. Early Cm* measurements with various benchmarks applications indicate that local-memory hit ratios of 0.8–0.9 (the fraction of total memory references directed to local rather than shared memory) were readily achieved.

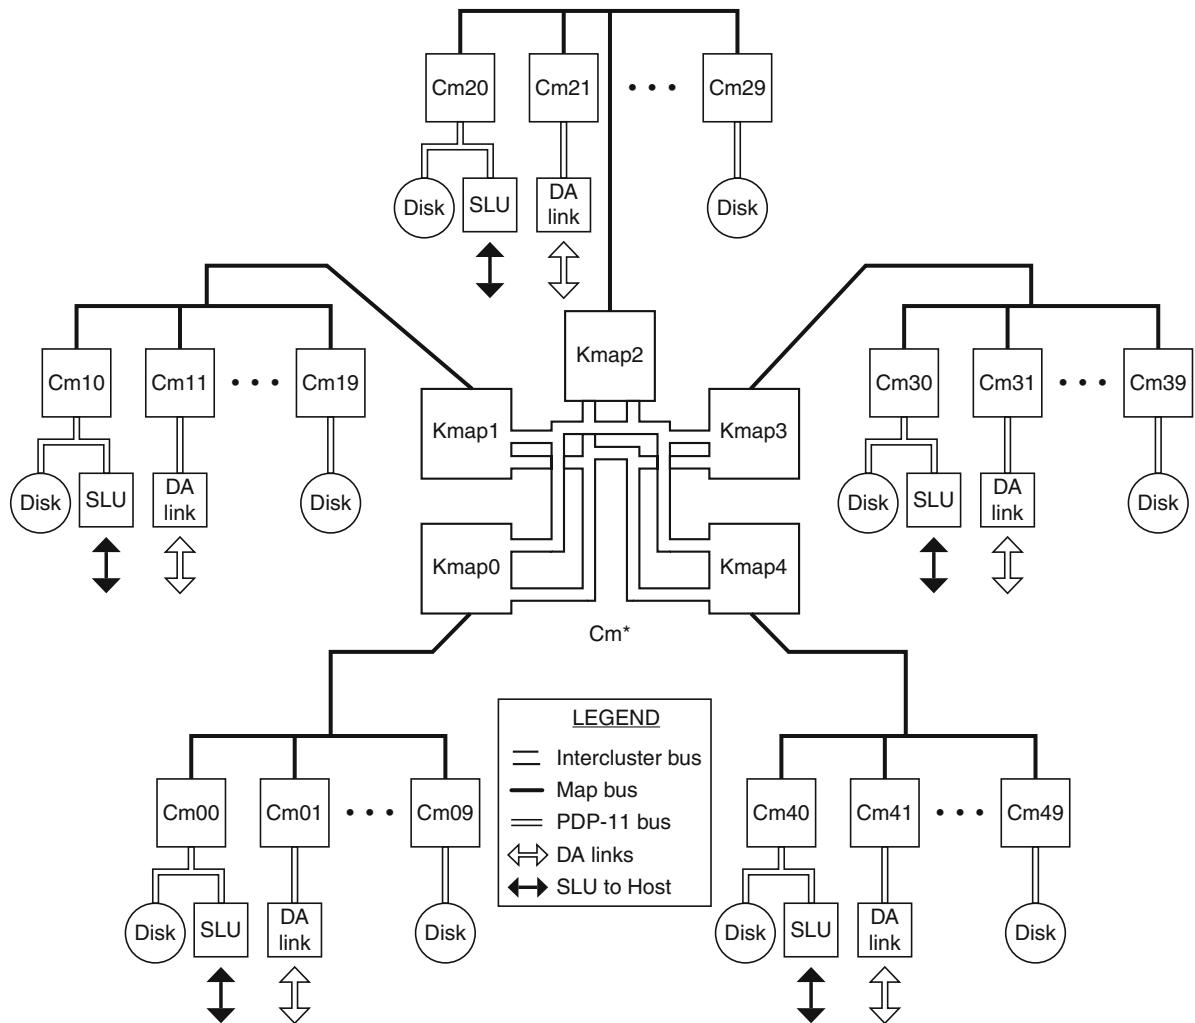

Initially, one self-contained module was envisioned that consisted of a processor, memory, and an intelligent interface. The result was termed a computer module (Cm). The address-mapping controller (Kmap) performed all the functions necessary for generating external memory requests and responding to external requests for its local memory. So that the capacity

for interprocessor communication would not be limited by any single communication path, each Kmap connected to two inter-Cm buses. Further investigation led to the conclusion that very little performance was lost by centralizing the modules' address-mapping and multiple-bus connection functions in a Kmap. The Kmap was shared by a number of computer modules, which saved at least half the cost of a one-Kmap-per-module design. The programmable high-performance Kmap was shared by several Cm's connected to an inter-Cm bus via simple interfaces (Slocals). The basic function of the Slocal was to act as a buffer between the processor and the inter-Cm bus and provide sufficient control functions to generate or respond to external memory requests.

Cm* Architecture

The original description of the design and implementation of Cm* appears in two papers [4, 10]; the design and switching of Cm* and a detailed account of one particular addressing structure are described by Swan [9].

Cm* consisted of 50 Cm's, connected together by a hierarchical, distributed switching structure depicted in Fig. 1. The lowest level of the switching hierarchy comprised Slocals, local switches that connect individual Cm's to the rest of the structure. Cm's were grouped together into clusters that were presided over by high-speed microprogrammable communication controllers called Kmaps. A Kmap provided the mechanism for Cm's in its cluster to communicate with each other, and cooperated with other Kmaps to service requests

Cm* - The First Non-Uniform Memory Access Architecture. Fig. 1 Cm* architecture

from its Cm's to access Cm's in nonlocal clusters. Besides this address-mapping function, since Kmaps were microprogrammable, it was usual to implement key operating-system functions in Kmap microcode.

All communication that involves Kmaps was performed via packet switching rather than circuit switching to avoid deadlock over dedicated switching paths. Packet-switched communication also allowed the processing of requests by the Kmaps to be overlapped, since switching paths did not need to be allocated for the duration of a request; this resulted in improved utilization of the switching structure. The interconnection structure between Cm* clusters was essentially arbitrary. The Kmap in each cluster had two bidirectional ports, each of which could be connected to a separate intercluster bus to achieve a variety of interconnection schemes. In the implemented configuration, all five Kmaps were connected to two intercluster buses, as shown in Fig. 1. The physical implementation of Cm* is shown in Fig. 2.

Cm's and Slocals

Each Cm was a processor-memory-switch combination, consisting of a standard off-the-shelf Digital Equipment Corporation (DEC) LSI-11 (the first single-board implementation of the PDP-11 instruction set), 64 K or 128 K bytes of memory, one or more I/O devices, and a custom-designed Slocal that connected the processor-memory combination to the rest of the system (Fig. 1). When the processor of a Cm initiated a memory reference, its Slocal was responsible for determining whether the reference was to be directed to local memory or out to the Kmap for further mapping. The Slocal used the four high-order bits of the processor's address, along with the current address space, to access a mapping table that determined whether the reference was to proceed locally or not. References that mapped to local memory proceeded with no loss of performance; references that mapped to another Cm were slower by a factor of three; and references that mapped to a Cm in another cluster were slowed again

Cm* - The First Non-Uniform Memory Access Architecture. Fig. 2 Physical structure of Cm* with four Cm's shown in the upper drawer and the K.map in the lower drawer

by a factor of three. These figures were the best possible ratios that could be achieved on Cm*, and therefore amount to constraints imposed by the hardware itself rather than to any microcode implementation features. All I/O devices in Cm* were connected to the various LSI-11 buses. Since there was no interprocessor communication mechanism other than the standard one for memory references, interrupts generated by an I/O device needed to be fielded by the processor to which the device is directly attached.

Kmaps: Transaction Controllers

Acting both as the switching center within a cluster, and as a node in a network of clusters, the Kmap served to coordinate synchronization and communication in Cm*. A fast (157-ns. cycle), horizontally microprogrammed (80-bit wide) microprocessor, the Kmap itself, consisted of three tightly coupled processors. The bus controller, or Kbus, acted as the arbitrator for the bus that connected Cm's in the local cluster to their Kmap; the Linc managed communication to and from the Kamp to other Kmaps; and the mapping processor, or Pmap, responded to requests from the Kbus and Linc, and performed most of the actual computation for a service request. The Pmap also directed the Kbus and Linc to perform any needed operations on behalf of the request being processed.

The Kmap was a transaction controller, sending and receiving message packets that contained requests and replies, following a protocol designed by the microprogrammer. The Kmap routinely mapped memory accesses by one processor into the local memory of another computer module. It needs to do so very rapidly and with little delay to achieve reasonable system performance. Thus, the Kmap contained some special hardware features designed to assist it in controlling many transactions at a high rate of speed.

The Kmap hardware supported eight separate Pmap processes, known as contexts, each with its own set of general-purpose registers and its own microsubroutine stack. Typically, each context was in charge of one transaction. When a context needed to wait for a message packet to return with the reply to some lower-level request, it had the Pmap switch to another context so that work on another transaction can proceed concurrently.

The Kmap also contained 5,120 words of random-access memory, called the data RAM, which the Pmap

can read and write with a delay of a few microinstructions. Because the data RAM was shared by all contexts, it typically held information that was of interest to more than one transaction, such as cached pieces of address-translation tables and mechanisms for synchronizing the use of other resources among different contexts.

Taken individually, each Kmap appeared to the Pmap microprogrammer as a nonpreemptive, hardware-scheduled multiprogramming system (since contexts were never interrupted, but suspended only when the microprogrammer directed). Taken collectively, the network of all Kmaps presented the microprogrammer with a distributed system based on message-packet intercommunication.

The Interface Between Kmap and Computer Module

The Pmap communicated with the computer modules in its cluster via the map bus, a packet-switched bus controlled by the Kbus. The Kbus fielded requests and replies from the computer modules, coordinated the transfer of data across the map bus between computer modules or between a computer module and a Pmap context, and kept track of which Pmap contexts are free to service new requests. Two queues, the Kbus out queue and the Pmap run queue, provided the interface between the Kbus and Pmap.

A request by a computer module to the Kmap is said to invoke some Kmap operation. The most frequent Kmap operation was the mapping of nonlocal access to a location in the physical memory of some computer module in the cluster. This was called a mapped reference. Each memory access issued by the processor of a computer module passed through its Slocal, which either routed the access directly to local memory or sent it out to the Kmap. A memory access handled by the Kmap also could be mapped back to the local memory of the issuing processor, but a direct local access was about three times faster.

For more complicated Kmap operations, the Pmap microprogrammer generally appropriated some subset of the computer module processor's virtual address space, designating specific addresses the processor could use to invoke other Kmap operations. These special Kmap operations were invoked in exactly the same manner as I/O operations are invoked on a computer that has memory-mapped device control registers.

The Interface Between Kmap and Kmap

Kmaps communicated with each other via an intercluster bus, a packet-switched bus that was jointly controlled by the Linc processors in each of the directly connected Kmaps. The Linc maintained queues of incoming and outgoing messages, interacted with the Kbus to activate and reactivate Pmap contexts, and provided the local storage for Pmap contexts to construct and inspect intercluster messages. Each Linc was interfaced to two independent intercluster buses.

An intercluster message contained up to eight 16-bit words of data, of which all words except the first were totally uninterpreted by the Linc. Each intercluster message was sent from an immediate source Kmap to an immediate destination Kmap. The number of the destination Kmap appeared in a fixed place in the message so that the Linc could determine which messages are sent to its cluster. Intercluster messages were of two types: forward messages, which invoked a new context at the destination Kmap, and return messages, which returned to a waiting context at the originating Kmap. A return message contained the context number of the to-be-reactivated Pmap context in a fixed place where the Linc could find it in order to inform the Kbus. These intercluster messages were designed to be used as a mechanism for implementing remote procedure calls between Kmaps.

In a configuration of the Cm* system, it was quite possible that two particular Kmaps had no intercluster bus in common and thus could not send messages directly to one another. Each Kmap connected directly to two intercluster buses, however, and as long as some path through a series of intermediate Kmaps could be found, the two Kmaps in question could still communicate, provided each of the intermediate Kmaps cooperated by forwarding the message closer to its ultimate destination.

Communication with Cm*

When software was first being developed on Cm*, there arose a need to let the software developer allocate certain resources (such as clusters and debugging tools) themselves and to protect these resources from being disturbed by other users. The Cm* Host system was a serial-line-oriented resource management facility. It

was initially implemented on a PDP-11/10 with 28 K words of memory.

Several communication lines connected the Host to components of Cm*, to terminals, and to other Carnegie Mellon University Computer Science Department computers. There were serial-line connections from the Cm* Host to ten individual Cm's, two of which were in each of the five clusters. Because the other 40 Cm's lacked serial-line connections, they needed to be loaded from other Cm's via a Kmap or from peripheral devices. The communication lines served two purposes. First, they allowed the user to communicate with other computers from Cm*, as some programs on Cm* interacted with programs on other machines. They also permitted the user to monitor debugging information on both machines simultaneously from one terminal.

In addition to its 50 Cm's, Cm* had three LSI-11's, known as hooks processors, which were used for debugging the Kmaps. These processors controlled the "hooks," which was a collective term for a set of hardware that was designed into each Kmap to permit complete external control and diagnosis. The hooks consisted of several control registers and other hardware within the Kmap, an LSI-11 interface to make the hardware accessible from an LSI-11, and a bidirectional hooks bus used to transmit information between the control hardware and the LSI-11 bus interface. The hooks appeared to an LSI-11 as a group of eight words in its physical address space. By reading and writing these words, the hooks processor had almost total control over the internals of the Kmap. It could load microcode; start, stop, and single-cycle the Pmap/Linc and Kbus clocks, read out most, and write some of the internal registers of the Pmap; disable certain error checks within the Pmap; and initialize the Kmap.

The diagnostic processor (DP) was added to the Cm* system to collect hardware reliability and availability information. It hosted a program called the Auto-Diagnostic Master, which ran diagnostics on Cm's that were otherwise idle. The DP was an LSI-11 with 28 K words of memory. It had two serial-line connections to the Cm* host. One connection provided a user interface through which one can request status reports about particular Cm's, particular clusters, or the entire Cm*. The second serial-line interface was used by the Auto-Diagnostic program as a command interface

to the Host. The program logged in over the second line, directs the Host to run diagnostics for it, and on operator request, transferred the statistics file to a PDP-10.

Because the system software developed for Cm* was written, compiled, and stored on a remote machine, object code frequently had to be transferred to Cm*. To facilitate high-speed transfers, a DA Link was developed to provide a 10-megabaud parallel DMA link between Cm* and a DEC-10. Between an unloaded LSI-11 and an unloaded DEC KL-10, these links could transfer more than 600,000 words per second. A file-transfer system residing on the DEC-10 provided reliable file transfers.

Cm* Experiments

An extensive set of experiments were conducted with Cm* involving two different operating systems. Many of the experiments focused on speedup, the ratio between the elapsed time required by the one-processor version of a parallel algorithm to the elapsed time for its N -processor counterpart. Speedup is usually between 1 and N . Three factors were responsible for the shape of the speedup curve (e.g., speedup as a function of the number of processors): algorithm penalty, implementation penalty, and their interaction [11].

The algorithm penalty is composed of the separation overhead (cost of process decomposition and data partitioning) and the reconstitution overhead (cost of the interchange and reporting of intermediate and final results). The implementation penalty is composed of access overhead (cost of accessing shared resources) and the contention for these shared resources. The interaction between the algorithm and implementation leads to two other types of overhead: the overhead of synchronization and the cost of adapting a parallel algorithm to a specific architectural implementation.

In addition, at the macro level, parallel algorithms on Cm* were divided into six classes: asynchronous, synchronous, multiphase, partitioning, pipeline, and transaction processing. These classes of parallel algorithm structures represented distinct cross-sections of the algorithm-overhead and implementation-overhead profiles. Once a parallel algorithm was classified into one of the six categories, one could predict how it would perform. Further, the characteristics of parallel

architectures were parameterized to predict the performance of a parallel implementation.

Summary

The Cm* architecture consisted of 50 computer modules, connected together by a distributed switching structure. The lowest level of the switching hierarchy consisted of Slocals, local switches that connected individual Cm's to the rest of the structure. Cm's were grouped together into clusters that were presided over by high-speed microprogrammable communication controllers called Kmaps. A Kmap provided the means for Cm's to communicate with other Kmaps to service requests for memory references to other clusters. In addition to address mapping, key operating-system functions generally were implemented in microcode.

Definition

The coarray programming model is an extension to the Fortran language that provides an explicit syntax and an explicit execution model for the development of parallel application codes.

Introduction

Fortran 2008 contains the coarray parallel programming model as a standard feature of the language [11]. It is the first time that a parallel programming model has been added to the language as a supported feature, portable across all platforms. Compilers supporting the model are available or under development from all the major compiler vendors.

The coarray programming model consists of two new features added to the language, an extension of the normal array syntax to represent data decomposition plus an extension to the execution model to control parallel work distribution.

Execution model

The coarray execution model is based on the Single-Program-Multiple-Data (SPMD) model where replications of a single program execute independently within their separate memory spaces. Each replication is called an image, and an intrinsic function,

```
p = num_images()
```

returns the number of images at run-time. The run-time system assigns local memory to each image, and each image executes asynchronously along independent paths through the program based on its own data and its own unique image index. Another intrinsic function,

```
me = this_image()
```

returns the image index at run-time. Image indices start at image number one following Fortran's default rule for lower bounds.

At times the independent images need to interact with each other to coordinate their activities. The programmer inserts image control statements in the program at appropriate points to synchronize images and to maintain memory consistency across images. The statement,

```
sync all
```

for example, imposes a full barrier across all images. Each image, when it encounters this statement, completes all memory activity, both local and remote, and then registers its presence at the barrier. No image executes any statement following the barrier until all images have registered at the barrier. It is the easiest way for the programmer to maintain memory consistency across images because memory in each image has reached a well-defined state. The programmer is responsible for knowing what state is the correct state across a barrier.

The programmer may also want to synchronize among subsets of images. Pairwise interaction, for example, may be accomplished by one image synchronizing with its neighbor to the right,

```
sync images(me+1)
```

and its partner synchronizing

```
sync images(me-1)
```

with its neighbor to the left.

The programmer may also control interaction among processors by inserting critical segments into the program,

```
critical
  :
end critical
```

where only one image at a time may enter the segment. The programmer may also use intrinsic locks to introduce more sophisticated locked segments similar to critical segments.

Coarrays and Codimensions

A coarray is a variable,

```
real :: x[*]
```

declared with a codimension. The codimension in square brackets [*] means that there is a real variable with the same name x assigned to the local memory of each image. By default the images are numbered starting with image number one, and the asterisk means that the upper bound on the codimension equals the number of images at run-time. The programmer writes code that is independent of the number of images and never writes code that assumes a particular number of images. If the programmer wants to think of image indices starting with number zero, or any other number p, the alternative declaration,

```
real :: x[p:*
```

allows for complete flexibility. The upper bound for the codimension is always an asterisk, and image indices lie between p and num_images() -p+1.

A normal array in Fortran is a set of scalar variables,

```
real :: y(n)
```

each member of the set labeled by an integer dimension index. In the same way, a coarray is a set of general objects, scalars, for example, in declaration (7) or arrays,

```
real :: z(n) [p:*
```

in declaration (10). Each image has an object of the same name, same type, and same size assigned to its local memory, and each object in the set is labeled by an integer codimension index. Coarray variables may be declared for any type including derived types,

```
type(someType) :: Q[p:*
```

providing the programmer a powerful tool for defining distributed data structures. The only exception is that a variable with the pointer attribute may not be declared as a coarray.

Codimensions may also be multi-dimensional,

```
type(someType) :: R[0:q,0:*
```

allowing the programmer to think of images as logically decomposed into, for example, a two-dimensional grid [9]. The final codimension is always an asterisk. An alternative form of the intrinsic function,

```
[myP,myQ] = this_image(R)
```

returns image indices [myP, myQ] relative to the codimensions defined by the declaration statement. The programmer may want, for example, to identify the east-west neighbors [4, 10] with co-indices [myP+1, myQ] and [myP-1, myQ] and north-south neighbors with co-indices [myP, myQ+1] and [myP, myQ-1].

Writing Code for the Coarray Model

Coarray variables are visible across all images. The programmer may, therefore, write code that moves data from one image to another by pointing to it with a co-index. For example, the code

```
real :: x[*],y
me = this_image()
y = x[me+1]
```

moves the value of the variable x [me+1], located in the local memory of the image to the right, into the variable y, located in the local memory of the image executing the statement. The variable y exists in the local memory of each image but, since it is not a coarray variable, it is visible only locally to each image. An image may also move values in the other direction,

```
x[me-1] = y
```

defining the value of x [me-1] in the local memory of the image to the left.

An image executes each statement it encounters according to the normal execution rules of Fortran. The image index in square brackets has nothing to do with execution. The images to the right and to the left know nothing about what other images may be doing with values of variables in their local memories. It is the programmer's responsibility to insert image control

statements into the program to control memory activity so that the state of memory across images is the state the program expects for correct behavior. For example, suppose image number one reads the value of an input variable that every image needs,

```
real :: n[*]
me = this_image()
if(me == 1) then
  read(*,*), n
  sync images(*)
else
  sync images(1)
  n = n[1]
end if
```

After reading the coarray variable `n` from standard input, image number one executes a `sync images(*)` statement notifying all the other images that it has the value in its local copy of the variable. The other images, meanwhile, execute the `sync images(1)` statement waiting for a signal from image number one. When they receive it, they each individually read the value `n[1]` from image number one without regard to what other images may be doing. They each are guaranteed to receive the correct value of the variable.

Multiple codimensions express the relationship between north-south and east-west neighbors in a natural way. A coarray variable with declaration

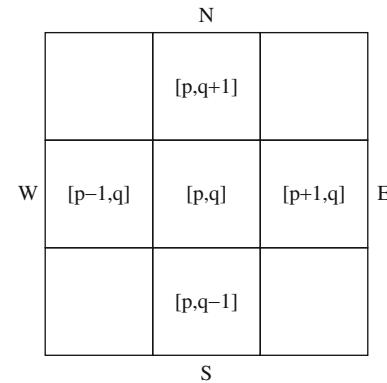

```
real :: v(0:m+1,0:n+1)[proc,*]
```

might represent a velocity field decomposed into a two-dimensional grid with overlapping halo cells around the edges to support, for example, a finite difference operator [4, 10]. At certain points in the calculation, these halo cells must be updated to maintain data consistency across images. With image indices as shown in Fig. 1, each image with image index `[p, q]` executes the halo exchange in the east-west direction,

```
v(:,n+1) = v(:,1)[p+1,q]
v(:,0)   = v(:,n)[p-1,q]
```

using a natural representation in coarray syntax. Notice that each statement moves an entire column of data from one image to another. The north-south exchange is similar.

Multiple codimensions also represent linear algebra operations naturally using blocked matrix decompositions [9]. The following code, for example,

Coarray Fortran. Fig. 1 Representation of a two-dimensional domain decomposition using codimensions for north-south-east-west directions

```
real,dimension(n,n),codimension[p,*]::a,b,c
do R=1,p
  c(:, :) = c(:, :) +
    matmul(a(:, :)[myP,R], b(:, :)[R,myQ])
end do
```

computes the matrix multiplication in parallel for a $[p, p]$ image decomposition and a global problem size that is a multiple of p . Each image accumulates the block of the result matrix that it owns by summing together the products of the blocks of the first matrix in the same row of images with the blocks of the second matrix in the same column of images [5]. When image indices are omitted from a coarray in a statement, such as `c(:, :)`, the indices default to the local values, `c(:, :) [myP, myQ]`, as in this example. This convention saves the programmer from specifying redundant information and helps the compiler to generate optimized code.

Object-Oriented Design with Coarrays

Starting with the Fortran 2003 standard [7], Fortran is now an object-oriented language. Objects declared as coarrays provide a powerful combination for defining distributed data structures with associated methods for communication between objects owned by different images.

Abstract Maps

The coarray model contains no distributed data structures. All objects are local objects assigned to the local memory of each image. Coarray objects are visible to

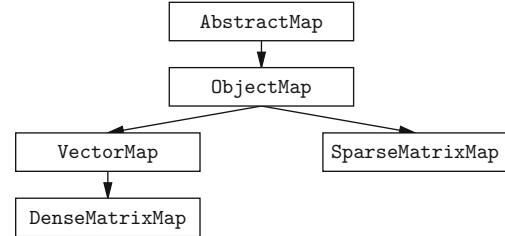

other images but other objects are not. To create distributed objects, the programmer defines derived types that are analogous with classes. Objects of this type may have a complicated structure that describes how the programmer wants data distributed across images. Multi-dimensional coarrays may not be enough to describe these structures.

One way to describe complicated distributions is through extensions of an abstract map,

```
type,abstract,public :: AbstractMap
contains
procedure(getNumberOfObjects),    &
  public,pass(this),deferred :: &
  getNumberOfObjects
proceduregetImageIndex),          &
  public,pass(this),deferred :: &
  getImageIndex
procedure(getLocalIndex),         &
  public,pass(this),deferred :: &
  getLocalIndex
  :
end type AbstractMap
abstract interface
  integer function getNumberOfObjects(this)
    import :: AbstractMap
    class(AbstractMap),intent(in) :: this
  end function GetNumberOfObjects
  :
end interface
```

This abstract object contains nothing more than a set of interfaces for deferred procedures that every map must contain. For example, the function `getNumberOfObjects()` returns the number of objects represented by the map. Another deferred function, `getImageIndex(k)`, returns the image index that owns global object `k` in its own local memory. Another function, `getLocalIndex(k)`, returns the object index used locally by the image that owns the global object `k`. Other functions, not listed, return the global object index corresponding to a local object, the number of objects owned by a specific image, and so forth. Any concrete map that extends this abstract map must implement each of these functions plus other procedures specific to a particular distribution.

Specific concrete maps are extensions of the abstract map as shown in Fig. 2. One extension, called an object map, might represent the decomposition of a set of unspecified objects. A specific kind of object might be a section of a vector with a corresponding map representing a particular decomposition such as a block-cyclic

Coarray Fortran. Fig. 2 Problem decomposition represented as extensions of an abstract map

distribution. The vector map might be extended to represent a block matrix structure with one vector map for the columns and another vector map for the rows. Another extension might represent a sparse vector or a sparse matrix structure [8, 9].

An object map is a composite function,

$$L^p = \Lambda^p(\Pi(G)),$$

loosely based on the Composite Design Pattern [4, 6] as shown in Fig. 3. A global set of n objects $G = \{G_1, \dots, G_n\}$ is first permuted,

$$\pi = \Pi(G),$$

such that

$$\pi_j = \Pi_j^i(G_i) \quad i, j = 1, \dots, n.$$

Subsets of these permuted objects are then projected to n_p local objects $L^p = \{L_1^p, \dots, L_{n_p}^p\}$ on specific images,

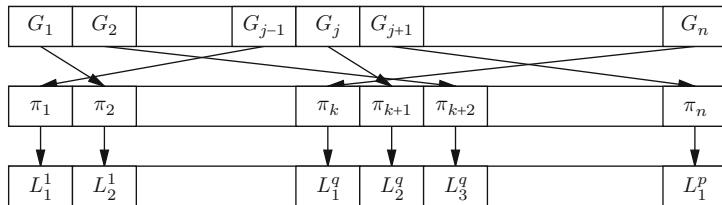

$$L^p = \Lambda^p(\pi),$$

such that

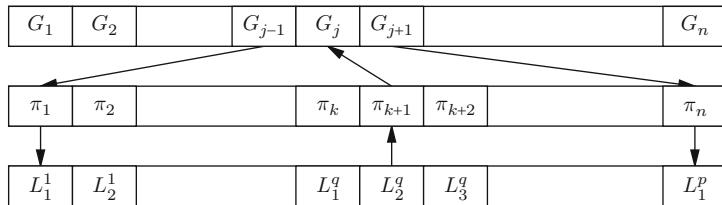

$$L_k^p = (\Lambda^p)_k^j(\pi_j), \\ k = 1, \dots, n_p, \\ p = 1, \dots, \text{num_images}()$$

represents local block k on image p .

The composite function has an inverse so that each image knows how its set of local objects is related to the set of global objects. Figure 4, for example, shows how image q locates its neighbor to the left for its second local object L_2^q as the first local object L_1^1 on image number 1 and its neighbor to the right as local object L_1^p on image number p . These relationships are encapsulated in procedures associated with each object that performs, for example, halo exchanges between distributed matrix objects.

Coarray Fortran. Fig. 3 A composite object map

Coarray Fortran. Fig. 4 Inverse map to nearest neighbors

Blocked Vector Maps

An important distributed object is a blocked vector. In this case the objects to be mapped are blocks of a global vector of size n where each block is a subsection of the global vector `block(n1 : n2)` with some rule for picking the lower bound $n1$ and the upper bound $n2$ for each block. These blocks are assigned to images, and the map keeps track of how many blocks go to each image, how the blocks are numbered locally on each image, and the relationship of the local blocks to the original global vector.

The programmer defines a Type `VectorMap` as an extension to the Type `AbstractMap` with whatever components it needs to define a map for a blocked vector and to implement the deferred functions, adding new functions as needed. For example, there may be a function, `getBlockSize(k)`, that returns the size of block k . The programmer also writes a constructor, a function with the same name as the type,

```
Type (VectorMap) :: map
map = VectorMap(n, blockSize)
```

that fills in all the required information for mapping a global vector of length n into blocks of size `blockSize` and assigning them to the local memory of each image. Other forms of the constructor, of course, might produce a more irregular decomposition of the global vector with different block sizes on each image and different numbers of blocks on each image.

Vector maps might also be extended to represent matrix maps using one vector map for rows of the matrix and another vector map for the columns of the matrix. Maps for irregular sparse matrices may also be designed where the objects represented in the map are sparse blocks of the matrix arranged and distributed in specific ways to match the requirements of specific algorithms for direct or iterative equation solvers. Furthermore, distributed data structures may be redefined dynamically to reflect changes in the physical system as the computation advances in time. A new map is created and the data is redistributed from the old map to the new map without having to change the details of the numerical algorithm.

Blocked Vectors

A blocked vector object,

```
Type :: BlockedVector
Type (VectorMap), pointer, private :: map
real, allocatable, target, private :: block(:, :)
contains
procedure, public, pass(this) :: getPointerToBlock
procedure, public, pass(this) :: haloExchange
:
end type BlockedVector
```

contains the data for each block in an allocatable component `block(:, :)` and a map that describes

the distribution of the global vector. One form of the constructor for a concrete object of this type

```
Type(BlockedVector) :: v
v = BlockedVector(map)
```

accepts an existing vector map as an argument. The constructor uses the map to determine the number of blocks and the block sizes for each image and allocates space appropriately,

```
Type(BlockedVector) &
function BlockedVector(map) result(this)
  Type(VectorMap), target, intent(in) :: map
  this%map=>map
  k=map%getNumberOfLocalBlocks()
  do i=1,k
    n = map%getBlockSize(i)
    allocate(this%block(0:n+1,i))
  end do
end function BlockedVector
```

It also assigns its vector map component to point to the dummy map argument. Notice that the constructor has allocated halo cells of width one to each block. The halo width may be an optional argument to the constructor and may in fact be zero.

Application to Partial Differential Equations

Consider a finite difference scheme applied to the one-dimensional shallow water equations [8]. The partial differential equations, defined by Cahn [4] and by Arakawa and Lamb [1], for the surface height $h(x, t)$ and the two velocity components $u(x, t)$ and $v(x, t)$, as functions of the space variable x and the time variable t , are the equations [1, Eqs. 23–25, p. 183]

$$\begin{aligned} \frac{\partial u}{\partial t} - Fv + G \frac{\partial h}{\partial x} &= 0 \\ \frac{\partial v}{\partial t} + Fu &= 0 \\ \frac{\partial h}{\partial t} + H \frac{\partial u}{\partial x} &= 0. \end{aligned}$$

In these equations, F is the Coriolis frequency, G is the acceleration of gravity, and H is the mean height of the surface, which is assumed to be small relative to the width of the space interval.

The fields u , v , h are represented as blocked vectors declared as coarrays,

```
type(BlockedVector), codimension[*] :: h, u, v
```

The constructor for the vector map builds a map,

```
type(VectorMap) :: map
map=VectorMap(n, k, p, w)
```

that describes a field with n grid points cut into blocks of size k distributed over p images. The halo width w equals one, wide enough for a two-point stencil for the first-order difference operator. Three calls to the constructor for a blocked vector create the three fields h , u , and v ,

```
h=BlockedVector(map)
u=BlockedVector(map)
v=BlockedVector(map)
h=h0
```

based on the same predefined vector map guaranteeing that all three fields have the same distribution. The statement $h=h0$ uses an overloaded assignment statement to initialize the field h from the array $h0(:)$ containing its initial values. The other fields have initial value zero set by their constructors.

Having created field objects, the programmer decides to let each image perform work on the local blocks that it owns. For each of its local blocks, an image obtains the length of the block and a pointer into the block, with or without halos depending on how it is used in the difference formula. Each image performs the appropriate finite difference operation independently of the others. Synchronization among images occurs within the halo exchange operation, which uses coarray syntax internally to update overlapping halo regions. With a loop over some predetermined number of time steps, $tMax$, the code might look like the following:

```
do t=1,tMax
  do b=1,u%getNumLocalBlocks()
    m = u%getBlockLength(b)
    hPtr => h%pointerToBlock(b)
    uPtr => u%pointerToBlockWithHalo(b)
    hPtr(1:m) = hPtr(1:m) &
    -0.5*H*(dt/dx)*(uPtr(2:m+1) &
    -uPtr(0:m))
  end do
  call h%haloExchange()
  do b=1,u%getNumLocalBlocks()
    m = u%getBlockLength(b)
    hPtr => h%pointerToBlockWithHalo(b)
    uPtr => u%pointerToBlock(b)
    vPtr => v%pointerToBlock(b)
    uPtr(1:m) = uPtr(1:m)+F*dt*vPtr(1:m) &
```

```

    - 0.5*G* (dt/dx) * (hPtr(2:m+1) &
    - hPtr(0:m))
vPtr(1:m) = vPtr(1:m) - F*dt*uPtr(1:m)
end do
call u%haloExchange()
call v%haloExchange()
end do

```

All the details of data distribution and all the details of how to exchange data between objects is hidden from the programmer. The blocked vector objects themselves contain all the necessary information, and the procedures associated with them know how to perform the required operations.

Summary

Fortran is a modern programming language. It is an object-oriented language, defined by the Fortran 2003 standard, and it is also a parallel language, defined by the Fortran 2008 standard. Programmers are able to develop modern application codes using object-oriented design combined with the coarray parallel programming model. Development within a single language avoids many of the complications that occur from differences between languages. New compilers will support the model and will make application codes portable across all platforms, and hardware vendors are designing new architectures that will support the model effectively.

Definition

Parallel code generation is the action of building a parallel code from an input sequential code according to some scheduling and placement information. Scheduling specifies the desired order of the statement instances with respect to each other in the target code. Placement specifies the desired target processor for each statement instance.

Discussion

Introduction

Exhibiting parallelism in a sequential code may require complex sequences of transformations. When they come from an expert in program optimization, they are usually expressed by way of directives like *tile* or *fuse* or *skew*. When they come from a compiler, they are typically formulated as functions that map every execution of every statement of the program in “time” (*scheduling*), to order them in a convenient way, and in “space” (*placement*), to distribute them among various processors.

Parallel code generation is the step in any program restructuring tool or parallelizing compiler that actually generates a target code which implements the user directives or the compiler mapping functions.

This task is challenging in many ways. *Feasibility* is the first challenge. Reconstructing a program with respect to scheduling and placement information at the statement execution level may seem an impossible problem at first sight. It has been addressed by working on a convenient representation of the problem itself, as it will be described momentarily. *Scalability* is another important issue. As compiler vendors try to ensure that compile time is (almost) linear in the code length, the code generation step must be fast enough to be integrated into production tools. *Quality* of the generated code must be paramount. The generated code should not be too long and should not include heavy control overhead that may offset the optimization it is enabling. Finally, *flexibility* must be provided to allow a large span of transformations on a large set of programs.

Representation of the Problem

To solve the code generation problem, it needs to be formalized in some way. A mathematical representation, known as the *polyhedral model* (also referred in the literature as the *polytope model* or the *polyhedron model*), is a convenient abstraction. It allows the description of the problem in a compact and expressive way. This representation is also the key to solving it efficiently thanks to powerful and scalable mathematical libraries as described in Sect. on ▶ Scanning Polyhedra. This model, with slight variations, has been used in most successful work on parallel code generation.

Two mathematical objects need to be defined for the parallel code generation problem. First, *iteration domains* provide the relevant information for code generation from the input code, they are detailed in Sect. on Representing Statement Instances: Iteration Domains. Second, *space-time mapping functions* provide the ordering and placement information to be implemented by the target code. They are described in Sect. on Representing Order and Placement: Mapping Functions.

Representing Statement Instances: Iteration Domains

The key aspect of the polyhedral model is to consider *statement instances*. A statement instance is *one* particular execution of a statement. Each instance of a statement that is enclosed inside a loop can be associated with the value of the outer loop counters (also called *iterators*). For instance, let us consider the polynomial multiply code in Fig. 1: the instance of statement S1 for $i = 2$ is $z[2] = 0$.

In the polyhedral model, statements are considered as functions of the outer loop counters that may produce statement instances: instead of simply “S1,” the notation $S1(i)$ is preferred. For instance, statement S1 for $i = 2$ is written $S1(2)$ and statement S2 for $i = 4$ and $j = 2$ is written $S1(4)_2$. The vector of the iterator values is called the *iteration vector*.

Obviously, dealing with statement instances does not mean that unrolling all loops is necessary. First because there would probably be too many instances to deal with, and second because the number of instances may not be known. For example, when the loops are bounded with constants that are unknown at compile time (called “parameters”), for instance, n in the example code in Fig. 1. A compact way to represent all the instances of a given statement is to consider the set of all possible values of its iteration vector. This set is called the statement’s *iteration domain*. It can be conveniently described by all the constraints on the various iterators that the statement depends on. When those constraints

```
do i = 1, n
  z[i] = 0
  do i = 1, n
    do j = 1, n
      z[i+j] = z[i+j] + x[i] * y[j] ! s2
    ! s1
```

a	b	c
Original code	Scheduling	Target code

Code Generation. Fig. 2 One-Dimensional scheduling example

are affine and depend only on the outer loop counters and some parameters, the set of constraints defines a *polyhedron* (more precisely this is a \mathbb{Z} -*polyhedron*, but *polyhedron* is used for short). Hence the name “polyhedral model.” A matrix representation with the following general form for any statement S is used to facilitate the manipulation of the affine constraints:

$$\mathcal{D}_S = \{\mathbf{x}_S \in \mathbb{Z}^{n_S} \mid A_S \mathbf{x}_S + \mathbf{a}_S \geq \mathbf{0}\}$$

where \mathbf{x}_S is the n_S -dimensional iteration vector, A_S is a constant matrix and \mathbf{a}_S is a constant vector, possibly parametric. For instance, here are the iteration domains for the polynomial multiply example in Fig. 1:

- $\mathcal{D}_{S1} = \left\{ \begin{pmatrix} i \end{pmatrix} \in \mathbb{Z} \mid \begin{bmatrix} 1 \\ -1 \end{bmatrix} \begin{pmatrix} i \end{pmatrix} + \begin{pmatrix} -1 \\ n \end{pmatrix} \geq \mathbf{0} \right\}$
- $\mathcal{D}_{S2} = \left\{ \begin{pmatrix} i \\ j \end{pmatrix} \in \mathbb{Z}^2 \mid \begin{bmatrix} 1 & 0 \\ -1 & 0 \\ 0 & 1 \\ 0 & -1 \end{bmatrix} \begin{pmatrix} i \\ j \end{pmatrix} + \begin{pmatrix} -1 \\ n \\ -1 \\ n \end{pmatrix} \geq \mathbf{0} \right\}$

Representing Order and Placement: Mapping Functions

Iteration domains do not provide any information about the order in which statement instances have to be executed, nor do they inform about the processor that has to execute them. Such information is provided by other mathematical objects called *space-time mapping functions*. They associate each statement instance with a logical date *when* it has to be executed and a processor coordinate *where* it has to be executed. In the literature, the part of those functions dedicated to time is called *scheduling* while the part dedicated to space is called *placement* (or *allocation*, or *distribution*).

In the case of *scheduling*, the logical dates express at which time a statement instance has to be executed, with respect to the other statement instances. It is typically denoted θ_S for a given statement S . For instance, let us consider the three statements in Fig. 2a and their scheduling functions in Fig. 2b. The first and third statements have to be executed both at logical date 1. This means they can be executed in parallel at date 1 but they have to be executed before the second statement since its logical date is 2. The target code implementing this scheduling using OpenMP pragmas is shown in Fig. 2c, where a fictitious variable t stands for the time. It can be seen that at time $t = 1$, both $S1$ and $S3$ are run in parallel, while $S2$ is executed afterward at time $t = 2$.

Logical dates may be multidimensional, like clocks: the first dimension corresponds to days (most significant), next one is hours (less significant), the third to minutes, and so on. The order of multidimensional dates with a decreasing significance for each dimension is called the *lexicographic* order. Again, it is not possible to assign one logical date to each statement instance for two reasons: this would probably lead to an intractable number of logical dates and the number of instances may not be known at compile time. Hence, a more compact representation called the *scheduling function* is used. A scheduling function associates a logical date with each statement instance of a statement. They have the following form for a statement S :

$$\theta_S(\mathbf{x}_S) = T_S \mathbf{x}_S + \mathbf{t}_S,$$

where \mathbf{x}_S is the iteration vector, T_S is a constant matrix, and \mathbf{t}_S is a constant vector, possibly parametric. Scheduling functions can easily encode a wide range of usual transformations such as skewing, interchange,

reversal, shifting tiling, etc. Many program transformation frameworks have been proposed on top of such functions, the first significant one being UTF (Unified Transformation Framework) by Kelly and Pugh in 1993 [8].

Placement is similar to scheduling, only the semantics is different: instead of logical dates, a placement function π_S associates each instance of statement S with a processor coordinate corresponding to the processor that has to execute the instance.

A space-time mapping function σ_S is a multidimensional function embedding both space and time information for statement S : some dimensions are devoted to scheduling while some others are dedicated to placement. For instance, a compiler may suggest the following space-time mapping for the polynomial multiply code shown in Sect. on Representing Statement Instances: Iteration Domains. Its first dimension is a placement that corresponds to a wavefront parallelism for S_2 and improves locality by executing the initialization of an array element by S_1 on the same processor where it is used by S_2 . The second dimension is a very simple constant scheduling that ensures the initialization of the array element is done before its use (it is usual to add the identity schedule at the last dimensions; however this will not be necessary for the continuation of this example):

$$\begin{aligned} \bullet \quad \sigma_{S1} \left(\begin{array}{c} i \\ j \end{array} \right) &= \left[\begin{array}{c} 1 \\ 0 \end{array} \right] \left(\begin{array}{c} i \\ j \end{array} \right) + \left(\begin{array}{c} 0 \\ 0 \end{array} \right) \\ \bullet \quad \sigma_{S2} \left(\begin{array}{c} i \\ j \end{array} \right) &= \left[\begin{array}{cc} 1 & 1 \\ 0 & 0 \end{array} \right] \left(\begin{array}{c} i \\ j \end{array} \right) + \left(\begin{array}{c} 0 \\ 1 \end{array} \right) \end{aligned}$$

While working in the polyhedral representation, the semantics of each dimension is not relevant: After code generation, each dimension will be translated to some loops that can be post-processed to become parallel or sequential according to their semantics (obviously semantics information can be used to generate a better code, but this is out of the scope of this introduction).

Putting Everything Together

Iteration domains can be extracted directly by analyzing the input code. They represent for each statement the set of their instances. In particular, they do not encode

any ordering information: Iteration domains are nothing but “bags” of unordered statement instances. On the opposite, the space/time mapping functions, typically computed by an optimizing or parallelizing algorithm, provide the ordering information for each statement instance. It is necessary to collect all this information into a polyhedral representation before the actual code generation. There exist two ways to achieve this task. Let us consider an iteration domain defined by the system of affine constraints $Ax + a \geq \mathbf{0}$ and the transformation function leading to a target index $y = Tx$. Any of the following formulas can be chosen to build the target polyhedron \mathcal{T} that embeds both instance and ordering information:

Inverse Transformation By noticing that $x = T^{-1}y$ it follows that the transformed polyhedron in the new coordinate system can be defined by:

$$\mathcal{T} : \{y \mid [AT^{-1}]y + a \geq \mathbf{0}\}.$$

Generalized Change of Basis Alternatively, new dimensions corresponding to the ordering in leading positions can be introduced (note that in the following formula, constraints “above” the line are equalities while constraints “under” the line are inequalities):

$$\mathcal{T} : \left\{ \left(\begin{array}{c} y \\ x \end{array} \right) \mid \left[\begin{array}{c|c} I & -T \\ 0 & A \end{array} \right] \left(\begin{array}{c} y \\ x \end{array} \right) + \left(\begin{array}{c} -t \\ a \end{array} \right) \geq \mathbf{0} \right\}.$$

The inverse transformation solution has been introduced since the seminal work on parallel code generation by Ancourt and Irigoin [1]. It is simple and compact but has several issues: the transformation matrix must be invertible, and even when it is invertible, the target polyhedra may embed some integer points that have no corresponding elements in the iteration domain (this happens when the transformation matrix is not unimodular, i.e., whose determinant is neither +1 nor -1). This necessitates specific code generation processing, briefly discussed in Sect. on Fourier–Motzkin Elimination-Based Scanning Method. The second formula is attributed to Le Verge, who named it the *Generalized Change of Basis* [11]. It does not require any property on the transformation matrix. Nevertheless, the additional dimensions may increase the complexity of the code generation process. It has been rediscovered independently from Le Verge’s work and used in production code generators only recently [2].

Both formulas are used, and possibly mixed, in current code generation tools, depending on the desired transformation properties. For instance, to apply the space-time mapping of the polynomial multiply proposed in Sect. on Representing Order and Placement: Mapping Functions, it is convenient to use the Generalized Change of Basis because the transformation matrices are not invertible:

$$\bullet \quad T_{S1} = \left\{ \begin{pmatrix} p \\ t \\ i \end{pmatrix} \in \mathbb{Z}^2 \mid \left[\begin{array}{c|cc} 1 & 0 & -1 \\ 0 & 1 & 0 \\ \hline 0 & 0 & 1 \\ 0 & 0 & -1 \end{array} \right] \begin{pmatrix} p \\ t \\ i \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ -1 \\ n \end{pmatrix} \geq \mathbf{0} \right\}$$

$$\bullet \quad T_{S2} = \left\{ \begin{pmatrix} p \\ t \\ i \\ j \end{pmatrix} \in \mathbb{Z}^3 \mid \left[\begin{array}{c|cc} 1 & 0 & -1 & -1 \\ 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 1 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & -1 \end{array} \right] \begin{pmatrix} p \\ t \\ i \\ j \end{pmatrix} + \begin{pmatrix} 0 \\ -1 \\ -1 \\ n \\ -1 \\ n \end{pmatrix} \geq \mathbf{0} \right\}$$

In the target polyhedra, whatever the chosen formula, the order of the dimensions is meaningful: The ordering is encoded as the lexicographic order of the integer points. Thus, the parallel code generation problem is reduced to generating a code that enumerates the integer points of several polyhedra, with respect to the lexicographic ordering.

Scanning Polyhedra

Once the target code information has been encoded into some polyhedra that embed the iteration spaces as well as the scheduling and placement constraints, the code generation problem translates to a *Polyhedra scanning* problem. The problem here is to find a code (preferably efficient) visiting each integral point of each polyhedra, once and only once, with respect to the lexicographic order. Three main methods have been successful in doing this. Fourier–Motzkin elimination-based techniques have been the very first, introduced by the seminal work of Ancourt and Irigoin [1]. They are discussed briefly in Sect. on Fourier–Motzkin Elimination-Based Scanning Method. While Fourier–Motzkin-based techniques aim at generating loop nests, an alternative method based on Parametric Integer Programming has been suggested by Boulet and Feautrier to generate lower-level codes [3]. This method is discussed briefly in

Sect. on Parametric Integer Programming-Based Scanning Method. Lastly, Quilleré, Rajopadhye, and Wilde showed how to take advantage of high-level polyhedral operations to generate efficient codes directly [14]. As this later technique is now widely adopted in production environments, it is discussed in some depth in Sect. on QRW-Based Scanning Method.

Fourier–Motzkin Elimination-Based Scanning Method

Ancourt and Irigoin [1] proposed in 1991 the first solution to the polyhedron scanning problem. Their work is based on the Fourier–Motzkin pair-wise elimination technique [15]. The scope of their method was quite restrictive since it could be applied to only one polyhedron, with unimodular transformation matrices. The basic idea was, for each dimension from the first one (outermost) to the last one (innermost), to project the polyhedron onto the axis and to deduce the corresponding loop bounds. For a given dimension i_k , the Fourier–Motzkin algorithm can establish that $L(i_1, \dots, i_{k-1}) + \mathbf{l} \leq c_k i_k$ and $c_k i_k \leq U(i_1, \dots, i_{k-1}) + \mathbf{u}$, where L and U are constant matrices, \mathbf{l} and \mathbf{u} are constant vectors of size m_l and m_u respectively, and c_k is a constant. Thus, the corresponding scanning code for the dimension i_k can be derived:

```

...
do  $i_k = \text{MAX}_{j=1}^{m_l} [(L_j(i_1, \dots, i_{k-1}) + l_j)/c_k],$ 
     $i_k \leq \text{MIN}_{j=1}^{m_u} [(U_j(i_1, \dots, i_{k-1}) + u_j)/c_k]$ 
...
Body
```

The main drawback of this method is the large amount of redundant control since eliminating a variable with the Fourier–Motzkin algorithm may generate up to $n^2/4$ constraints for the loop bounds where n is the initial number of constraints. Many of those constraints are redundant and it is necessary to remove them for efficiency.

Most further works tried to extend this first technique in order to reduce the redundant control and to deal with more general transformations. Le Fur presented a new redundant constraint elimination policy by using the simplex method [10]. Li and Pingali [13] as well as several other authors proposed to relax the unimodularity constraint of the transformation to an invertibility constraint by using the Hermite Normal

Form [15] to avoid scanning “holes” in the polyhedron. Griebl, Lengauer and Wetzel [5] relaxed the constraints of code generation further to transformation matrices with non-full rank, and also presented preliminary techniques for scanning several polyhedra using a single loop nest. Finally, Kelly, Pugh, and Rosser showed how to scan several polyhedra in the same code by generating a naive perfectly nested code and then (partly) eliminating redundant conditionals [9]. Their implementation relies on an extension of the Fourier–Motzkin technique called the Omega test. The implementation of their algorithm within the Omega calculator is one of the most popular parallel code generators [7].

Parametric Integer Programming-Based Scanning Method

Boulet and Feautrier proposed in 1998 a parallel code generation technique that relies on Parametric Integer Programming (PIP for short) to build a code for scanning polyhedra [3]. The PIP algorithm computes the lexicographic minimal integer point of a polyhedron. Because the minimum point may not be the same depending on the parameter values, it is returned as a tree of conditions on the parameters where each leaf is either the solution for the corresponding parameter constraints or \perp (called *bottom*), that is, no solution for those parameter constraints.

The basic idea of the Boulet and Feautrier algorithm (in the simplified case of scanning one polyhedron) is to find the first integer point of the polyhedron, called *first*, then to build a function *next* which for a given integer point returns the next integer point in the polyhedron according to the lexicographic ordering. Both *first* and *next* computations can be expressed as a problem of finding the lexicographic minimum in a polyhedron. Finally, the code can be built according to the following canvas, where x is an integer point of the polyhedron that represents the iteration domain:

```

 $x = \text{first}$ 
1 if  $x = \perp$  then goto 2
    Body
     $x = \text{next}$ 
    goto 1
2 ...

```

Generalizing this method to many polyhedra implies combining the different trees of conditions and subsequent additional control cost and code duplication. While this technique has no widely used implementation, it is quite different than the others since it does not aim at generating high-level loop statements. This property may be relevant for specific targets, for example, when the generated code is not the input of a compiler but of a high-level synthesis tool.

QRW-Based Scanning Method

Quilleré, Rajopadhye, and Wilde proposed in 2000 the first code generation algorithm that builds a target code without redundant control *directly* [14]. While previous schemes started from a generated code with some redundant control and then tried to improve it, their technique (referred as the QRW algorithm) never fails at removing control, and the processing is easier. Eventually it generates a better code more efficiently.

The QRW algorithm is a generalization to several polyhedra of the work of Le Verge, Van Dongen and Wilde on loop nest synthesis using polyhedral operations [12]. It relies on high-level polyhedral operations (polyhedral intersection, union, projection, etc.), which are available in various existing polyhedral libraries. The basic mechanism is, starting from (1) the list of polyhedra to scan and (2) a polyhedron encoding the constraints on the parameters called the *context*, to recursively generate each level of the abstract syntax tree of the scanning code (AST).

The algorithm is sketched in Fig. 3 and a simplified example is shown in Figs. 4–6. It corresponds to the generation of the code implementing the polynomial multiply space-time mapping introduced in Sect. on Representing Order and Placement: Mapping functions. Its input is the list of polyhedra to scan, the context and the first dimension to scan. This corresponds to Fig. 4 in our example, with the first dimension to scan being p . The first step of the algorithm intersects the polyhedra with the context to ensure no instance outside the context will be executed. Then it projects them onto the first dimension and separates the projections into disjoint polyhedra. For instance, for two polyhedra, this could correspond to one domain where the first polyhedron is “alone,” one domain where the second polyhedron is “alone” and one domain where the two polyhedra coexist. This is depicted in Fig. 5 for our example: it depicts the projection onto the p axis and the

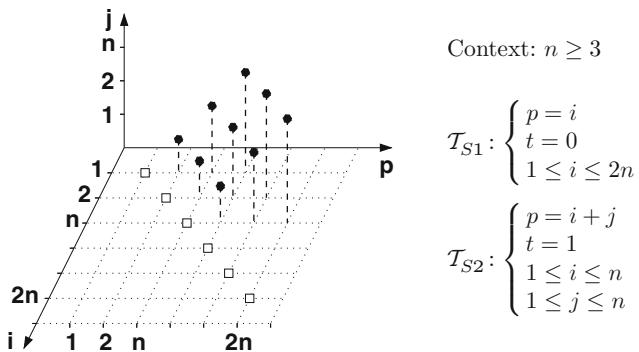

QRW: build a polyhedron scanning code AST without redundant control.

Input: a polyhedron list, a context C , the current dimension d .

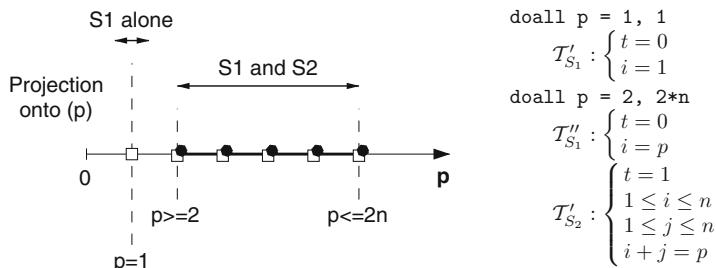

Output: the AST of the code scanning the input polyhedra.

1. Intersect each polyhedron in the list with the context C
2. Project the polyhedra onto the outermost d dimensions
3. Separate these projections into disjoint polyhedra (this generates loops for dimension d and new lists for dimension $d+1$)
4. Sort the loops to respect the lexicographic order
5. Recursively generate loop nests that scan each new list with dimension $d+1$, under the context of the dimension d
6. Return the AST for dimension d

Code Generation. Fig. 3 Sketch of the QRW Code Generation Algorithm

Code Generation. Fig. 4 QWR Code Generation Example (1/3): Polyhedra to Scan and Context Information. The graphical representation does not show the degenerated scheduling dimension t

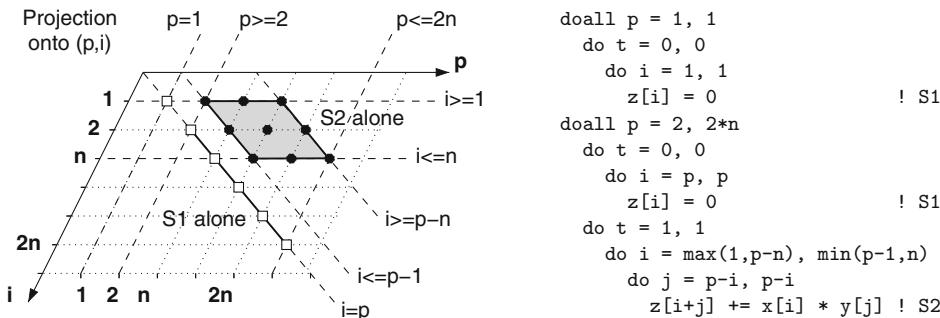

Code Generation. Fig. 5 QWR Code Generation Example (2/3): Intersection with the Context, Projection, and Separation onto the First Dimension. Two disjoint polyhedra are created: one where S_1 is alone on p (it has only one integer point but a loop is generated to scan it, for consistency) and one where S_1 and S_2 are together on p . In the right side, the new polyhedra to scan have been intersected with the context (for the next step, p is a parameter as well as n)

separation (it can be seen here that the domain where S_2 is “alone” is empty). The constraints on dimension p for the resulting polyhedra give directly the loop bounds.

As the semantics of the placement dimension is to distribute instances across different processors, this loop is parallel. Then the algorithm recursively generates

the next dimension loops for each disjoint polyhedron separately. The final result is shown in Fig. 6 for our example.

The QRW algorithm is simple and efficient in practice, despite the high theoretical complexity of most polyhedral operations. However, in its basic form, it

Code Generation. Fig. 6 QWR Code Generation Example (3/3): Recursion on the Next Dimensions. First, the projection/separation on (p, t) is done. It is trivial because t is a constant in every polyhedron: it only enforces disjunction and ordering of the polyhedra inside the second `doall` loop. Next the same processing is applied for (p, t, i) : the loop bounds of the remaining dimensions can be deduced from the graphical representation (the trivial dimension t is not shown)

tends to generate codes with costly modulo operations, and the separation process is likely to result in very long codes. Several extensions to this algorithm have been proposed to overcome those issues [2, 16]. CLooG, a popular implementation of the extended QRW technique demonstrated effectiveness of the algorithm [2]. It is now used in production environments such as in GCC or IBM XL.

Parallel Code Generation Today

For a long time, scheduling and placement techniques were many steps forward code generation capabilities. In 1992, Feautrier provided a general scheduling technique for multiple polyhedra and general affine functions [4]. At this time, the only code generation algorithm available had been designed in 1991 by Ancourt and Irigoin and supported only one polyhedron and unimodular scheduling functions [1]. Some scheduling functions had to wait for nearly one decade to be successfully applied by a code generator.

Since then, the challenge of feasibility has been tackled: State-of-the-art parallel code generators can handle any affine transformation for many iteration domains. Moreover, the scalability of code generators is good enough to enable parallel code generation as an option in production compilers. However, the quality of the generated code is still not guaranteed. Summarily, code generators are very good for simple (unimodular) transformations, reasonably good when the coefficients of the transformation functions are small and unpredictable in the general case. The flexibility challenge

is also solved only partly because only regular codes that fit the polyhedral model can be processed and only affine transformations can be applied.

Future Directions

Two challenges of parallel code generation are partly solved: quality and flexibility. To achieve the best results, autoparallelizers have to take into account some constraints related to code generation that may conflict with the extraction of parallelism, for example, limiting the absolute value of the transformation coefficients or relying on unimodular transformations. However, there exists an infinity of transformations that implement the same mapping but have different properties with respect to code generation. Finding “code generation friendly” equivalent transformations is a promising solution to enhance the generated code quality.

Several directions are under investigation to provide parallel code generation with more flexibility. Irregular extensions have been successfully implemented to some polyhedral code generators and ambitious techniques based on polynomials instead of affine expressions may be the next step for parallel code generation [6].

Bibliographic Notes and Further Reading

We detailed in Sect. on ►[Scanning Polyhedra](#) the three main techniques designed for parallel code generation. The reader will find a deeper level of details in the related papers. Kelly, Pugh, and Rosser's paper on code generation for multiple mappings provides the extensive description of the techniques behind the Omega Code Generator [9]. Boulet and Feautrier's paper on code generation without do-loops gives thorough depiction of the PIP-based code generation technique [3]. Finally, the details of the most powerful code generation technique known so far are provided in Quilleré, Rajopadhye, and Wilde's paper on generation of efficient nested loops from polyhedra [14]. This reading is complemented by Bastoul's paper, which details several extensions to their algorithm and demonstrates robustness of the extended technique for production compilers [2].

Collective Communication

ROBERT VAN DE GEIJN¹, JESPER LARSSON TRÄFF²

²University of Vienna, Vienna, Austria

Synonyms

[Group communication](#); [Inter-process communication](#)

Definition

Collective communication is communication that involves a group of processing elements (termed *nodes* in this entry) and effects a data transfer between all or some of these processing elements. Data transfer may include the application of a reduction operator or other transformation of the data. Collective communication functionality is often exposed through library interfaces or language constructs. Collective communication is a natural extension of the message-passing paradigm.

Discussion

Introduction

Many commonly encountered communication patterns and computational operations involving data distributed across sets of processing elements (nodes) can be represented as *collective communication* in which all nodes in a (sub)set of nodes collaborate to carry out a specific data redistribution or data reduction operation. Making such operations available in parallel programming languages, interfaces, or libraries has a number of advantages:

- It simplifies parallel and distributed programming, relieving the user from explicitly expressing complex communication patterns by means of more primitive communication operations.
- It raises the level of abstraction at which algorithms can be expressed and abstracts away details of the underlying parallel communication system.
- It makes it easier to reason about algorithm correctness and communication cost.
- It improves the functional portability of applications and contributes toward performance portability.
- It makes it possible to schedule complex communication patterns to efficiently exploit capabilities and specific properties of the underlying communication system.
- It introduces a productive separation of concerns between the application and interface developers.

Collective communication operations are found in some form in most parallel programming interfaces and languages, notably in the *Message-Passing Interface* (MPI) [14], in Partitioned Global Address Space (PGAS) languages like UPC [5], in libraries for *Bulk Synchronous Processing* (BSP) [2, 11] and many others, but also in application-specific and special purpose libraries. By capturing patterns of communication and computation, collective communication is relevant not only for distributed memory parallel systems, but also for systems with shared memory between all or subsets of nodes. Collective communication indeed serves to abstract away such system characteristics, and can serve as a higher-level bridging model for ensuring (performance) portability of applications across systems with different communication capabilities. Research on efficient algorithms for collective communication under

various computation and communication models and on practical implementations has been intensive over the past decades, and many good algorithms have found their way into common practice.

Many algorithms and applications are naturally and effectively expressed in a coarse-grained style as a sequence of local computations and collective communication operations. It has been argued that collective communication is more fundamental than explicit point-to-point or one-sided communication for expressing parallel computations [7]. Collective communication is a natural generalization of message-passing point-to-point communication that explicitly involves two nodes, and one-sided communication that explicitly involves only one node.

A Motivating Example

Consider a matrix-vector multiplication $y = Ax$, where A is an $n \times n$ matrix and x and y are column vectors to be solved in parallel. Let the p compute nodes be indexed from 0 to $p - 1$, assume for simplicity that p divides n , and that the input is evenly distributed among the nodes as described below.

Algorithm 1

Partition A , x , and y :

$$A \rightarrow \begin{pmatrix} A_0 \\ A_1 \\ \vdots \\ A_{p-1} \end{pmatrix}, \quad x \rightarrow \begin{pmatrix} x_0 \\ x_1 \\ \vdots \\ x_{p-1} \end{pmatrix},$$

$$\text{and } y \rightarrow \begin{pmatrix} y_0 \\ y_1 \\ \vdots \\ y_{p-1} \end{pmatrix},$$

where A_k has n/p rows, and x_k and y_k are of size n/p . Assume that initially A_k , x_k , and y_k are assigned only to node k , $k = 0, \dots, p - 1$.

1. Collect all x_k 's on all nodes (allgather) so that the entire x is available on all nodes.

2. In parallel compute $y_k = A_k x$ locally on each node k , $k = 0, \dots, p - 1$.

Step 1 is an example of the collective communication operation commonly referred to as allgather. Each node contributes a subvector and after the operation all nodes have collected the full vector. Locally, each node performs $O(n/p \times n)$ arithmetic operations, and under reasonable communication assumptions $O(n)$ time is required for the allgather step (see entry on ► [Allgather](#)). The local memory consumption is $O(n^2/p + n)$.

Algorithm 2

Partition A , x , and y :

$$A \rightarrow \begin{pmatrix} A_0 & A_1 & \dots & A_{p-1} \end{pmatrix}, \quad x \rightarrow \begin{pmatrix} x_0 \\ x_1 \\ \vdots \\ x_{p-1} \end{pmatrix},$$

and $y \rightarrow \begin{pmatrix} y_0 \\ y_1 \\ \vdots \\ y_{p-1} \end{pmatrix}$,

where A_k has n/p columns, and x_k and y_k are of size n/p , and assume that initially A_k , x_k , and y_k are assigned only to node k , $k = 0, \dots, p - 1$.

1. In parallel, compute the n element vector $y^{(k)}$ on each node $k = 0, \dots, p - 1$ by $y^{(k)} = A_k x_k$.
2. Compute the vector $y = y^{(0)} + y^{(1)} + \dots + y^{(p-1)}$ and store the final subvector y_k on node k , $k = 0, \dots, p - 1$.

The operation in Step 2 is an example of a collective reduction operation known as reduce-scatter. This operation computes a global result by element-wise summing n element vector contributions from all participating nodes, leaving parts of the result scattered elements over the nodes. Locally, each node performs $O(n \times n/p)$ arithmetic operations, and under reasonable communication assumptions, the reduce-scatter step can be done in $O(n)$ time (see entry on ► [Reduce and scan](#)).

Unless the matrix A has additional structure that can be exploited both in the local computations and in the collective communication, neither Algorithm 1 nor 2 is scalable beyond $p \geq n$ compute nodes. Sequential matrix-vector multiplication takes $O(n^2)$ operations, and parallel efficiency cannot be maintained with increasing p beyond n if n is kept constant. The algorithms illustrate the use of collective operations. Exploiting both ideas and using instead a two-dimensional partitioning of the matrix lead to a scalable algorithm which naturally relies on collective communication, as discussed later in this entry.

Classification of Collective Operations

The basic collective communication operations that will be described next can be divided into either *redistribution* (pure data transfer) or *reduction* operations that also entail a computation on the transferred data. They can further be classified along the following lines.

Rooted/non-rooted: In *rooted* (or *asymmetric*) operations, a specified node (the *root*) is either the sole origin of data to be redistributed or the sole destination of data or results contributed by the nodes involved in the communication. In *non-rooted* (or *symmetric*) operations all nodes contribute and receive data.

For rooted collectives, it is typically assumed that all nodes know the identity of the root node.

Regular/irregular: A collective operation is *regular* if the amount of data contributed or received by each involved node is the same, whereas for *irregular* collective operations, different nodes can contribute and/or receive different amounts of data.

For regular collectives, it is typically assumed that all processes know the amount of data to be redistributed; irregular operations may not make this assumption, and each node may know only the amount of data it has to contribute or receive in the operation.

Homogeneous/nonhomogeneous data: The data involved may either be *homogeneous* as in simple arrays of elements of the same datatype, or *nonhomogeneous* and consist of elements of different types, possibly stored in a nonconsecutive layout.

Synchronizing/non-synchronizing: A collective operation is *synchronizing* if a node starting the collective operation cannot continue its operation before all other nodes have commenced and reached a certain point in the operation. In contrast, in *non-synchronizing* operations, each node may be allowed to continue as soon as data from/to that node required for the operation have been sent and received.

Blocking/nonblocking: *Blocking* collective operations keep each node engaged until it has completed its involvement in the operation. Collectives may also be *nonblocking*, meaning that initiation and completion of the operation are separated. As soon as a node has initiated a nonblocking operation it may perform other tasks, with collective communication logically taking place in the background. Collective communication with nonblocking semantics might be able to leverage this for overlapping communication with other useful (application level) computation.

The rooted/non-rooted dichotomy can alternatively be captured by the trichotomy all-to-all/all-to-one/one-to-all. Not all commonly found collective communication operations follow these taxonomies. Collective reduction operations can additionally be classified according to the types of operations and transformations that are allowed on the data. Finally, the power of programming interfaces with explicit collective communication is characterized not only by the types and set of collective operations included, but also on the

capability to perform collective communication on subsets of nodes.

Commonly Used Collective Communications

The semantics (before-after) of some commonly identified collective communication operations in scientific computing are explained in the following and depicted in Figs. 1–3. Here, x , $x^{(j)}$, and y are vectors of data, and x_k , $x_k^{(j)}$, and y_k are subvectors of x , $x^{(j)}$, and y , respectively. Input vector $x^{(j)}$ is assumed to be owned by node j which means that this vector is stored in some form in the local memory of node j .

Data Redistribution Operations

The first set of collective communications redistribute or duplicate data from one or more nodes to one or more nodes.

Broadcast: One node (the *root*) owns a vector of data, x , that is to be copied to all other nodes. After the operations, all nodes have a copy of that data.

Scatter: One node (the *root*) owns a vector of data, x , that is partitioned into subvectors, x_0, \dots, x_{p-1} . Upon completion, node k owns x_k , $k = 0, \dots, p - 1$.

Gather: The inverse of the scatter operation, the subvectors x_k are gathered into the complete vector x at the *root*.

Allgather: The allgather operation is like the gather operation, except that all nodes receive all of the data. The operation is also known as all-to-all broadcast, concatenation, and gossiping, and is equivalent

Operation	Before			After		
	Node 0	Node 1	Node 2	Node 0	Node 1	Node 2
Broadcast	x			x	x	x
Scatter	Node 0 x_0 x_1 x_2	Node 1	Node 2	Node 0 x_0	Node 1 x_1	Node 2 x_2
Gather	Node 0 x_0	Node 1 x_1	Node 2 x_2	Node 0 x_0 x_1 x_2	Node 1	Node 2

Collective Communication. Fig. 1 Rooted redistribution operations. For illustration node 0 is chosen as root

Operation	Before			After		
	Node 0	Node 1	Node 2	Node 0	Node 1	Node 2
Allgather	x_0	x_1	x_2	x_0	x_0	x_0
All-to-all	$x_0^{(0)}$ $x_1^{(0)}$ $x_2^{(0)}$	$x_0^{(1)}$ $x_1^{(1)}$ $x_2^{(1)}$	$x_0^{(2)}$ $x_1^{(2)}$ $x_2^{(2)}$	$x_0^{(0)}$ $x_0^{(1)}$ $x_0^{(2)}$	$x_1^{(0)}$ $x_1^{(1)}$ $x_1^{(2)}$	$x_2^{(0)}$ $x_2^{(1)}$ $x_2^{(2)}$
Permutation	$x^{(0)}$	$x^{(1)}$	$x^{(2)}$	$x^{(\pi^{-1}(0))}$	$x^{(\pi^{-1}(1))}$	$x^{(\pi^{-1}(2))}$

Collective Communication. Fig. 2 Non-rooted redistribution operations. For the permutation collective, π is a permutation of $\{0, \dots, p - 1\}$ mapping node i to node $\pi(i)$

Operation	Before			After		
	Node 0	Node 1	Node 2	Node 0	Node 1	Node 2
Reduce	$x^{(0)}$	$x^{(1)}$	$x^{(2)}$	$y = \bigoplus_{j=0}^{p-1} x^{(j)}$		
Reduce-scatter	$x_0^{(0)}$ $x_1^{(0)}$ $x_2^{(0)}$	$x_0^{(1)}$ $x_1^{(1)}$ $x_2^{(1)}$	$x_0^{(2)}$ $x_1^{(2)}$ $x_2^{(2)}$	$y_0 = \bigoplus_{j=0}^{p-1} x_0^{(j)}$	$y_1 = \bigoplus_{j=0}^{p-1} x_1^{(j)}$	$y_2 = \bigoplus_{j=0}^{p-1} x_2^{(j)}$
Allreduce	$x^{(0)}$	$x^{(1)}$	$x^{(2)}$	$y = \bigoplus_{j=0}^{p-1} x^{(j)}$	$y = \bigoplus_{j=0}^{p-1} x^{(j)}$	$y = \bigoplus_{j=0}^{p-1} x^{(j)}$
Prefix	$x^{(0)}$	$x^{(1)}$	$x^{(2)}$	$y^{(0)} = \bigoplus_{j=0}^0 x^{(j)}$	$y^{(1)} = \bigoplus_{j=0}^1 x^{(j)}$	$y^{(2)} = \bigoplus_{j=0}^2 x^{(j)}$

Collective Communication. Fig. 3 Rooted and non-rooted reduction operations. For illustration of the reduce collective, node 0 is chosen as root. Only the inclusive all prefix sums operation is depicted

to a gather to some root followed by a broadcast from that root, or to p (simultaneous) gather operations with roots $i = 0, \dots, p - 1$, each gathering the same vector x .

All-to-all: Each node $i, i = 0, \dots, p - 1$ sends subvector $x_k^{(i)}$ to node k for all $k = 0, \dots, p - 1$. It is sometimes emphasized that in contrast to the allgather operation, this is a *personalized* all-to-all *exchange* in that each node contributes a different subvector to each other node. The all-to-all operation is equivalent to p (simultaneous) scatter operations with roots $i = 0, \dots, p - 1$, or p (simultaneous) gather operations each scattering or gathering a different vector $x^{(i)}$. The operation is also sometimes referred to as a *transpose* (of the matrix of subvectors $x_i^{(j)}$).

Permutation: For a given permutation π of the set $\{0, \dots, p - 1\}$ each node $i, i = 0, \dots, p - 1$ sends vector x_i to node $\pi(i)$. After the operation, node $\pi(i)$ owns vector $x^{(\pi^{-1}(i))}$.

The input subvectors x_i and $x_i^{(j)}$ are not necessarily required to have the same number of elements. *Regular* redistribution operations would require subvectors to have the same size, whereas *irregular* collectives would not make this requirement.

Reduction Operations

Nodes often compute partial results that have to be *reduced* (combined) to yield a final result. This is often abstracted as collective communication in the following

way. Let \oplus be an associative, binary operator on the set of elements of the input vectors $x^{(j)}$. The operator is extended to full vectors by element-wise application. More precisely, let $x^{(j)}$ for $j = 0, \dots, p-1$ be vectors of size n . Then

$$x^{(j)} \oplus x^{(k)} = \begin{pmatrix} x_0^{(j)} \oplus x_0^{(k)} \\ x_1^{(j)} \oplus x_1^{(k)} \\ \vdots \\ x_{n-1}^{(j)} \oplus x_{n-1}^{(k)} \end{pmatrix}$$

for any j and $k, j, k = 0, \dots, p-1$.

Collective reduction operations now compute $y = \oplus_{j=0}^k x^{(j)}$, either for the specific $k = p-1$ or for all $k = 0, \dots, p-1$. By the associativity of \oplus this is well defined (brackets can be omitted); it may or may not be assumed/required that the operator \oplus be commutative. The collective reduction operations further differ in how the elements of y are left distributed among the nodes.

Reduce: A designated *root* node receives the result y .

For emphasis, this collective operation is sometimes called *reduction-to-one*.

Allreduce: The result y is duplicated to all nodes.

Reduce-scatter: The result y is distributed among the nodes so that node k ends up with a subvector y_k of y .

All prefix sums: All *prefix sums* $y^{(k)} = \oplus_{j=0}^k x^{(j)}$ are computed and the k th prefix $y^{(k)}$ stored at node $k, k = 0, \dots, p-1$. This collective communication operation is often termed *scan*.

The requirement that \oplus must be associative enables parallelization of the operations, since partial results can be computed concurrently and later combined. Likewise, commutativity may make more efficient implementations possible. Because the prefix sum for node k includes the input vector of node k itself, the operation described is sometimes referred to as the *inclusive* all prefix sums operation. An *exclusive* prefix-sums operation would compute $y^{(k)} = \oplus_{j=0}^{k-1} x^{(j)}$ with some special provision for node 0. Note that the k th inclusive prefix sum can trivially be computed from the exclusive k th prefix sums, but not vice versa, unless an inverse operation is given for \oplus .

Alternatively, some of the reduction patterns above could be formulated as operations on row vectors instead. In this formulation, a single element y would be computed by $y = \oplus_{j=0}^{p-1} \oplus_{i=0}^{n_j-1} x_i^{(j)}$, where n_j is the size of the vector $x^{(j)}$ residing with node j .

Barrier Synchronization

Sometimes applications require nodes to synchronize in the sense that no node shall continue beyond a certain point in its execution, e.g., enter the next stage in a computation before all nodes have reached that stage. A (semantic) barrier to ensure this is typically classified as a collective communication operation, although no data transfer or computation is implied.

Barrier is often used for temporal side effects, achieving an actual synchronization between a (large) set of nodes as sometimes required for bench-marking purposes.

A Motivating Example (continued)

We again discuss $y = Ax$ but now view the p nodes as forming a $r \times c$ mesh.

Algorithm 3

1. Partition A , x , and y :

$$A \rightarrow \begin{pmatrix} A_{00} & A_{01} & \dots & A_{0,p-1} \\ A_{10} & A_{11} & \dots & A_{1,p-1} \\ \vdots & \vdots & \ddots & \vdots \\ A_{p-1,0} & A_{p-1,1} & \dots & A_{p-1,p-1} \end{pmatrix}, \quad x \rightarrow \begin{pmatrix} x_0 \\ x_1 \\ \vdots \\ x_{p-1} \end{pmatrix},$$

$$\text{and } y \rightarrow \begin{pmatrix} y_0 \\ y_1 \\ \vdots \\ y_{p-1} \end{pmatrix},$$

where A_{ij} has n/p rows and columns, and x_i and y_i are of size n/p .

2. Assume that initially A_{ij} , x_i , and y_i are assigned to nodes as illustrated in Fig. 4. Each node has $p/r \times p/c = p$ submatrices and one subvector of size n/p .
3. Allgather x_j 's within columns of nodes.

$y_8^{(0)}$	A_{80}	A_{81}	A_{82}	$y_8^{(1)}$	A_{83}	A_{84}	A_{85}	$y_8^{(2)}$	A_{86}	A_{87}	A_{88}
x_0	x_1	x_2		x_3	x_4	x_5		x_6	x_7	x_8	

Collective Communication. Fig. 5 After allgather of subvectors of x within columns and local matrix-vector multiplication

4. In parallel, compute the local part of each y_i on the appropriate node:

$$y_i^{(k)} = \sum_{\text{local } j} A_{ij}x_j$$

as illustrated in Fig. 5.

5. Reduce-scatter within rows of nodes to compute $y_i = \sum y_i^{(k)}$.

Since the extra local memory and time required for the gathered and reduced subvectors is only $O(cn/p)$ and $O(rn/p)$, respectively, this algorithm can be shown to be essentially scalable by keeping local memory use on each node constant and keeping the ratio of r and c constant. Notice that Algorithm 1 results by taking $c = 1$ and Algorithm 2 by taking $r = 1$.

The example illustrates that often collective communications must be performed within subsets (e.g., a row

or column of a mesh) of nodes. For parallel interfaces that do not support formation of subsets of nodes, the algorithm is difficult to express.

Interfaces

Message-Passing Interface (MPI)

A widely used parallel interface with an explicit, rich set of collective communication operations is the *Message-Passing Interface* (MPI) [14]. The MPI collectives are widely used in applications. MPI includes all collective communication operations of Figs. 1–3, except for permutation, as well as a barrier synchronization collective. Collective communication is effected by library calls, and for each operation, all nodes (in a set of nodes) eventually have to make the same call, also for the *rooted* operations for which an explicit root argument (that need to be given by all nodes involved

in the call) designates the root node. All collectives in MPI are *blocking* but *non-synchronizing*, except for `MPI_Barrier`, meaning that a node (*process* in MPI terminology) is allowed to continue as soon as it has contributed and received its required data. Collectives like `MPI_Allreduce` and `MPI_Allgather` are of course non-synchronizing only in the trivial case where all processes contribute data of size zero. The redistribution collectives, except for `MPI_Bcast`, come in both *regular* (e.g., `MPI_Allgather`) and *irregular* variants (e.g., `MPI_Allgatherv`), the latter termed *vector* variants and designated by the “v” suffix. For the regular collective operations, the size of the data is given at the call of the operation, such that nodes know the size of the data involved in the operations. For the irregular operations, each node only specifies the size of the data to be contributed and received by itself. This means that in irregular all-to-all communication, no node can from the outset know what communication will be entailed between other nodes, which makes it impossible to compute efficient communication schedules without additional communication. MPI incorporates general, powerful, and convenient mechanisms for collective communication with *nonhomogeneous* data, which again increases algorithmic and software complexity of MPI library implementations.

The MPI reduction operations correspond exactly to those listed in Fig. 3 and are all *regular*, except for `MPI_Reduce_scatter` which allows blocks (sub-vectors) of different sizes to be distributed across the nodes. A regular variant also exists. For the reduction operations, a set of standard, arithmetical and logical binary operators is predefined and it is furthermore possible for the application to introduce its own user-defined operators; these are required to be associative. MPI provides vague quality guarantees on the reductions, mostly relevant for reductions with floating point numbers, for instance, that the same result is computed on all nodes in an `MPI_Allreduce`, that the result is independent of the physical placement of the nodes in the system, or that all elements of result vectors are computed in the same order and so forth. Such requirements sometimes complicate the practical design and implementation of reduction collectives.

Finally, MPI has powerful mechanisms for forming named subsets of nodes (namely, process groups

and communicators), and collective communication can take place on any such subset of nodes.

Partitioned Global Address Space (PGAS) Languages

Partitioned Global Address Space (PGAS) languages strive to hide the details of communication from users to improve programmability and/or reduce overhead. PGAS languages and implementations nevertheless benefit from explicit collective communication, and such languages provide collective communication as either integral parts of the language as in X10 [17], or standard libraries as in Unified Parallel C (UPC) [5]. The standard UPC library provides the operations listed in Figs. 1 and 2, including a permutation collective (absent in MPI), in *regular* variants, and restricted to mostly *homogeneous* data. Placement of input and result vectors is mostly determined implicitly by the so-called affinity of the data elements. In particular the root node is the node to which the input (for `upc_all_broadcast`) or result (for `upc_all_gather`) has affinity. Blocking and synchronization properties can be flexibly controlled by a mode given with each collective call. Unlike MPI, the reduction operations `upc_all_reduce` and `upc_all_prefix_reduce` are operations on row vectors that produce a single result or prefix sum for each node. At the time of this writing UPC collectives are over the full set of nodes, i.e., UPC does not support the formation of node subsets over which collective communication can be performed.

Coarray Fortran 2.0 (CAF 2.0) addresses some of these issues and provides a full and very general set of collective operations that can be applied over arbitrary teams of nodes [12].

Bulk Synchronous Processing Libraries

Bulk synchronous or coarse-grained processing is a parallel algorithmic design approach that structures applications into phases of local computation on local data interleaved with phases of global exchange or routing. This approach naturally relies on collective communication as explicated by the exchange phases, but can additionally benefit from explicit collective communication for realizing special communication patterns. This is based on the observation that applications often entail specific communication patterns that are

both conveniently expressed as collective communication and much more efficiently implemented by specialized algorithms than by relying on the general routing communication of the next routing phase. Most practical realizations of the Bulk Synchronous Processing (BSP) model included explicit collective communication operations [2, 8, 11] as explained here, typically in a nonblocking form. Some BSP libraries [2] supported formation of subsets of nodes.

Numerical Libraries

Numerical libraries that explicitly have or expose collective communication operations include ScaLAPACK and PLAPACK. See the entries for these libraries.

Other Collective Interfaces and Frameworks

Other, more specialized collective communication operations than those described in this entry are sometimes included in higher-level interfaces and frameworks, or in application-specific libraries. For instance, libraries like PETSc and Trillinos have collective computation (reduction) operations, and I/O libraries like pnetCDF and HDF5 have collective data movement operations. As an example, algorithmic libraries may include merging and sorting primitives and parallel operations on data structures in their repertoire. The skeletal approach to parallel programming [15] expresses applications in terms of instances of higher-level generic patterns, many of which entail collective communication. Such approaches provide considerable expressive flexibility and often a very rich set of collective communication and computation patterns. A concrete example in this direction is the MapReduce framework [4].

Algorithms

Algorithmic and further details on some of the most important of the operations described above are given in related entries. Basic techniques for collective communication implementation are found under the Broadcast entry, which should be read first. The symmetric operations allgather and all-to-all are treated in separate entries, and discuss techniques not used by Broadcast. The Reduce to root operation can often be treated as the inverse of Broadcast (with additional operation). The fundamental all prefix sums collective

is treated more extensively in a separate entry, and completes the tour of basic techniques for the implementation of collective communication on distributed memory systems.

Bibliographic Notes and Further Reading

The benefits of encapsulating certain collective communication patterns as specific collective operations in languages, interfaces and libraries have been realized from the early days of parallel computing, especially in scientific computing [6]. For distributed memory systems explicit collective communication is a natural extension to the message-passing paradigm. Convergence between many different message-passing languages and libraries in the early 1990s led to definition of a common *Message-Passing Interface* [10], well noted for the important role given to collective communication. The advantages of and need for interfaces and libraries with fast and efficient collective communication to better exploit the underlying, concrete communication system was realized and argued in a number of papers, e.g., [1, 13]. The study of algorithms for efficient collective communication likewise dates back to the early days of distributed memory parallel computing [6, 16]. Another early approach to systematic collective communication algorithm design can be found in [9]. A comprehensive discussion of practical implementations for most of the collective communications discussed here can be found in [3]. There has been a huge amount of research and development work on efficient realization of these collectives for a large variety of (often extremely high-performance) systems. It is a major goal

for MPI implementers to provide well-performing collective communication for the intended target systems. In [18] semantic relationships between different collective operations were used to urge implementers to provide consistently well-performing collective operations in order to enhance performance portability of applications written in MPI.

Definition

Collective Communication involves more than one processor participating in one communication operation. Collective communication operations are: broadcast, barrier synchronization, reduction, gather, scatter, all-to-all complete exchange, and scan. Network support for collective communication provides architectural support for efficient and scalable collective operations with low processor overhead.

Discussion

Introduction

Collective communication operations aim at reducing both latency and network traffic with respect to the case where the same operations are implemented with a sequence of unicast messages. The significance of collective communication operations for scalable parallel systems has been emphasized by their inclusion in widely used parallel programming models, such as the Message Passing Interface (MPI) [27]. A large number of parallel applications depend on the performance benefits provided by collective operations. MPI libraries strive to provide the best possible performance for collective operations, since they are the key for good end

application performance. Consequently, a large number of algorithms and advanced network support for collective communication have been proposed. The commonly used collective communication operations are: broadcast, barrier synchronization, reduction, gather, scatter, all-to-all complete exchange, and scan.

Broadcast is a very common operation needed in a parallel system to distribute code and data from a host process to a set of processes before computation begins. This is especially useful for SPMD style programming. During the computational phase of distributed memory applications, this operation is used to distribute data among other processes. In the literature, it is also known as a *one-to-all* operation with non-personalized data movement. If multiple broadcasts happen at the same time from different processes, it is called as a *many-to-all* operation. If the data is distributed to only a subset of processes, the operation is called a *multicast*. In MPI, this operation is called MPI_Bcast.

Barrier synchronization is a common operation in parallel systems to synchronize execution of multiple processes. Primarily, it is used to support a producer-consumer relationship of shared data. Functionally, this operation involves *many-to-one* communication followed by a *one-to-many* communication operation. In MPI, this operation is called MPI_BARRIER.

Reduction operations are used widely in distributed memory systems and consist of computing a single value out of data sent by the different participating processes. Commonly used reduction operations are max, min, sum, or any user-defined operations. The MPI specification includes two forms of reduction MPI_Reduce and MPI_Allreduce. In MPI_Reduce, the result is available only on the root process, and in MPI_Allreduce, the result is available on all participating processes.

Gather operation is defined as gathering of data from a set of member processes by a member. This involves gathering personalized data (different data from different processes). In MPI, it is called MPI_Gather. *Scatter* is the reverse operation of Gather. MPI also provides MPI_Allgather that performs an all-to-all broadcast.

All-to-all complete exchange combines scatter and gather. In this operation, every member has some personalized data to send to every other group member. A sequence of interleaved gather and scatter steps

are used in this operation to achieve the desired data movement. This operation is used in distributed memory systems to *redistribute* data.

Scan operation involves reduction of data with ranks. Sometimes, this operation is also referred to as *parallel prefix* computation. Unlike regular reduction, this operation is carried out in such a way that a member of rank i only receives reduction results data associated with members of ranks 0 to i . This operation is used widely in image processing and visualization applications.

Architectural Support for Collective Communication

The importance of collective operations in parallel computing is underscored by the increasing network and architectural support for improving collective operation performance. There are three major types of network support for collective operations: (a) adapter support, (b) switch support, and (c) dedicated networks for collectives. The network support aims to improve latency and improve bandwidth. Another important performance metric for collective operations is tolerance to system noise. As the number of processes involved in a collective operation increases, short delays at individual processes start to accumulate over the various stages of the collective and adversely affect the overall time taken for the collective. This is called as *system noise*. Tolerance to noise means that the collective operations should be able to proceed regardless of other tasks running on the processor, a technique called *application-bypass*. These techniques can be enabled through intelligent network adapters, switches or by having dedicated collective communication networks. In addition to these, MPI libraries have advanced software support for bridging the gap between low-level architectural support and higher-level user collective operations.

Adapter-Based Support

Compute nodes are attached to the network via network adapters. Adapters are the closest to the end processors, and therefore can be used to perform a wide variety of network offload mechanisms. Intelligent adapters with processors can be used to perform complex operations on incoming network data. They can also be used to offload a series of operations that the adapter

then continues to perform, thus freeing up the host processor to return to computation. The following are some of the adapter-based network support that have been employed by leading high-performance network vendors over the past few decades.

Myrinet

Myrinet is a high-performance full-duplex network which uses NICs with programmable processors. Myrinet provides a user-level message passing system (GM) which uses the programmable NICs for much of the protocol processing. GM consists of three components: a kernel module, a user-level library, and a control program (MCP) which runs on the NIC processor. The driver loads the MCP on to the NIC when it is loaded. It is possible to modify the MCP and cross-compile for the network processor. Researchers have modified the control program to support advanced collective operations. The modified MCP can be accessed through new interfaces by the MPI library. Finally, collective operations of the end application can be offloaded to the NIC. In effect, the MCP (through multiple finite state machines) will tell the NIC the times at which it should initiate the various send and receive operations which form the basis of the collective operation. Myrinet also provides useful primitives such as *multi-send* which allows the user to offload a series of send operations to the NIC. Such primitives are extremely useful to design collective algorithms such as *barrier* and *broadcast*. In tree-based collective algorithms, although operations like *multi-send* reduce the overhead of the broadcast operations at the root processes, the intermediate nodes would still require involvement from the host processor to progress the collective operation. Researchers have devised *application-bypass* techniques through a modified MCP that enable intermediate network adapters in the collective tree to forward messages from the NIC itself, thereby mitigating effects of system noise.

Quadrics

The Quadrics interconnect had very advanced network adapter support. The Quadrics network access library is called *Elan*. Elan exposes a protected, programmable network interface to end users through vendor-provided programming libraries (QSNet). These libraries are built in a layered fashion with higher-level

programming libraries (*Elanlib*) built on top of lower level point-to-point communication primitives. Elanlib provides two barrier functions, *elan_gsync()* and *elan_hgsync()*. The latter takes advantage of the hardware broadcast primitive and provides a very efficient and scalable barrier operation. However, it requires that the calling processes are well synchronized in their stages of computation. Otherwise, it falls back on the *elan_gsync()* to complete the barrier with a tree-based gather-broadcast algorithm.

InfiniBand RDMA Enabled Collectives

Remote Direct Memory Access (RDMA) is a technique using which a process can directly access the memory locations of some other process, without participation of the remote process. InfiniBand is one of the networks that provides high-performance RDMA. Using the RDMA primitives, efficient collective operations can be designed. The main benefits of RDMA collectives over regular point-to-point collectives are: (a) communication calls can bypass several intermediate software layers, (b) reduce number of message copies to and from bounce buffers (bounce buffers can be directly accessed by InfiniBand), (c) reduce protocol handshakes, such as *rendezvous* for large MPI messages, and (d) reduce the total number of registration operations, i.e., perform one larger memory registration, instead of several smaller ones.

These mechanisms can further be enhanced for shared memory processor (SMP)-based systems by performing the collective operation in two steps. In the first step, all processes local to a node write their data to a common shared buffer. This is then exchanged over the network to remote nodes by designated processes called *leaders*. The third step involves the leader process distributing the data to the local processes through shared memory.

InfiniBand Collective Offload

Collective operations defined in the current MPI-2 standard are blocking operations. This implies that the applications need to wait until collective operations complete before doing any other compute tasks. Since collective operations involve many processes, their latency is bound to increase as systems scale. Several researchers have also observed that system noise can potentially affect the latency of blocking collective

operations, and hence the performance of end applications. It is widely believed that hiding the latency of collective operations can strongly benefit the performance of parallel applications. InfiniBand vendors, such as Mellanox, have recently introduced new network adapters, such as the ConnectX-2 that offer network-offload features. Host processors can create arbitrary task-lists comprising of send and receive operations and post them to the work request queue of the network interface. The network interface can independently execute these task lists without further intervention from the host processors. This *application-bypass* technique has the potential advantage of minimizing the effects of system noise along with offering more CPU cycles to applications for performing compute tasks.

MPI libraries are designed in a highly efficient, scalable manner to leverage the full functionality of these network interfaces. Non-blocking collective operations designed in this manner can potentially allow applications to scale better by countering the effects of system noise and allowing applications to hide the time required for collective operations by overlapping them with compute tasks. A new revision to the MPI standard, MPI-3, is likely to standardize non-blocking collective communication.

Switch-Based Support

Network switches form the backbone of the interconnect. High-performance networks have point-to-point links to maximize performance. Switches are responsible for routing packets from source nodes to destination nodes. Since switches are in a central position, it is a very attractive point to introduce network support for collective communication. The following architectural supports are available in Quadrics and InfiniBand switches for collective communication operations.

Quadrics

The Quadrics network features hardware support for collective communication. Each process can map a portion of the address space into global memory. These addresses constitute virtual shared memory. The switch provides hardware-based broadcast. This broadcast is reliable, i.e., no software mechanism is required to ensure that broadcast packets reach their destinations.

The broadcast mechanism replicates packets to particular switch output ports, with the capability of broadcasting to a subset of processors. Using the broadcast mechanism, both broadcast and barrier collectives can be implemented.

InfiniBand Multicast

Modern networks such as InfiniBand provide hardware-based *multicast* operation. The multicast operation gives the ability for a process to send a single message to a specific subset of processes which may be on different end nodes. Such a hardware-based multicast capability provides the following benefits: (a) only one send operation is needed to initiate the multicast, greatly reducing the host overhead at the sender, and (b) packets can be duplicated at the switch ports, reducing network traffic.

InfiniBand multicast does not guarantee reliable delivery. It is based on Unreliable Datagram (UD) transport. Software-based solutions to ensure reliability need to be provided. MPI library designers must take this into account. As with the RDMA-based approach, this scheme can also be enhanced for current generation of SMP systems. Such studies have already been done by researchers for IB systems and they show considerable improvement in performance as opposed to a non-SMP-aware approach.

InfiniBand Fabric Channel Accelerator

The Fabric Channel Accelerator technology from Voltaire (now merged with Mellanox) introduced this feature in 2009. The aim of this feature is to enable high-level optimizations in InfiniBand switches by employing a general purpose CPU on the switch itself. The CPU on the switch can then manage communications to different nodes. The individual nodes can connect to the CPU on the switch over Unreliable Datagram (UD) transport. The FCA library and algorithms then implement reliability on top of the unreliable transport. MPI libraries can talk with the FCA library to implement collective operations. Several commonly used collectives, such as barrier, broadcast, and reduce are supported.

Support Through Dedicated Networks

The most advanced support for collective operations is by dedicating entire networks for efficient implementation of collective operations. The communication

requirements of point-to-point and collective operations are often very different. Collective operations are very sensitive to latency and system noise. The following section describes the dedicated architectural support provided in IBM BlueGene system to accelerate collectives.

BlueGene

The IBM BlueGene system featured one of the most advanced support for scalable collective operations. The compute nodes were connected through five networks: a 3-D torus network for point-to-point messaging, a global collective network, a global barrier and interrupt network, and two other Ethernet networks for control and I/O. The global collective network is useful for speeding up commonly used MPI collective communications constructs. And the global barrier network quickly synchronizes state across all processes in the system. The BlueGene/L system had collective network with bandwidth up to 350 MBps with 1.5 μ s latency. The later BlueGene/P system featured collective network bandwidth of 850MBps and 1.3 μ s per tree traversal. The global barrier and interrupt network has a hardware latency of 0.65 μ s.

In addition to the hardware support, the IBM MPI libraries provide many advanced collective communication algorithms that map the hardware resources to user collective operations.

Software Optimizations

In addition to network support, software optimizations also play an important role in the performance of collective operations on modern platforms. There are two major ways by which software optimizations may be employed for collective operations: (a) algorithm design based on network topology, and (b) algorithm design in multi-core and many-core systems.

Large supercomputer systems must scale with increasing node count. One of the major problems with scaling is the number of links required to interconnect the system. An all-to-all connectivity *crossbar* connection requires N^2 links, which is clearly not scalable. In response, system designers have employed 2-D, 3-D meshes, k-dimensional Tori, and other interconnection topologies. The IBM BlueGene and Cray systems have used 3-D torus for their large-scale systems. Algorithms that implement collective operations must be designed

with these topologies in mind. The IBM BlueGene and Cray feature several such algorithmic optimizations.

Modern compute servers are based on multi/many-core architectures and offer high compute densities. Interestingly, these architectures have also introduced a new design space for collective algorithms. Since many processes share the same address space within a compute node, they can communicate directly through memory with smaller latency. Suppose we consider a MPI_Bcast operation. One or more processes within a node can be chosen as the *leaders* and they communicate over the network to receive the data from the root. These leaders then broadcast the data to the other processes that are within the same compute node, directly through memory. Researchers have also extended this concept to consider the network topology to further improve the latency of collective operations. These algorithms are particularly useful on large-scale systems, where compute nodes are organized across multiple racks and inter-rack communication are costlier.

Collectives Today

Owing to their ease of use and portability, collective communication operations are used extensively in scientific parallel applications. Hence, it is critical to improve the performance and scalability of collective operations. Most of the current research in this field is focused on two important aspects: (a) improving the latency of collective operations through enhanced software designs that leverage the advanced multi-core architectures and network features and (b) designing non-blocking collective operations that allow applications to achieve communication/computation overlap.

Many MPI libraries such as MVAPICH2 [23], OpenMPI [8], Intel-MPI use aggressive shared-memory-based designs to optimize latency of blocking collective operations on modern multi-core architectures. However, the performance of collective operations also strongly depends on the topology of interconnection networks. Supercomputing systems use complex network architectures ranging from fat-trees to 3-D Torus and hypercubes. Researchers are exploring alternatives to detect the system topology and design collective algorithms in a topology-aware manner to achieve lower latency.

As parallel applications are scaled out to tens of thousands of processes, it becomes necessary to hide the costs associated with collective operations. Non-blocking collective operations are widely believed to address this requirement. The goal of such an interface is to allow applications to perform compute tasks, while the collective operations are in progress. The biggest challenge of designing collective operations in this manner is that they need to be progressed, with little intervention from the host processors. Researchers are exploring ways to offload collective operations to modern network interfaces so that the host processors can be directly used to perform application-level compute tasks.

Future Directions

Given the current growth in multiprocessor chip designs, next-generation compute servers are expected to offer hundreds to thousands of compute cores. Next-generation networks are expected to offer a rich set of advanced features, apart from guaranteeing lower communication overheads. Designing algorithms to minimize the communication latency of blocking collective operations will continue to be a critical aspect of any communication library. At the same time, designing an efficient set of non-blocking collective operations that allow parallel applications to hide the communication latency promises to improve application performance. Communication libraries offering a high performance, scalable suite of collective operations can significantly improve the performance of scientific applications on next-generation systems. The upcoming MPI-3 standard will include non-blocking communication operations. In order to leverage the latency hiding properties of non-blocking collectives, end parallel applications will need to be redesigned.

Bibliographic Notes and Further Reading

Optimizing collective operations across various networks and systems has been an area of active research

for several years. Researchers have investigated optimizing collective communication on the IBM BlueGene supercomputers in [1, 2, 5, 6, 21]. Designs that leveraged various features offered by Quadrics and Myrinet networks to improve the performance of collective operations were proposed in [3, 4, 12, 13, 34–37]. Researchers have explored the challenges associated with off-loading collective operations to network adapters in [9, 10, 31, 32]. Software-based optimizations that consider the network topology and multi-core architectures to improve collective operations were proposed by various researchers in [11, 18–20, 24–26, 28, 33]. The impact of system noise on the performance of collective operations and real-world applications were studied in [7, 14, 15, 29, 30]. Recently, researchers have proposed the need for an efficient non-blocking interface for collective operations in [16, 17].

Combinatorial Search

LAXMIKANT V. KALÉ, PRITISH JETLEY
University of Illinois at Urbana-Champaign, Urbana, IL, USA

Synonyms

[State space search](#)

Definition

Combinatorial search involves the systematic exploration of the space of configurations, or *states*, of a problem domain. A set of *operators* can transform a given state to a series of successor states. The objective of the exploration is to find one, all, or optimal goal states satisfying certain desired properties, possibly along with a path from the start state to each goal. Combinatorial search has widespread applications in optimization, logic programming, and artificial intelligence.

Discussion

Given an implicitly defined set, combinatorial search involves finding one or more of its members that satisfy specific properties. More formally, it entails the systematic assignment of discrete values from a finite range to

each of a collection of variables. Each member of the set represents a configuration or *state* that the basic elements of the problem domain can assume. Therefore, the set is also called a *state space*. Combinatorial optimization problems lend themselves particularly well to expression in this *state space search* paradigm. The basic components of state space search are the *enumeration* of states and their *evaluation* for fitness according to the criteria defined by the problem. Since the state space of these problems can be extremely large, explicit generation of the entire space is often impossible due to memory and time constraints. Therefore, the set of possible states is generated on the fly, by transforming one state into another through the application of a suitable operator. However, in the absence of a mechanism to detect the generation of duplicates, this procedure might begin exploring a path of infinite length, thereby failing to terminate. This is the problem of *infinite regress*, and can be mitigated by one of two techniques. The first relies on the comparison of a generated state with its ancestors, which are stored either in a distributed table or passed from a parent to its newly-created child state. Another approach constrains the search procedure to consider only cost-bounded solutions. This is the case, for instance, in the Iterative Deepening A* algorithm discussed later. In certain situations, the search may be guided by a *heuristic* measure of distance between states: those considered closer to the goal may be given priority of consideration over those believed to be more distant.

Searching for All Feasible Solutions

A basic combinatorial search problem is one in which all feasible configurations of the search space are desired. An example is the *N*-Queens problem: find all configurations of *N* queens on an $N \times N$ chessboard such that no queen *attacks*, i.e., shares the same row, column, or diagonal, with another. In a particular formulation, a state of the problem is represented by a configuration of the chessboard in which each of the first k rows holds a non-attacking queen and the remaining $N - k$ are empty. The enumeration process can be described as a tree search. The root represents a state in which no queens have been placed on the board. The rest of the search tree is defined implicitly as follows: given a state s with k non-attacking queens placed in the first k rows, its child state has the same arrangement of queens as s , and an

additional queen placed in the next empty row. Defining the search tree in this fashion is advantageous: the tree can be preemptively pruned at nodes that cannot possibly yield solutions. In the running example, child states are only generated if they do not produce conflicts with previously placed queens.

The search strategy described above is a type of *multistep decision procedure* (MDP). Each step of the algorithm generates a new state s from its parent p by deciding an element of the configuration space. At step $k+1$ of N -Queens, this element is the position of a queen in row $k+1$ of the $N-k$ remaining rows. An MDP ensures that no duplicate states are generated. In particular, there can be no recurring states along the path from the start to the current state, so that infinite regress cannot occur.

The tree search defined above is useful even when the configurations are defined differently. Consider the problem of finding a knight's tour on the chessboard: Starting at a square and using only legal moves, can a knight visit every square on the board exactly once, returning finally to the starting square? This is a special instance of the Hamiltonian Circuit Problem: given a graph, a circular path must be found that visits every vertex exactly once. Here, the vertices correspond to squares on the chessboard. An edge (u, v) connects vertex u to v such that v can be reached in one knight-move from u . To enumerate all such tours, a tree search might define a state as a knight's path of length k originating at the start. Each child extends the path by adding a move to it.

Variable Selection

Given a particular node in the search tree, there is a choice of which branch to select when considering new children. This is called *variable selection*. Continuing with the N -Queens example, at step $k+1$, *any* of the remaining $N-k$ rows may be chosen as the recipient of the $k+1$ -th queen, not just the $k+1$ -th row on the chessboard. The size of the tree beneath the current node (and therefore the effort involved,) can be significantly affected by the choice of branching variable. A good heuristic is to select the most constrained variable at each step. In the N -Queens example, this would mean placing the next queen in the row with the fewest non-attacked squares.

Parallelization

In a sequential search, the tree is typically explored in its entirety by a depth-first procedure. A stack is used to hold unexplored children at each level. Given a search tree of depth d and branching factor b , this only requires $O(bd)$ memory, in contrast to the $O(b^d)$ size of the search space. A parallel implementation of this search procedure requires the distribution of work into discrete chunks called *tasks*. To ensure the efficient execution of these tasks on processors, the inter-related issues of task creation, *grainsize* control, and load balance must be considered. Grainsize can be defined roughly as the ratio of computation work to number of messages sent. There is a certain overhead in creating tasks, and a separate overhead if the task description is moved to another processor. Thus, it is important to keep the *average* grainsize above a certain threshold to limit the impact of parallel overhead. At the same time, no single task should be so large as to make all processors wait for its completion.

A parallel search may define a task as the subtree beneath a single tree node. Grainsize estimation then requires a simple metric which is correlated to the computational cost of a node. In N -Queens this could be the number of queens that remain to be placed. It is not an exact measure: sometimes a node with many queens remaining may still generate very little work under it, because of the impossibility of finding a solution there. With a suitable metric formulated, a threshold amount of work may be set, below which new tasks are not created; such subtrees are explored sequentially. Continuing with the N -Queens example, an efficient serial backtracking mechanism may be employed when, say, only $m \leq N$ queens remain. The threshold m could be estimated by the exploration of small parts of the search space.

Another technique defines a task as a set of frontier nodes. The exploration proceeds in a depth-first manner, maintaining an explicit stack. At some point, the stack may be split in two (or more) pieces, with each piece assigned to a new task on a possibly different processor. Typically, nodes near the bottom of the stack are used to create a new task. However, *vertical splitting* has also been proposed, wherein half of the unexplored branches at each level of the stack are picked to form starting positions for a new task. This strategy works

well for irregular search spaces, but can be expensive for deep stacks.

The literature discusses two methods to determine *when* stacks are split. The first combines grainsize control with the load balancing strategy: in “work-stealing” a processor’s stack is split upon receipt of a request for work from an idle processor. The idea was first described by Lin and Kumar [1] and later formalized by the Cilk system [2]. An alternative, due to Kalé et al. [3], aims to separate the two issues: the amount of work done by a task is tracked. Once an amount of work above a certain threshold T has been performed, the stack is split into k pieces, each assigned to a new task. This ensures that the grainsize is $T/(k + 1)$. However, care must be taken to avoid long chains of large tasks, i.e., when exactly one child has significant work, whereas others do not.

Load Balancing

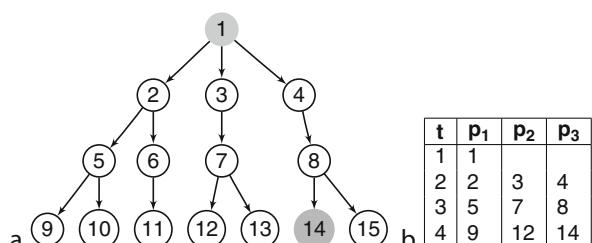

Early literature classifies load balancers as *sender-* or *receiver-initiated*. Work-stealing is a receiver-initiated load balancing technique. When a processor has no work, it steals work from a randomly chosen processor. It has been shown that random stealing of shallow nodes is asymptotically optimal, in that it leads to near-linear speedups [2]. The stealing mechanism could vary from messaging (on distributed memory systems) to exclusive shared queue access. In contrast, sender-initiated schemes assign newly spawned tasks to some processor, either randomly, or based on a load metric such as a queue size.

This taxonomic distinction fails to hold for load balancing schemes where each processor monitors the size of its own queue and that of its “neighbors,” periodically rebalancing them. Initially, a created task is placed on the creating processor’s queue. Unlike random assignment, this avoids unnecessary communication. Depending on the thresholds used to exchange queues and the periodicity of load exchanges, such schemes can tune themselves effectively. At one extreme, they can approximate work-stealing, where neighborhoods are global, an empty queue is used as a trigger, and rebalancing is done by selecting a random neighbor. Another advantage is their proactive agility: they increase efficiency by moving work before a processor goes idle. However, these schemes create more communication traffic.

Searching for Any Feasible Solution

Unlike the N -Queens or graph coloring problems where the objective is to identify *all* ways of satisfying given constraints, certain situations require the generation of *any* satisfactory configuration. A classic example is the 3-SAT problem. **Value ordering** becomes an important heuristic in this context: given b children of a node, explore the subtree of that child next whose subtree is most likely to contain a solution. Problem-specific figures of merit are used to order children. For instance, a simple 3-SAT heuristic might rank the two values possible for a variable (true or false) in decreasing order of the number of clauses satisfied by each.

The same parallelization techniques as outlined for the all-solutions search may be used, modifying them to terminate when a solution is found. However, note the *speculative* nature of the methods in this context: regions of the tree that may not be visited in a sequential procedure are searched concurrently in the hope that a solution may be found quicker. This can lead to anomalies in parallel performance [4], because nodes are not visited in the same order by the parallel algorithm. In the worst case, an added processor may generate useless work for other processors in the form of nodes that do not yield solutions. This situation is referred to as a *detrimental speedup anomaly*. On the other hand, as illustrated in Fig. 1, this addition of resources could lead to superlinear speedups (the *acceleration anomaly*.) Even on a fixed processor count, variations in the timing

Combinatorial Search. Fig. 1 Acceleration anomaly in parallel depth-first search: (a) illustrates the state space tree of a problem. Search begins at node 1; node 14 is the goal state. A serial depth-first search for the first solution takes 14 steps; (b) shows a schedule for the parallel depth-first search of the same tree with three processors. The search takes four steps, for a speedup of $14/4 = 3.5 > 3$

of load balancing could lead to widely differing execution spans between runs. Kalé et al. [3] obtain consistent speedups by prioritizing node exploration in the following manner: if a node with k children has priority q , each child's priority is obtained by appending its $\log k$ bit rank to q . This leads to a lexicographic ordering of tree nodes. Therefore, all descendants of a node's left child have higher priority than the right child's descendants. A prioritized queue (on a shared memory machine) or a prioritized load balancing scheme is used to steer processors toward high priority work. This scheme also leads to low memory usage: the search frontier forms a characteristic broom shape that sweeps the state space in accordance with the ordering on the nodes. Assuming a constant branching factor, the total memory usage with p processors is $O(p + d)$ rather than the $O(pd)$ requirement of the depth-first tree. On distributed memory machines, achieving this bound depends on the quality of the prioritized load balancer. Furthermore, since such schemes move work from the left part of the tree to all processors, they tend to have a sizable communication overhead. Therefore, a simple depth-first search may be more suitable in some cases.

Searching for an Optimal Solution

Some problems assign measures of fitness to feasible solutions. This renders certain solutions “better” than all others by some metric, so that the objective becomes the search for an *optimal* solution. Examples include integer programming, solving the 15-puzzle (or Rubik’s cube) with the fewest moves, and the search of a graph for a least cost Hamiltonian cycle. One could use the all-solutions methods discussed previously, and then select the best solution among all found. However, this is typically wasteful, and more efficient search methods are available.

A* Search and Iterative Deepening

In many problems, it is possible to define a heuristic function that, given a node n , computes a lower bound on the cost of any solution in the subtree beneath it. Such a function is called an *admissible* heuristic. For instance, in the 15-puzzle, the number of tiles that are out of place is an admissible heuristic: at least that many moves are needed to attain the goal state, since only one tile is shifted per move. (The “Manhattan distance” of each tile from its final position is a stronger heuristic.)

The lower bound on the *total* cost of a node is the sum of this value and the cost of arriving at it from the start. If unopened nodes are processed in ascending order of their lower-bounds, it can be shown that the first solution found is optimal [5]. This is called the A* search procedure. The A* strategy leads to an exponentially sized node queue; by contrast, depth-first search is highly memory efficient. The Iterative Deepening A* (IDA*) technique developed by Korf [6] combines the best properties of the two. It is applicable when the solution cost is quantized. For example, the number of moves needed in the 15-puzzle is an integer. If there is no solution of d moves, the procedure looks for a solution of $d + 2$ moves. (Because of parity arguments, the number of moves needed for a given starting state is known to be either even or odd.) A depth-first search bounded by a cost d may then be organized. An admissible heuristic is used to stop the search below nodes with cost lower bounds greater than d . If there is no solution of cost d , the bound is increased to the next possible value ($d+2$ for the 15-puzzle), and the search is restarted. Although there is duplication of the higher levels of the search tree, this technique is asymptotically optimal in the amount of work done [6]. Further, it offers control over the amount of memory used, while maintaining the property that the first solution found is the optimal one. Moreover, this method precludes the problem of infinite regress without the need for duplicate detection.

An effective parallelization of IDA* is described by Kalé et al. [3]. It uses bitvector prioritization to overlap execution of multiple iterations with different bounds. This ensures that the last iteration (the one in which the solution is found) is executed in a way that minimizes speculative loss, leading, as before, to consistent and monotonic speedups. In addition, the latter part of one iteration, where it winds down causing low processor utilization, is speculatively overlapped with the start of the next, thus improving efficiency.

Branch-and-Bound

Optimization problems can also be solved using the branch-and-bound technique, wherein properties of partial solutions are used to discard infeasible portions of the search tree. This can reduce the effort expended in finding optimal solutions. The main components of this mechanism are the *branching* and *bounding* procedures. Given a node n in the search tree, the branch

procedure generates a finite number of children. The bounding procedure assigns to each child a cost bound that determines when the child is explored, and whether it is explored at all. Nodes are pruned if they need not be explored. In addition, the bounding function must be *monotonic*: the bound of a node may be no better than the bound of its parent. An *exploration* mechanism is required to choose between the children of a node generated at each step. Such a mechanism may prioritize children based on their depth or their estimated ability to yield a solution. The procedure terminates when all subproblems have either been explored or pruned.

Consider the Traveling Salesman Problem. Whereas more efficient bounding techniques have been discussed in the literature, the following naïve procedure is presented for the purpose of exposition. A node n represents a partial solution comprising paths between cities such that they form a (possibly incomplete) tour. The children of n are enumerated by listing cities which can be visited from the most recently added destination. A partial solution has a cost bound equal to the length of the path that it represents. This is a monotonic lower bound, since the cost of a path through a child of n is at least as great as the cost of a path through n itself. The algorithm tracks the cost c of the cheapest complete tour encountered up to a certain point in the search. Notice that the tree can be pruned at children with lower bounds *greater* than c . Starting with an empty tour, all possible tours may be considered using this procedure.

The basic data structure in the branch-and-bound is a prioritized queue that stores the nodes comprising the frontier of the search. Anomalous speedups can result if these nodes are processed in an unordered fashion. The literature suggests *unambiguous* heuristic functions [7] for shared queues of nodes. Such a function h differentiates between nodes based on their values, so that for nodes n_1 and n_2 , $h(n_1) = h(n_2) \Leftrightarrow n_1 = n_2$. Even with consistent speedups, performance is bound by queue locking and access overheads. These can be mitigated by the use of concurrent priority queues.

In distributed memory implementations, the frontier may either be stored in a centralized or distributed manner. The former strategy usually engenders *master-slave* parallelism, where the master processor distributes work from a central node pool to worker processors.

This approach retains complete information about the global state of the search, thereby enabling an optimal exploration of the frontier without any speculative work. However, it is not scalable due to the bottleneck at the master. Distributing the node pool affords more autonomy to individual processors. Efficiency can be increased if a processor broadcasts newly encountered lower bounds to others. This helps other processors discard nodes that cannot yield optimal solutions. However, since it is hard to track node quality, effort might be wasted in exploring infeasible nodes for want of accurate bound information. *Quality equalization* may be performed to reduce speedup anomalies and distribute useful work equitably. This is either done periodically or when an associated trigger is activated. Equalization involves the movement of promising nodes between processors, which can be done in a hierarchical fashion to reduce communication. Grama and Kumar [8] and Kalé et al. [3] survey such parallel branch-and-bound techniques.

Bidirectional Search

Problems such as Rubik's Cube stipulate a priori the exact configuration of the goal state. In such problems, a *bidirectional* search may be employed to construct a path to the goal from the start state. By initiating two paths of search, one moving forward from the start state and the other backward from the goal, the size of the search space explored can be reduced substantially. On average, a unidirectional search of a tree of depth d and branching factor b visits $O(b^d)$ states to find an optimal solution. In contrast, by starting two opposing searches that meet, on the average, at depth $d/2$, only $O(b^{d/2})$ states are explored.

There are two main ways of organizing the forward and backward searches. The first method uses a backward depth-first procedure to exhaustively explore the tree starting from the goal, up to a certain height h above it. The states generated by this backward search are stored in the *intermediate goal layer*, the size of which is limited by the amount of memory available. The forward search is a (memory efficient) depth-first procedure or a best-first search with iterative deepening. Instead of checking for goal states, the forward search looks for each enumerated state in the intermediate layer. A match indicates the presence of a solution.

For distributed memory systems, the intermediate layer may either be replicated on every processor, or distributed across all available processors. Using replicas of the intermediate layer lowers the communication cost of the algorithm, but forces a reduction in the depth of the backward search. Kalé et al. [3] describe the use of distributed tables in multiprocessor bidirectional search.

A second class of bidirectional search schemes uses best-first techniques in either direction. This approach has its pitfalls: The frontiers of the forward and backward search may pass each other, resulting in two non-intersecting paths (in opposite directions) from the start to the goal. Therefore, instead of doing less work, the algorithm will have performed more work than a unidirectional search, yielding poor performance. To overcome this situation, *wave-shaping* algorithms attempt an intersection between the forward and backward search frontiers. Nelson and Toptsis [9] survey bidirectional search and provide parallel variants of pioneering uniprocessor techniques. Pohl presented the original non-wave-shaping uniprocessor bidirectional search. De Champeaux and Sint formulated a wave-shaping algorithm which estimates the distance between the advancing frontiers to encourage an intersection. This was improved upon by Politowski and Pohl to reduce the computational complexity of the heuristic.

Kaindl and Kainz [10] provide empirical evidence suggesting that bidirectional search is inefficient not because of non-intersecting frontiers, but because of the effort expended in trying to establish the optimality of the various paths constructed upon their meeting. Even with the most efficient implementations, bidirectional search can sometimes fail to provide the expected speedups, because of the structure of the problem's state space. Consider the game of peg-solitaire. The initial states of the game have many pegs but few spaces to allow jumps, so that there are few available moves. As the balance between free spaces and pegs becomes more even, more moves can be made and the branching factor increases. Toward the terminal stages of the game, few pegs remain on the board and the average branching factor once again reduces dramatically. Therefore, the state space of peg-solitaire does not form a tree that fans out with increasing depth. Consequently, a unidirectional search from the start state visits significantly

fewer than $O(b^d)$ nodes, and there is no practical advantage to using bidirectional search.

Game Tree Search

Game-playing can be represented by trees that trace the sequence of moves made by adversaries. Levels of these trees are marked MAX and MIN in an alternating fashion, depicting the moves made by the player and the opponent respectively. The leaves represent the various outcomes of the game, and are assigned values commensurate with their estimated favorability. However, the enumeration of all possible outcomes and paths to their corresponding leaves can be prohibitively expensive. Chess, for example, has on the order of 10^{43} states. Therefore, given a current state, modern game-playing strategies limit the search for good states to a certain *look-ahead* depth d from it. The *minimax principle* posits that under the assumption of rational play, an optimal strategy can be formulated by picking the most favorable child c of the current node n at each turn. A good approximation of the optimal move at n can be computed by evaluating all nodes under it up to a sufficient depth d , and choosing the best child c . Using a depth-first procedure, this requires $O(b^d)$ time and $O(bd)$ space, where b is the branching factor.

Alpha-Beta Pruning

The alpha-beta pruning procedure tracks the values of nodes encountered in the left-to-right, depth-first traversal of the tree to reduce the amount of work done in searching for optimal moves. For this purpose, the procedure tracks the lower bound on projected value of each MAX node (α) and the upper bound on the projected value for each MIN node (β). Consider a MAX node n that has two MIN children l and r . Suppose that the value of its left child l is found to be $v(l) = 15$. Then, the procedure may prune the tree at any children of r once it processes a c such that r is the parent of c and $v(c) < 15$. This pruning reduces the number of nodes significantly. However, the left-to-right order of tree traversal makes it challenging to formulate an efficient parallelization.

Parallel forms of the algorithm address the different kinds of node in the tree. *Principal Variation Splitting* evaluates the leftmost branch of a game tree before allowing the parallel evaluation of sibling nodes. Ideally,

the leftmost branch represents the optimal sequence of moves for the player (game tree branches are generally ordered so that the principal variation is the leftmost branch of the tree) and so yields the tightest bounds for the pruning of the rest of the tree, greatly reducing the amount of work done in parallel. Once the leftmost branch l has been scored, sibling nodes are evaluated in parallel using the bounds obtained from l . The siblings of a node n to its right may be sent refinements of bounds as these are calculated by n . The amount of parallelism is limited by the branching factor of the problem. Further, load imbalance between siblings causes synchronization delays.

The *Young Brothers Wait Concept* (YBWC) orders nodes similarly: the first child of a node (the *eldest* brother) must be explored before the others (the *younger* brothers) are examined. This scheme extends parallel evaluation beyond the principal variation nodes. Processors are said to *own* nodes if they are evaluating the subtrees beneath them. Initially, all processors except one, p_0 , are idle. Processor p_0 is given ownership of the root node. Idle processors request work from those that have satisfied the YBWC sibling order constraint, i.e., those processors that have evaluated at least one eldest brother n . This establishes a master–slave relationship between the sender and the recipient of work, and marks a *split-point* at N , which is the parent of n . The master and the slave cooperate to solve the tree under N . Further, a master that has become idle can request work from a slave that has not completed evaluation. Improved bound and cut-off information is shared with collaborating processors. A stronger formulation [11] of the parallelism constraint has been used to yield good speedups in chess-playing on distributed memory machines. *Dynamic Tree Splitting* uses a similar collaboration technique in the context of shared memory systems. However, split-points are chosen according to constraints expressed in terms of the α and β values of nodes.

The Deep Blue computer chess system [12] used a master-slave approach to parallelism. Upper levels of the tree were evaluated by the master, the slave processors being allotted work as the search grew deeper. To alleviate the performance bottleneck at the master, slave nodes were always kept busy with “on-deck” jobs. Since search was performed using a hybrid

software-hardware approach, load was balanced by pushing long hardware searches into software, and by sharing large pieces of work between workers. In 1997, Deep Blue defeated the then-reigning world champion Garry Kasparov.

AND-OR Tree Search

AND-OR trees arise naturally in the execution of logic programs, and in the problem-solving and planning literature within artificial intelligence. The min-max trees used in evaluating two-person games also reduce to AND-OR trees for the special case when the value of a node can only be a win or a loss. Another example of such trees arises in the graph coloring problem, when subgraphs may be colored independently following the coloring of a partitioning layer of vertices.

In logic programming terminology, the top-level query is a conjunction of literals called *goals*. Typically, multiple clauses are available to solve a given literal. Each clause is a conjunction of literals. The evaluation of a query then naturally leads to an AND-OR tree. There are two kinds of node in an AND-OR tree: an AND-node requires solutions to each of its children, whereas an OR-node requires a solution to at least one of its children. Search procedures used for simple state space search may be extended to this case. In particular, to *construct* a solution, an AND-node requires that information be sent up from its subtrees. A number of approaches to the effective organization of this search procedure have been surveyed, chiefly in the context of logic programming, by Gupta et al. [13].

An interesting issue concerns the dependence between the sub-problems represented by the children of AND nodes. Consider a query such as: $p(a, X), q(b, Y), r(c, X, Y, Z)$. Upper case letters represent variables that are instantiated by a solution. A solution to p may require that X have a value d , and a solution to q may require that Y have a value e . Unless there is a solution to r that also has $X = d$ and $Y = e$, these solutions to p and q are not useful. Therefore, the search space under r is constrained by using solutions produced by p and q . Whereas the subtrees corresponding to p and q can be explored in parallel, for r , a subtree can only be created for each instance produced by the cross-product of solutions to p and q . This “consumer-instance” parallelism is supported by the REDUCE-OR

process model [14]. Further, to avoid wasted work, the occurrence of duplicate states along distinct paths must be addressed. This issue is separate from the problem of infinite regress described earlier, which arose due to the generation of duplicates along the *same* path. To avoid duplication of effort, the newer state may be made a client for the result generated by the older instance. The issue of duplicates arises in other search patterns as well (Game Tree Search, IDA*, etc.) In these paradigms, it may be advisable to terminate one of these two paths, depending on their (under)estimated costs.

More Search Techniques

Several search techniques exist in addition to the ones described in this chapter. Path finding in the context of imperfect graph information is done using dynamic algorithms such as D* and LPA*. Little work has been done on the parallelization of these techniques.

Many *metaheuristic* techniques have been developed. The metaheuristic approach uses generalized search mechanisms, usually inspired by physical and natural phenomena, in lieu of problem-specific heuristics and techniques. Examples include Genetic Algorithms, Simulated Annealing, Local and Tabu Searches, etc. The use of graphics processors as offload devices to aid the solution of such state space search problems has also been considered recently.

Definition

The Community Climate System Model, CCSM, is a parallel climate model consisting of four parallel geo-physical component models (atmosphere, land, ocean, and sea ice) that exchange boundary data periodically through a parallel coupler component. It is a freely available community model developed by researchers funded by the US Department of Energy (DOE), the National Aeronautics and Space Administration (NASA), and the National Science Foundation (NSF), and maintained at the National Center for Atmospheric Research. CCSM targets a wide variety of computing platforms, ranging from workstations to the largest DOE, NASA, and NSF supercomputers.

Discussion

Introduction

Investigating the impact of climate change is a computationally expensive process, and as a result modern climate models are designed to take advantage of high performance computing (HPC) architectures. The Community Climate System Model (CCSM) is the best known of a series of climate models that have been developed by and maintained at the National Center for Atmospheric Research (NCAR), with contributions from external researchers funded by the US Department of Energy (DOE), National Aeronautics

and Space Administration, and National Science Foundation. In 2010 the model was extended and renamed the Community Earth System Model (CESM). This article focuses on CCSM, reserving a brief discussion of CESM for section ►“Community Earth System Model”.

CCSM consists of a system of four parallel geophysical component models (atmosphere, land, ocean, and sea ice) that exchange two-dimensional boundary data (flux and state information) periodically through a parallel coupler. The coupler coordinates the interaction and time evolution of the component models, and also serves to remap the boundary-exchange data in space. The atmosphere model is CAM, the Community Atmosphere Model. The ocean model is POP, the Parallel Ocean Program. The land model is CLM, the Community Land Model. The sea ice model is CICE, the Community Ice Code.

All component models are hybrid parallel application codes, using MPI, the Message Passing Interface, to define and coordinate distributed-memory parallelism and OpenMP to define and coordinate shared-memory parallelism. The components are all, for the most part, written in Fortran 95, though this is not a requirement. CCSM is unusual among parallel computational science models in that the hybrid message-passing/shared-memory parallel programming paradigm was implemented within many of the component models early on, and is now supported in all components except the coupler. It has been found that using both message-passing and shared-memory parallelism has been critical for achieving good performance on many past and current HPC architectures. Another unusual aspect of CCSM is that it is a community code that is evolving continually to evaluate and include new science. In consequence it has been very important that CCSM be easy to maintain and port to new systems, and that CCSM performance be easy to optimize for new systems or for changes in problem specification or processor count.

CCSM supports a large range of computational grid resolutions, with current production runs spanning a nominal 3° horizontal grid (approximately 4,600 grid points per vertical level for the atmosphere and land and 11,600 for the ocean and sea ice) for paleoclimate simulations, to 0.25° atmosphere and land horizontal grids (approximately 885,000 grid points per level) and 0.1° resolution ocean and sea ice grids

(approximately 8,640,000 grid points per level) that can resolve global tropical cyclones. Furthermore, the atmosphere component can span the range of altitudes from the Earth's surface to the thermosphere. CCSM also supports a variety of physical process options. Examples include different atmospheric chemistry packages and the option to run with a full carbon/nitrogen biogeochemical cycle in the ocean and land. [Figure 1](#) is a snapshot of precipitable water from a high resolution simulation.

For low resolution simulations and less expensive physical process options, CCSM can be run on small clusters and even on a laptop computer. For high resolution simulations and the more computationally expensive physics options, the largest available supercomputers are required, both to satisfy the memory requirements and to achieve a reasonable throughput rate for the simulations.

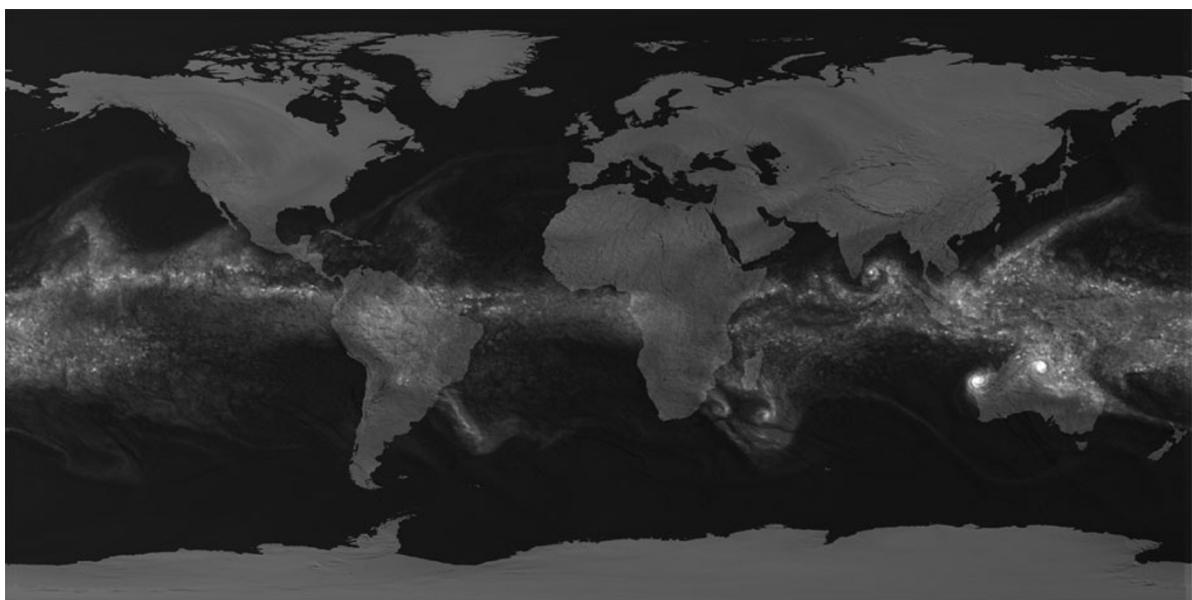

Each component model is a parallel application code in its own right, and was developed for the most part independently from the other component models. These are discussed in turn. Common technologies used in multiple components are also described.

Terminology

To help differentiate between MPI and OpenMP-based parallelism, processes will be referred to as MPI processes or tasks. Computational threads associated with an MPI process but which are spawned by the OpenMP runtime system will be referred to as OpenMP threads.

Each component model utilizes one or more spatial computational grids with at least two horizontal indices, e.g., representing longitude and latitude, and one vertical index. All grid points with a given horizontal location are referred to as a "vertical column." For some of the component models each grid point also represents a geographical region surrounding that physical location. In this case a grid point is also referred to as a "grid cell."

Component models approximate the solution at a discrete set of simulation times, with results at one simulation time dependent only on data and results associated with the same or earlier simulation times. Moreover, results for earlier simulation times are always completed before the computation for a later time is begun. The computation for a given simulation time is a "timestep."

Community Climate System Model. Fig. 1 A snapshot of the column integrated precipitable water from a high-resolution CCSM simulation. The snapshot is from early January and shows well-resolved winter-time cyclone activity in the Indian Ocean. Visualization courtesy of J. Daniel of Oak Ridge National Laboratory

The parallel implementation of each component model is based on one or more decompositions of a computational grid, with each MPI process assigned data and the responsibility of computing results associated with a subset of the grid. Computing the next timestep for a given subset of the grid will sometimes require data and results associated with grid points external to the subset. These external grid points are referred to as the “halo” for the grid subset. For a parallel algorithm based on grid decomposition, a “halo update” is the interprocess communication required to acquire the halo information that resides in the memory space of other processes.

Community Climate System Model

The first fully coupled system in the CCSM line of development, version 1 of the Community Climate System Model (CCSM1), was released in 1996. Although CCSM1 included support for both distributed-memory multiprocessor systems (via message passing) and parallel shared-memory vector systems, it was officially supported only on the NCAR Cray computing systems. A subsequent minor release added support for the SGI Origin 2000 system. CCSM2, the Community Climate System Model version 2, was released in 2002 and was the first version to use CAM, CLM, and POP for the atmosphere, land, and ocean component models, respectively. Target architectures included IBM SP systems, SGI Origin 2000, and Compaq/DEC Alphaserver. Version 3 (CCSM3) was released in June 2004 and version 4 (CCSM4) was released in April, 2010. CCSM4 was the first public release to use CICE for the sea ice component. CCSM4 theoretically runs on any distributed-memory system with an MPI library and a compiler capable of compiling CCSM and required libraries, such as netCDF. At the high end, CCSM4 ran on Cray XT, IBM BlueGene/P, and IBM Power6 cluster systems in 2010.

For science reasons, the atmosphere, land, and sea ice models are partially serialized in time, limiting the fraction of time when all four CCSM components can execute simultaneously. In the first three versions of CCSM each component model and the coupler were run as separate executables assigned to nonoverlapping processor sets. As of CCSM4, the entire system is now run as a single executable and there is greatly increased

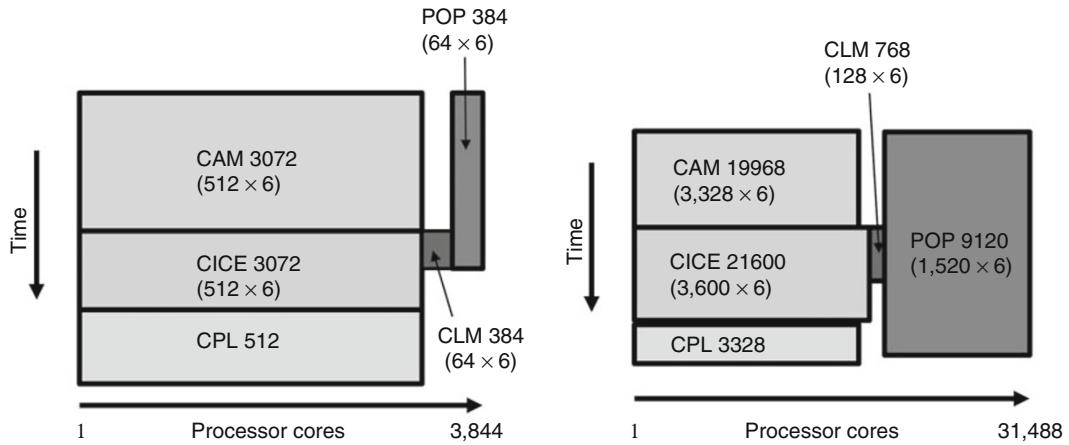

flexibility to select the component processor layout. It is typical for the atmosphere, land, and sea ice model to run on a common set of processors, while the ocean model runs concurrently on a disjoint set of processors. This is not a requirement, however, and CCSM can now run all components on disjoint processor subsets, all on the same processors, or any combination in between.

Each component model has its own performance characteristics, and the coupling itself adds to the complexity of the performance characterization. The first step in CCSM performance optimization is to determine the optimized performance of each of the component models for a number of different processor counts. This performance information is then used to determine how to assign processors to components in order to optimize the performance of CCSM as a whole. Cartoons of two example configurations for a Cray XT5 are displayed in Fig. 2. Figure 3 describes the performance scaling for the larger of the two problems used in Fig. 2.

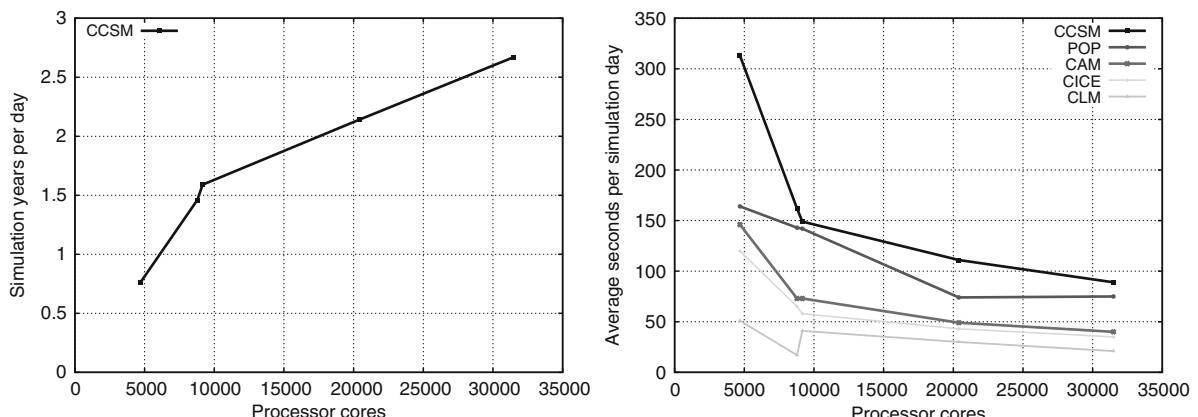

Community Atmosphere Model

CAM and its predecessors were all developed at NCAR. The first version (CCM0) was completed in 1982, followed by CCM1 in 1987, CCM2 in 1992, and CCM3 in 1996. CCM2 and prior versions targeted shared-memory parallel vector systems. An experimental distributed-memory parallel version of CCM2 was developed through the DOE CHAMMP (Computer Hardware, Advanced Mathematics, and Model Physics) program, targeting the Intel Delta initially and later ported to other systems including the Intel Paragon, IBM SP, and Cray T3E. However, CCM3 was the first official release with a distributed-memory parallelization option. In 2002, a new version was released and the name of the model was changed to the Community Atmosphere Model, to better reflect its role in the fully coupled climate system. CAM was also a significant departure from the CCM in terms of its software architecture, resulting in much improved extensibility, maintainability, portability, and parallel performance.

CAM is characterized by two computational phases: the dynamics, which advances the evolutionary equations for the atmospheric flow, and the physics, which approximates subgrid phenomena such as precipitation processes, clouds, long- and short-wave radiation, and

Community Climate System Model. Fig. 2 Cartoons of two example configurations for a Cray XT5 with two hex-core processors per compute node. The left configuration is for a simulation using one degree resolution horizontal grids on 3,844 processor cores. The right configuration is for a simulation using quarter degree resolution atmosphere/land grids and tenth degree ocean/sea ice grids on 31,488 processor cores. The number of cores used is listed per component, as well as the number of MPI tasks and number of OpenMP threads per task (*tasks* × *threads*). The time direction indicates the relative amount of time spent in each component, and whether components run sequentially or concurrently with each other. Note that the coupler will sometimes run sequentially with the ocean, for example, when the ocean and atmosphere are communicating, and sometimes concurrently

Community Climate System Model. Fig. 3 Example CCSM performance scaling on a Cray XT5 with two hex-core processors per compute node. The left graph is the throughput rate for a simulation using quarter degree resolution atmosphere/land and tenth degree ocean/sea ice horizontal grids. The right graph is the average wallclock seconds per simulation day for CCSM and for the atmosphere, land, ocean, and sea ice component models. For a given total processor core count, cores were assigned to each component so as to minimize total execution time. The number of cores assigned per component did not always increase with the total number of cores

turbulent mixing. Separate data structures and parallelization strategies are used for the dynamics and physics. The dynamics and physics are executed in

turn during each model simulation timestep, requiring that some data be rearranged between the two data structures each timestep.

CAM includes multiple compile-time options for the dynamics, referred to as dynamical cores or dycores. During 2010–2011 the most utilized dycore was a finite-volume flux-form semi-Lagrangian dynamical core (FV) formulated originally by Lin and Rood [8]. FV uses a tensor-product latitude \times longitude \times vertical-level computational grid over the sphere. A Lagrangian vertical coordinate is used to define flux volumes, within which the horizontal dynamics evolve. Vertical transport is modeled through evolution of the geopotential along each vertical column. A conservative Lagrangian surface remap is performed each model time step. Other supported dycores include an Eulerian global spectral method (EUL) and a spectral element method (SEM). Like FV, EUL uses a latitude \times longitude horizontal computational grid. In contrast, SEM uses a quasi-uniform “cubed sphere” horizontal grid that avoids the clustering of grid points near the poles that is typical of latitude \times longitude grids. All options as of June 2010 are described in [9].

The parallel implementation of the FV dycore is based on two-dimensional tensor-product “block” decompositions of the computational grid into a set of geographically contiguous subdomains. Each subdomain is assigned to a single process and no more than one block is assigned to any MPI process. A latitude-vertical decomposition is used for the main dynamical algorithms and a latitude-longitude decomposition is used for the Lagrangian surface remapping and (optionally) geopotential calculation. Halo updates are the primary MPI communications required by computation for a given decomposition. OpenMP is used for additional loop-level parallelism.

CAM physics is based on vertical columns and dependencies occur only in the vertical direction. Thus computations are independent between columns. The parallel implementation of the physics is based on a fine-grain latitude-longitude decomposition. Each subdomain, referred to as a “chunk,” is a collection of vertical columns. Multiple chunks can be assigned to a single MPI process, and OpenMP parallelism is applied to the loops over these chunks.

Transitioning from one grid decomposition to another, for example, latitude-vertical to latitude-longitude or dynamics to physics, may require that information be exchanged between processes. If the decompositions are very different, then every process may need to exchange data with every other process. If

they are similar, each process may need to communicate with only a small number of other processes (or possibly none at all).

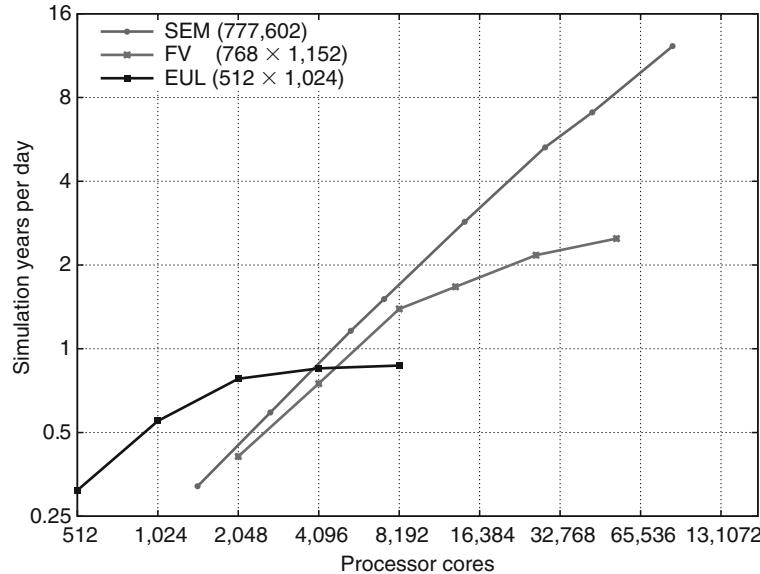

The computational cost in the physics is not uniform over the vertical columns, with the cost for an individual column depending on both geographic location and on simulation time. Some physics decompositions are better than others in equidistributing this cost (“balancing the load”) across the processes. A number of predefined physics decompositions are provided that attempt to minimize the combined effect of load imbalance and the communication cost of mapping to/from the dynamics decompositions. The optimal choice is a function of the problem specification, computer system, and number of processors used.

Historically CAM has been the performance bottleneck in fully coupled climate simulations. In consequence many performance optimization options have been implemented in the model, to make it easier to optimize performance for different problem specifications and target computer systems. Despite this flexibility, the parallel scalability of the model is limited when using either the FV or EUL dycores. As shown in Fig. 4, new dycores such as SEM demonstrate significantly improved scalability and will almost certainly become the default in the near future.

Community Land Model

CLM was developed at NCAR. It evolved from the effort to expand the strictly biogeophysical LSM, the NCAR Land Surface Model, to include the carbon cycle, vegetation dynamics, and river routing. The first version, CLM2.0, was released in 2002. Two major releases of the model have occurred since then, CLM3.0 and CLM4.0. The latter releases use MPI for distributed-memory parallelism and OpenMP for shared-memory parallelism. CLM is a single column (snow-soil-vegetation) model of the land surface, and in this aspect it is embarrassingly parallel.

Spatial land surface heterogeneity in CLM is represented as a nested subgrid hierarchy in which grid cells are composed of multiple landunits, snow/soil columns, and plant functional types (PFTs). Each grid cell can have a different number of landunits, each landunit can have a different number of columns, and each column can have multiple PFTs. The landunits represent the broadest spatial patterns of subgrid heterogeneity and

Community Climate System Model. Fig. 4 CAM throughput as a function of processor core count on an IBM BG/P with one quad-core processor per compute node for example simulations using the EUL, FV, and SEM dycores, respectively. Horizontal grid resolution used with each dycore is reported as either total number of grid points or as the dimensions of a two-dimensional grid. When using the FV dycore, the simulation used the same quarter degree grid as that used for Fig. 2. Grid resolutions when using the EUL and SEM dycores were chosen so that all simulations achieved comparable numerical accuracy. SEM data courtesy of M. Taylor of Sandia National Laboratories

currently are glacier, lake, wetland, urban, and vegetated. Columns represent potential variability in the soil and snow within a single landunit. Finally, PFTs represent differences in functional characteristics between categories of plants. Currently, up to 16 possible PFTs that differ in physiology and structure may coexist on a single column. All fluxes to and from the surface are defined at the PFT level.

Grid cells are grouped into blocks (called “clumps”) of nearly equal computational cost, and these clumps are subsequently assigned to MPI processes. When run serially or with MPI-only parallelism, each process has only one clump. When OpenMP is enabled, the number of clumps per process is set to the maximum number of OpenMP threads available.

The computational cost of a grid cell is approximately proportional to the number of plant functional types (PFTs) contained within it so some gridcells will be higher cost than others. Since similar PFTs tend to cluster geographically, balancing the workload across MPI processes requires that geographically distinct gridcells be assigned to each MPI process to improve load balance. In CLM, grid cells are distributed

to clumps in a segmented round robin approach with the expectation that each clump will contain grid cells from a variety of geographic locations. Clumps are then assigned in a round-robin fashion to the processes. This decomposition strategy provides performance portability across a wide range of computer architectures.

Parallel Ocean Program

POP is a descendant of the Bryan-Cox-Semtner class of models [1]. It was developed at Los Alamos National Laboratory (LANL) in 1992, designed specifically to take advantage of high-performance computer architectures. POP was written initially in a data parallel formulation using CM Fortran and targeting the Thinking Machines CM-2 and CM-5 systems, but has since moved to a traditional message-passing implementation.

POP approximates the three-dimensional primitive equations for fluid motions on a generalized orthogonal computational grid on the sphere. Each timestep of the model is split into two phases. A three-dimensional “baroclinic” phase uses an explicit time integration

method. A “barotropic” phase includes an implicit solution of the two-dimensional surface pressure using a preconditioned conjugate gradient solver.

The parallel implementation is based on a two-dimensional tensor-product “block” decomposition of the horizontal dimensions of the three-dimensional computational grid. Blocks are then distributed to MPI processes. The vertical dimension is not decomposed. The amount of work associated with a block is proportional to the number of grid cells located in the ocean. Grid cells located over land are “masked” and eliminated from the computational loops. OpenMP parallelism is applied to loops over blocks assigned to an MPI process. The number of MPI processes and OpenMP threads to be used are specified at compile-time. This information is used to generate enough blocks so that all computational threads are assigned work.

The parallel implementation of the baroclinic phase requires only limited nearest-neighbor MPI communication (for halo updates) and performance is dominated primarily by computation. The barotropic phase requires both halo updates and global sums (implemented with local sums and a call to MPI_Allreduce for a small number of scalars) for each iteration of the conjugate gradient algorithm. The solution of the implicit system can require hundreds of iterations, and parallel performance of the barotropic phase is dominated by the communication cost of the halo updates and global sum operations.

Two different approaches to domain decomposition are supported currently: “cartesian” and “spacecurve.” The cartesian option decomposes the grid onto a two-dimensional virtual processor grid, and then further subdivides the local subgrids into blocks to provide work for OpenMP threads. This generates an efficient decomposition for halo communication. The cartesian option tends to be most efficient when using one block per thread. The spacecurve option begins by eliminating blocks having only “land” grid cells. A space-filling curve ordering of the remaining blocks is then calculated, and an equipartition of this one-dimensional ordering of the blocks is used to assign blocks to processes. The land block elimination step tends to improve load balance compared to the cartesian option. This is most effective if the blocks are small, which can lead to assigning more than one block per thread. However, the spacecurve distribution, with potentially

smaller blocks and generally more complex communication patterns, can incur higher communication cost in halo updates. For any given POP resolution, the optimal block size and decomposition strategy depends on the computer architecture and the processor count.

Community Ice Code

The CICE sea ice model was developed at LANL in the mid-1990s, with version 2 released to the public in 1999. It was designed to be integrated into a coupled climate model, and, in particular, to be compatible with POP. Version 4 was selected to be the sea ice component in CCSM4, replacing the Community Sea Ice Model (CSIM) that was used in CCSM3. However CSIM is closely related to CICE and much of the following discussion applies to CSIM as well.

The CICE sea ice model is formulated on a two-dimensional horizontal grid representing the earth’s surface. An orthogonal vertical dimension exists to represent the sea ice thickness. Similar to POP, the parallel implementation decomposes the horizontal dimensions into equal-sized two-dimensional blocks that are then assigned to processes. The blocks can be distributed using relatively arbitrary algorithms. The vertical dimension is not decomposed.

CICE supports both distributed-memory and shared-memory parallelism over the same dimension, namely grid blocks. The primary interprocess communication operation is a halo update. No global sums are required in the prognostic calculation, but global sums are used when calculating diagnostics. Currently the CICE decomposition is static and set at initialization. The performance of the CICE model is highly dependent on both the block size and the decomposition.

The relative cost of computing on the sea ice grid varies significantly both spatially and temporally over a climate simulation because the sea ice distribution is changing constantly. It varies most dramatically on seasonal timescales but can also vary on interannual timescales. This has a huge impact on the load balance of the sea ice model in a statically decomposed model. The load balance will be generally optimized if grid cells from varied geographical locations (high latitude / tropics, northern / southern hemisphere) are assigned to each process. This is similar to the CLM and CAM physics decomposition load balance issues.

In addition, CICE performs regular and frequent halo updates with a resultant performance cost that depends on the amount of data communicated and the number of messages sent. Halo updates are written such that all data communicated between two processes are aggregated into a single message, thereby minimizing the total number of messages needed to carry out a halo update for more unusual decompositions. CICE halo communication can be minimized by assigning neighbor blocks to the same process, minimizing edge lengths, and minimizing the number of neighbors and, hence, messages communicated.

As in POP, the load balance and halo cost compete for optimal static load balance. At lower processor counts, load balance is more important. As processor count is increased, halo cost becomes increasingly important. As a compromise, strips of neighboring gridcells that span relatively large swaths of latitude tend to be grouped into blocks using a simple two-dimensional decomposition. At higher processor count, this tends to result in relatively long, skinny blocks on the physical grid and relatively high cell aspect ratios for communication. The optimal decomposition for any hardware and resolution depends strongly on the processor count. Weighted space-filling curves and other decompositions have been implemented in CICE and are being explored as a means to improve performance at higher resolution. In addition, other techniques such as dynamic load balancing and improved overlap of work and interprocess communication are being explored to improve performance and scalability.

Coupler

The CCSM coupler is responsible for several actions including rearranging data between different process sets, interpolating (mapping) data between different grids, merging data from different components, flux calculations, and diagnostics. Many of the algorithms are trivially parallel and require no communication between grid cells.

The first CCSM couplers of the late 1990s were run on a single processor and communication between components was implemented using PVM, the Parallel Virtual Machine. Eventually, PVM was replaced by MPI and the coupler was parallelized. The first coupler parallelized for MPI distributed-memory parallelism was released with CCSM3 in 2004 and was based

largely on the Model Coupling Toolkit (MCT) Library developed at Argonne National Laboratory. The coupler released as part of CCSM4 in 2010 underwent significant architectural revisions, but still relied heavily on the MCT library to support decompositions and parallel operations.

The coupler receives grid information in parallel at runtime from all of the model components. Domain decompositions are determined on the fly based upon the model resolutions, the component model decompositions, and the processors used by the coupler. The coupler treats the grids as one-dimensional arrays of grid points so relatively arbitrary decompositions can be implemented to optimize performance. The coupler does not require information about grid point connectivity within each domain. Work is either completely local or data is referenced by global grid indices for non local operations, as specified by input files.

Both rearrangement and mapping require inter-process communication. Rearrangement is handled by MCT “routers” that define the required message exchanges. Routers are created at model initialization and reused throughout the model run. All required data communications between a pair of processes are aggregated into a single message exchange, and data are rearranged using a minimal number of messages.

Mapping of fields between two grids is done in parallel using the MCT rearrangement logic described above. The required mapping weights are precomputed, read in during initialization, and decomposed onto the processes based upon two possible mapping implementations. The first implementation assigns weights defining the mapping from the source grid to the destination grid using the decomposition of the source grid. Partial sums computed on the source grid decomposition are then rearranged to the destination grid decomposition, where final sums are computed. The second implementation rearranges the data from the source grid onto the destination grid decomposition. The mapping of the source grid data to the destination grid is then computed using the destination grid decomposition. The number of floating point operations are nearly identical in both cases. The difference is whether data are mapped primarily using the source or destination grid decomposition. The most efficient mapping method depends mostly on the relative sizes of the source and destination grids.

Parallel I/O

An efficient parallel I/O subsystem is a critical component of a parallel application code. Limiting external storage accesses to a single master process creates a serial bottleneck, degrading parallel performance and scalability of the application as a whole, and/or exhausting local memory. Allowing all processes to access the external storage, especially access to the same file, can lead to failure or very poor performance when thousands (or hundreds of thousands) of processes are involved. To address this need for CCSM, a new parallel I/O library called PIO has been developed and included in CCSM4.

PIO was initially designed to allow better memory management for very high resolution simulations, by relaxing the requirement for retaining the memory corresponding to the global two-dimensional horizontal resolution on the master I/O task. Since then, PIO has developed into a general purpose parallel I/O library that serves as a software interface layer designed to encapsulate the complexities of parallel I/O and to make it easier to replace the lower level software backend. PIO has been implemented throughout the entire CCSM system and currently supports serial I/O using netCDF and parallel I/O using pnetCDF.

PIO calls are collective. An MPI communicator is set in a call to the PIO initialization routine and all tasks associated with that communicator must participate in all subsequent calls to PIO. One of the key features of PIO is that it takes the model's decomposition and redistributes it to an "I/O-friendly" decomposition on the requested number of I/O tasks. In using the PIO library, the user must specify the number of I/O tasks to be used, the stride or number of tasks between I/O tasks and whether the I/O will use the serial netCDF or pnetCDF library. By increasing the number of I/O tasks, the user can easily reduce the serial I/O memory bottleneck even with the use of serial netCDF.

Community Earth System Model

Version 1 of the CESM, the Community Earth System Model, was released in June, 2010. The CESM is a superset of CCSM4 in that it can be configured to run the same science scenarios as CCSM4. However, the CESM also contains options for a terrestrial carbon cycle and dynamic vegetation, atmospheric chemistry

and aerosol dynamics, and ocean ecosystems and biogeochemical coupling, all necessary for an earth system model, as distinct from a purely physical model like CCSM4. While enabling the new CESM model options will change the performance characteristics of a simulation, increasing the computational cost and amount of I/O primarily, the prior discussion of the parallel algorithms in the component models and in the coupled model apply to the CESM virtually unchanged.

Bibliographic Notes and Further Reading

Washington and Parkinson [12] is a comprehensive introduction to climate modeling. The 2003 DOE report "A Science-Based Case for Large-Scale Simulation" [10] includes estimates of the computational requirements for continued progress in computational climate science, arguing for the necessity of parallel simulation models targeting the highest performing computing platforms. A more recent discussion of the need for high performance computing in computational climate science is available in [11].

Detailed information on CCSM and CESM is available at the URLs

<http://www.cesm.ucar.edu/models/ccsm4.0/> and

<http://www.cesm.ucar.edu/models/cesm1.0/>

respectively. For descriptions of the climate science capabilities of CCSM3, see Collins et al. [2]. Papers documenting CCSM4 and CESM1 are in preparation, and will be cited at the above URLs when available.

The parallel implementation and performance characteristics of CCSM and of the component models have been documented in numerous journal and proceedings articles. Early work was reported in the proceedings of a series of conferences on the use of parallel processing in meteorology that were held at the European Center for Medium Range Weather Forecasting beginning in the mid-1980s, in particular see [6, 7]. An overview of many elements of this early work is available in a 1995 special issue of *Parallel Computing* on parallel computing in climate and weather modeling [4].

A description of more current aspects of the software engineering of CCSM component models is contained in a 2005 special issue of the *International Journal of High Performance Computing Applications* on climate modeling [5]. A recent overview of the software design of CCSM as a whole appeared in [3].

Definition

Here it is asked which applications should run in parallel and correspondingly which areas of computational science will benefit from parallelism. In studying this it will be discovered which applications benefit from particular hardware and software choices. A driving principle is that in parallel programming, one must map problems into software and then into hardware. The architecture differences in source and target of these maps will affect the efficiency and ease of parallelism.

Discussion

Introduction

I have an application – can and should it be implemented on a parallel architecture and if so, how should

this be done and what are appropriate target hardware architectures, what is known about clever algorithms and what are recommended software technologies? Fox introduced in [1] a general approach to this question by considering problems and the computer infrastructure on which they are executed as complex systems. Namely each is a collection of entities and connections between them governed by some laws. The entities can be illustrated by mesh points, particles, and data points for problems; cores, networks, and storage locations for hardware; objects, instructions, and messages for software. The processes of deriving numerical models, generating the software to simulate model, compiling the software, generating the machine code, and finally executing the program on particular hardware can be considered as maps between different complex systems. Many performance models and analyses have been developed and these describe the quality of map. It is known that maps are essentially never perfect and describing principles for quantifying this is a goal of this entry. At a high level, it is understood that the architecture of problem and hardware/software must match; given this we have quantitative conditions that the performance of the parts of the hardware must be consistent with the problem. For example, if two mesh points in problem are strongly connected, then bandwidth between components of hardware to which they are mapped must be high. In this discussion, the issues of parallelism are being described and here there are two particularly interesting general results. Firstly a space (the domain of entities) and a time associated with a complex system are usually defined. Time is nature's time for the complex system that describes time dependent simulations. However, for linear algebra, time for that complex system is an iteration count. Note that for the simplest sequential computer hardware there is no space and just a time defined by the control flow. Thus in executing problems on computers one is typically mapping all or part of the space of the problem onto time for the computer and parallel computing corresponding case where both problem and computer have well defined spatial extent. Mapping is usually never 1:1 and reversible, and "information is lost" as one maps one system into another. In particular, one fundamental reason why automatic parallelism can be hard is that the mapping of problem into software has thrown away key information about the space-time structure of original problem. Language designers in this field try to

find languages that preserve key information needed for parallelism while hardware designers design computers that can work around this loss of information. For an example, use of arrays in many data parallel languages from APL, HPF, to Sawzall can be viewed as a way to preserve spatial structure of problems when expressed in these languages. In this article, these issues will not be discussed in depth but rather it will be discussed what is possible with "knowledgeable users" mapping problems to computers or particular programming paradigms.

Simple Example

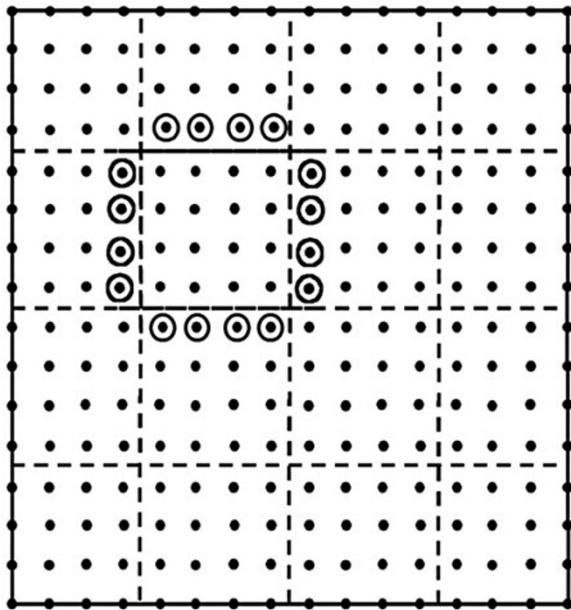

The simple case of a problem whose complex system spatial structure is represented as a 2D mesh is considered. This comes in material science when one considers local forces between a regular array of particles or in the finite difference approach to solving Laplace or Poisson's equation in two dimensions. There are many important subtleties such as adaptive meshes and hierarchical multigrid methods but in the simplest formulation such problems are set up as a regular grid of field values where the basic iterative update links nearest neighbors in two dimensions.

If the points are labeled by an index pair (i, j) , then Jacobi's method (not state of the art but chosen as simplicity allows a clear discussion) can be written

$$\phi(i, j) \text{ is replaced by } (\phi_{\text{Left}} + \phi_{\text{Right}} + \phi_{\text{Up}} + \phi_{\text{Down}})/4 \quad (1)$$

where $\phi_{\text{Left}} = \phi(i, j - 1)$ and similarly for ϕ_{Right} , ϕ_{Up} , and ϕ_{Down} .

Such problems would usually be implemented on a parallel architecture by a technique that is often called "domain decomposition" or "data parallelism" although these terms are not very precise. Parallelism is naturally found for such problems by dividing the domain up into parts and assigning each part to a different processors as seen in Fig. 1. Here the problem represented as a 16×16 mesh is solved on a 4×4 mesh of processors. For problems coming from nature this geometric view is intuitive as say in a weather simulation, the atmosphere over California evolves independently from that over Indiana and so can be simulated on separate processors. This is only true for short time extrapolations – eventually information flows between these sites and

Computational Sciences. Fig. 1 Communication structure for 2D complex system example. The dots are the 256 points in the problem. Shown by dashed lines is the division into 16 processors. The circled points are the halo or ghost grid points communicated to processor they surround

their dynamics are mixed. Of course it is the communication of data between the processors (either directly in a distributed memory or implicitly in a shared memory) that implements this eventual mixing.

Such block data decompositions typically lead to a SPMD (Single Program Multiple Data) structure with each processor executing the same code but on different data points and with differing boundary conditions. In this type of problem, processors at the edge of the (4×4) mesh do not see quite the same communication and compute complexity as the “general case” of an inside processor shown in Fig. 1. For the local nearest neighbor structure of Eq. 1, one needs to communicate the ring of halo points shown in figure. As computation grows like the number of points (grain size) n in each processor and communication like the number on edge (proportional to \sqrt{n}), the time “wasted” communicating decreases as a fraction of the total as the grain size n increases. Further one can usually “block” the communication to transmit all the needed points in

a few messages as latency can be an important part of communication overhead.

Note that this type of data decomposition implies the so-called “owner’s-compute” rule. Here each data point is imagined as being owned by the processor to which the decomposition assigns it. The owner of a given data-point is then responsible for performing the computation that “updates” its corresponding data values. This produces a common scenario where parallel program consists of a loop over iterations divided into compute-communicate phases:

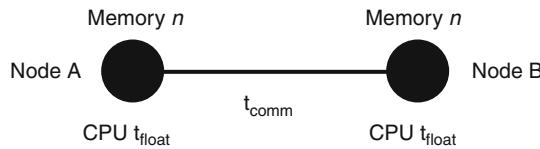

- *Communicate*: At the start of each iteration, first communicate any outside data values needed to update the data values at points owned by this processor.
- *Compute*: Perform update of data values with each processor operating without need to further synchronize with other machines.

This general structure is preserved even in many complex physical simulations with fixed albeit irregular decompositions. Dynamic decompositions introduce a further step where data values are migrated between processors to ensure load balance but this is usually still followed by similar communicate-compute phases. The communication phase naturally synchronizes the operation of the parallel processors and provides an efficient barrier point which naturally scales. The above discussion uses a terminology natural for distributed memory hardware or message passing programming models. With a shared memory model like OpenMP, communication would be implicit and the “communication phase” above would be implemented as a barrier synchronization.

Performance Model

Our current Poisson equation example can be used to illustrate some simple techniques that allow estimates of the performance of many parallel programs.

As shown in Fig. 2, the node of a parallel machine is characterized by a parameter t_{float} , which is time taken for a single floating point operation. t_{float} is of course not very well defined as depends on the effectiveness of cache, possible use of fused multiply-add and other issues. This implies that this measure will have some application dependence reflecting the goodness of the

Computational Sciences. Fig. 2 Parameters determining performance of loosely synchronous problems

match of the problem to the node architecture. We let n be the grain size – the number of data points owned by a typical processor. Communication performance – whether through a shared or distributed memory architecture – can be parameterized as

$$\begin{aligned} & \text{Time to communicate } N_{\text{comm}} \text{ words} \\ &= t_{\text{latency}} + N_{\text{comm}} \cdot t_{\text{comm}} \end{aligned} \quad (2)$$

This equation ignores issues like bus or switch contention but is a reasonable model in many cases. Latencies t_{latency} can be around $1\mu\text{s}$ on high performance systems but is measured in milliseconds in a geographically distributed grid. t_{comm} is time to communicate a single word and for large enough messages, the latency term can be ignored which will be done in the following.

Parallel performance is dependent on load balancing and communication and both can be discussed but here it is focused on communication with problem of Fig. 1 generalized to N_{proc} processors arranged in an $\sqrt{N_{\text{proc}}}$ by $\sqrt{N_{\text{proc}}}$ grid with a total of N mesh points and the grain size $n = N/N_{\text{proc}}$. Let $T(N_{\text{proc}})$ be the execution time on N_{proc} processors and two contributions are found to this ignoring small load imbalances from edge processors. There is a calculation time expressed as $n \cdot t_{\text{calc}}$ with $t_{\text{calc}} = 4t_{\text{float}}$ as the time to execute the basic update Eq. 1. In addition the parallel program has communication overhead, which adds to $T(N_{\text{proc}})$ a term $4\sqrt{n} \cdot t_{\text{comm}}$. Now the speed up formula is found:

$$\begin{aligned} S(N_{\text{proc}}) &= T(1)/T(N_{\text{proc}}) \\ &= N_{\text{proc}}/(1 + t_{\text{comm}}/(\sqrt{n} \cdot t_{\text{float}})) \end{aligned} \quad (3)$$

It is noted that this analysis ignores the possibility available on some computers of overlapping communication and computation which is straightforwardly included. The above formalism can be generalized most conveniently using the notation that

$$S(N_{\text{proc}}) = \varepsilon \cdot N_{\text{proc}} = N_{\text{proc}}/(1 + f), \quad (4)$$

which defines efficiency ε and overhead f . Note that it is preferred to discuss overhead rather than speed-up or efficiency as one typically gets simpler models for f as the effects of parallelism are additive to f but for example occur in the denominator of Eq. 3 for speedup and efficiency. The communication part f_{comm} of the overhead f is given by combining Eqs. 3 and 4 as

$$f_{\text{comm}} = t_{\text{comm}}/(\sqrt{n} \cdot t_{\text{float}}) \quad (5)$$

Note that in many instances, f_{comm} can be thought of as simply the ratio of parallel communication to parallel computation. This equation can be generalized to essentially all problems we will later term loosely synchronous. Then in each coupled communicate-compute phases of such problems, one finds that the overhead takes the form:

$$f_{\text{comm}} = \text{constant} \cdot t_{\text{comm}}/(n^{1/d} \cdot t_{\text{float}}) \quad (6)$$

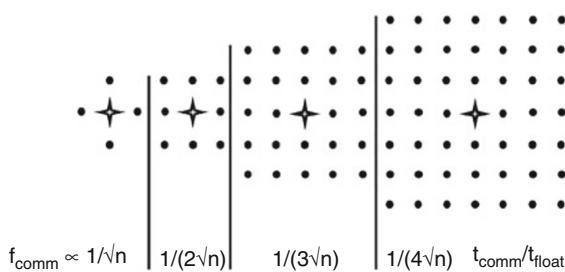

Here d is an appropriate (complexity or information) dimension, which is equal to the geometric dimension for partial differential based equations or other geometrically local algorithms such as particle dynamics. A particularly important case in practice is the 3D value $d = 3$ when $n^{-1/d}$ is just surface/volume in three dimensions. However Eq. 6 describes many non geometrically local problems with for example the value $d = 2$ for the best decompositions for full matrix linear algebra and $d = 1$ for long range interaction problems. The Fast Fourier Transform FFT finds $n^{1/d}$ in Eq. 6 replaced by $\ln(n)$ corresponding to $d = \infty$.

From Eq. 4, it can be found that $S(N_{\text{proc}})$ increases linearly with N_{proc} as long as N_{proc} is increased with fixed f_{comm} which implies fixed grain size n , while t_{comm} and t_{float} are naturally fixed. This is scaled speedup where the problem size $N = n \cdot N_{\text{proc}}$ also increases linearly with N_{proc} . The continuing success of parallel computing even on very large machines can be considered as a consequence of equations like Eq. 6 as the formula for f_{comm} only depends on local node parameters and not on the number of processors. Thus as we scale up the number of processors keeping the node hardware and application grain size n fixed, we will get scaling performance – speedup proportional to N_{proc} . Note this implies that total problem size increases proportional to N_{proc} – the defining characteristic of scaled speedup.

Complex Applications Are Better for Parallelism

The simple problem described above is perhaps the one where the parallel issues are most obvious; however it is not the one where good parallel performance is easiest to obtain as the small computational complexity of the update Eq. 1 makes the communication overhead relatively more important. There is a fortunate general rule that as one increases the complexity of a problem, the computation needed grows faster than the communication overhead and this will be illustrated below. Jacobi iteration does have perhaps the smallest communication for problems of this class. However it has one of largest ratios of communication to computation and correspondingly high parallel overhead. Note one sees the same effect on a hierarchical (cache) memory machine, where problems such as Jacobi Iteration for simple equations can perform poorly as the number of operations performed on each word fetched into cache is proportional to number of links per entity and this is small (four in the 2-D mesh considered above) for this problem class.

As an illustration of the effect varying computational complexity, it can be seen in Fig. 3 how the above analysis is altered as one changes the update formula of Eq. 1. The size of the stencil parameterized can now be systematically increased by an integer l and it can be found how f_{comm} changes. In the case where points are particles the value of l corresponds to the range of their mutual force and in the case of discretization of partial differential equations l measures the order of the approximation.

Computational Sciences. Fig. 3 Communication structure as a function of stencil size. The figure shows 4 stencils with from left to right, range $l = 1, 2, 3$

The communication overhead is found to decrease systematically as shown in Fig. 3 as the range of the force increases. The general 2D result is:

$$f_{\text{comm}} \propto t_{\text{comm}} / (l \cdot \sqrt{n} \cdot t_{\text{float}}) \quad (7)$$

This is valid for l which is large compared to 1 but smaller than the length scale corresponding to region stored in each processor. In the interesting limit of an infinite range ($l \rightarrow \infty$) force, the analysis needs to be redone and one finds the result that is independent of the geometric dimension

$$f_{\text{comm}} \propto t_{\text{comm}} / (n \cdot t_{\text{float}}) \quad (8)$$

which is of the general form of Eq. 6 with complexity dimension $d = 1$. This is the best-understood case where the geometric and complexity dimensions are different. The overhead formula of Eq. 8 corresponds to the computationally intense $O(N^2)$ algorithms for evolving N-body problems. The amount of computation is so large that the ratio of communication to computation is extremely small.

Application Architectures

The analysis above can be applied to many SPMD problems and addresses the matching of “spatial” structure of applications and computers. This drives needed linkage of individual computers in a parallel system in terms of topology and performance of network. However this only works if we can match the temporal structure and this aspect is more qualitative and perhaps controversial. The simplest ideas here underlined the early SIMD (Single Instruction Multiple Data) machines that were popular some 20 years ago. These are suitable for problems where each point of the complex system evolves with the same rule (mapping into machine instruction) at each time. There are many such problems including for example the Laplace solver discussed above. However many related problems do not fit this structure – called *synchronous* in [1] – with the simplest reason being heterogeneity in system requiring different computational approaches at different points. A huge number of scientific problems fit a more general classification – *loosely synchronous*.

Here SPMD applications can be seen which have the compute-communication stages described above but now the compute phases are different on different processors. One uses load balancing methods to ensure that the computational work on each node is balanced but not on each machine instruction but rather in a coarse grain fashion at every iteration or time-step – whatever defines the temporal evolution of the complete system. Loosely synchronous problems fit naturally MIMD machines with the communication stages at macroscopic “time-steps” of the application. This communication ensures the overall correct synchronization of the parallel application. Thus overhead formulae like Eqs. 5 and 6 describe both communication and synchronization overhead. As this overhead only depends on local parameters of the application, it is understood why loosely synchronously can get good scalable performance on the largest supercomputers. Such applications need no expensive global synchronization steps. Essentially all linear algebra, particle dynamics and differential equation solvers fall in the loosely synchronous class. Note synchronous problems are still around but they are run on MIMD (Multiple Instruction Multiple Data) machines with the SPMD model.

A third class of problems – termed *asynchronous* – consists of asynchronously interacting objects and is often people’s view of a typical parallel problem. It probably does describe the concurrent threads in a modern operating system and some important applications such as event driven simulations and areas like search in computer games and graph algorithms. Shared memory is natural for asynchronous problems due to low latency often needed to perform dynamic synchronization. It wasn’t clear in the past but now it appears this category is not very common in large scale parallel problems of importance. The surprise of some at the practical success of parallel computing can perhaps be understood from people thinking about asynchronous problems whereas its loosely synchronous and *pleasantly parallel* problems that dominate. The latter class is the simplest algorithmically with disconnected parallel components. However the importance of this category has probably grown since the original 1988 analysis [2] when it was estimated as 20% of all parallel computing. Both Grids and clouds are very natural for this class

which does not need high performance communication between different nodes. Parameter searches and many data analysis applications of independent observations fall into this class.

From the start, we have seen a fifth class – termed metaproblems – which refer to the coarse grain linkage of different “atomic” problems. Here synchronous, loosely synchronous, asynchronous and pleasingly parallel are the atomic classes. Metaproblems are very common and expected to grow in importance. One often uses a two level programming model in this case with the metaproblem linkage specified by workflow and the component problems with traditional parallel languages and runtimes. Grids or Clouds are suitable for metaproblems as coarse grain decomposition does not usually require stringent performance.

These five categories are summarized in Table 1 which also introduces a new category *MapReduce++* which has recently grown in importance to described data analysis. Nearly all the early work on parallel computing focused on simulation as opposed to data analysis (or what some call data intensive applications). Data analysis has exploded in importance recently [3] correspondingly to growth in number of instruments, sensors and human (the web) sources of data.

Summary

Problems are set up as computational or numerical systems and these can be considered as a “space” of linked entities evolving in time. The spatial structure (which is critical for performance) and the temporal structure which is critical to understand the class of software and computer needed were discussed. These were termed “basic complex systems” and characterized by their possibly dynamic spatial (geometric) and temporal structure. The difference between the structure of the original problem and that of computational system derived from it have been noted. Much of the past experience can be summarized in parallelizing applications by the conclusion:

Synchronous and Loosely Synchronous problems perform well on large parallel machines as long as the problem is large enough. For a given machine, there is

Computational Sciences. Table 1 Application classification

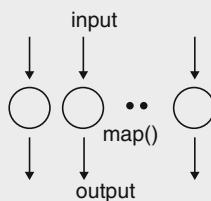

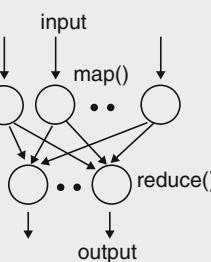

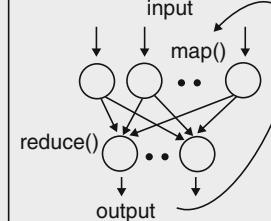

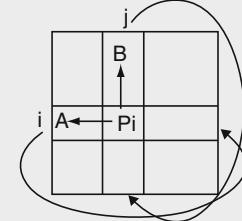

#	Class	Description	Machine Architecture
1	Synchronous	The problem class can be implemented with instruction level Lockstep Operation as in SIMD architectures	SIMD
2	Loosely Synchronous (or BSP Bulk Synchronous Processing)	These problems exhibit iterative Compute-Communication stages with independent compute (map) operations for each CPU that are synchronized with a communication step. This problem class covers many successful MPI applications including partial differential equation solution and particle dynamics applications.	MIMD on MPP (Massively Parallel Processor)
3	Asynchronous	Illustrated by Compute Chess and Integer Programming; Combinatorial Search often supported by dynamic threads. This is rarely important in scientific computing but at heart of operating systems and concurrency in consumer applications such as Microsoft Word.	Shared Memory
4	Pleasingly Parallel	Each component is independent. In 1988, Fox estimated this at 20% of the total number of applications [2] but that percentage has grown with the use of Grids and data analysis applications including for example the Large Hadron Collider analysis for particle physics.	Grids moving to Clouds
5	Metaproblems	These are coarse grain (asynchronous or dataflow) combinations of classes (1–4) and (6). This area has also grown in importance and is well supported by Grids and described by workflow of Section 3.5.	Grids of Clusters
6	MapReduce++	It describes file(database) to file(database) operations which has three subcategories given below and in Table 2 . (6a) Pleasingly Parallel Map Only – similar to category 4 (6b) Map followed by reductions (6c) Iterative “Map followed by reductions” – Extension of Current Technologies that supports much linear algebra and data mining	Data-intensive Clouds (a) Master-Worker or MapReduce (b) MapReduce (c) Twister

The MapReduce++ category has three subdivisions (a) “map only” applications similar to pleasingly parallel category; (b) The classic MapReduce with file to file operations consisting of parallel maps followed by parallel reduce operations; (c) captures the extended MapReduce introduced in [4–10]. Note this category has the same complex system structure as loosely synchronous or pleasingly parallel problems but is distinguished by the reading and writing of data. This comparison is made clearer in [Table 2](#). Note nearly all early work on parallel computing discussed computing with data on memory. MapReduce and languages like Sawzall [11] and Pig-Latin [12] emphasize the parallel processing of data on disks – a field that until recently was only covered by database community

a typical sub-domain size (i.e. the grain size or size of that part of the problem stored on each node) above which one can expect to get good performance. There will be a roughly constant ratio of parallel speedup to N_{proc} if one scales the problem with fixed sub-domain

size and total size proportional to N_{proc} . This conclusion has been enriched by study of grids and clouds with an emphasize on pleasingly parallel and MapReduce++ style problems often with a data intensive focus. These also parallelize well.

Bibliographic Notes and Further Reading

The approach followed here was developed in [1, 13] with further details in [2, 14]. The extension to include data intensive applications was given in [8, 15]. There are many good discussions of speedup including Gustafson's seminal work [16] and the lack of it – Amdahl's law [17]. The recent spate of papers on MapReduce [4, 7] and its applications and extensions [4–12, 15] allow one to extend the discussion of parallelism from simulation (which implicitly dominated the early work) to data analysis [3].

Computer Graphics

JOHN C. HART

University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

The field of computer graphics is concerned with developing algorithms for visual simulation, and has both benefitted from parallel computing, especially to achieve real-time rendering rates, and contributed to parallel computing, especially through streaming architectures and programming languages.

Discussion

The field of computer graphics embodies algorithms for generating and manipulating images, representing and constructing shapes, and simulating and capturing motion. These algorithms often lend themselves naturally to parallel approaches due to the regularity of its

data, e.g., image pixels, light rays, mesh elements, or moving particles.

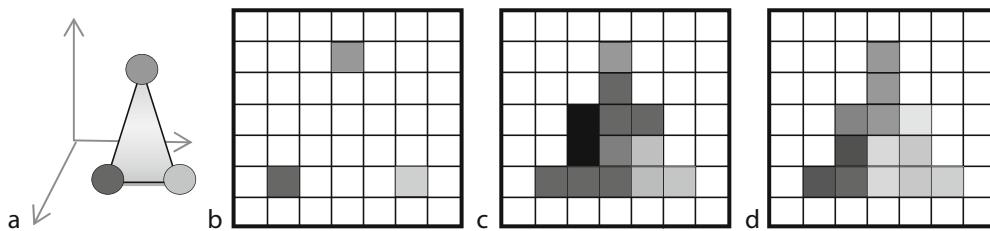

Many operations in computer graphics are specializations of more general numerical, scientific, and combinatorial algorithms that have been parallelized in more general settings. The distribution of light in a scene is a recurrent integration, often solved with Monte Carlo methods. Linear system solvers including iterative methods, conjugate gradients, and multigrid methods are used for meshing, rendering and animating 3-D objects and scenes, and a wide variety of powerful image editing operations. Combinatorial optimization algorithms like GraphCut can be used to merge texture elements. N-body solutions have been used to find a light equilibrium and for surface reconstruction from scattered point data. Hence parallel computer graphics is often simply finding the appropriate numerical or combinatorial method, usually from scientific computing, and parallelizing that algorithm for deployment on a graphics platform, sometimes capitalizing on the reduced precision and other approximations afforded to visual simulation.

Much of the remainder of parallel graphics work has focused on rendering, particularly maximizing the quality of rendering while maintaining a desired rate of image production (e.g., real-time). Rendering is the process of taking a computer representation of a scene of one or more shapes and constructing one or more images depicting that scene. Rendering can be photorealistic, based on a physical model of light, or expressive, based on a perceptual model of the viewer. Renderings can be of contrived scenes for entertainment, or of data for visualization, and can range from real time (faster than 30 images/s) to interactive (around 10 images/s) to offline (taking minutes, hours, and even days per image). In all cases, parallelism provides a toolbox for achieving greater image generation throughput.

Modern rendering falls into three categories: rasterization, ray tracing, and micropolygons, and the remainder of this discussion describes the parallelism used to accelerate these rendering algorithms to support real-time graphics.

Rasterization

Rasterization has been the primary rendering method for real-time graphics and parallelism is used to increase

Computer Graphics. Fig. 1 Vertices from a mesh polygon in a 3-D scene (a) are shaded and transformed independently in parallel into screen pixel locations (b). Screen pixels between these locations are interpolated by rasterization (c) and processed independently in parallel (d), in this example, saturating the color

the number and quality of rasterized polygons. To rasterize each polygon in a mesh, the polygon's vertices must first be shaded and transformed from scene coordinates to pixel locations. These operations are pipelined and lend themselves naturally to parallel processing since the vertices can be processed completely independently from each other (Fig. 1).

The actual rasterization process fills in the screen pixels between the pixel locations of the screen projected polygon vertices, interpolating any attributes (e.g., color) that accompany the vertices. These pixels are then further processed for texturing and fine-detail shading, which also can be trivially parallelized since the pixel computations are independent of each other.

This vertex and pixel parallelism has been implemented in a variety of graphics architectures over many decades, leading to the modern graphics processing unit (GPU). Since the computations are independent and identical over all vertices, and similarly over all pixels, single-instruction-multiple-data (SIMD) processing is utilized, and evolved into present day GPU single-process-multiple-data (SPMD) processing. For efficient processing GPU programs must still remain sensitive to SIMD performance issues, such as control flow divergence. Though we distinguish between vertex shaders and pixel shaders by their position in the graphics pipeline, the same processing array is used for both.

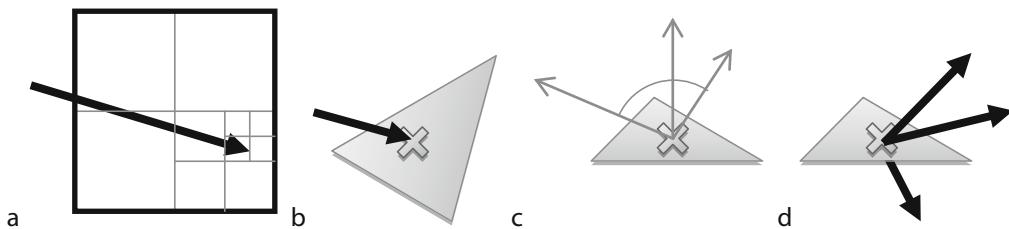

In order to support a wider variety of shading effects, these parallel vertex and pixel processes have supported custom programming, which led to the modern programmable GPU which can support programmable vertex and pixel “shaders.” For example, “skinning” is a vertex shader that smoothly deforms an elbow by interpolating at each elbow mesh vertex the rotated coordinate frame of the upper arm with the rotated

coordinate frame of the forearm. Pixel shaders were primarily motivated by the need to interpolate surface normals between vertices and compute shading per pixel, instead of computing shading per vertex and interpolating the vertex color across the polygon pixels.

Since these processes are independent and SIMD, their parallel processing is quite efficient, which made the GPU an attractive parallel computational platform for “general purpose” parallel programming, called GPGPU programming. As parallel graphics processing developed, general purpose programs (e.g., computing a Mandelbrot set or a Voronoi diagram) had to be formulated as multiple passes of polygon rendering programs to be accelerated by the GPU. Modern GPUs do not require disguising general-purpose applications as graphics rasterization tasks. They support a “compute” mode that disables rasterization and allows the SIMD processors to execute directly on input data, and can be programmed directly with general purpose parallel streaming languages, development environments, and libraries such as Nvidia’s CUDA, OpenCL, and Intel’s ArBB.

Ray Tracing

By leveraging the power of parallel processing enabled by the GPU and the multicore PC, ray tracing is becoming a viable alternative to rasterization for the real-time rendering needs of video games, virtual environments, and interactive visualization. Whereas rasterization finds for each polygon which pixels it covers, ray tracing finds for each pixel which polygons cover it (in both cases displaying for each pixel the closest polygon in the view direction). For each pixel, ray tracing constructs a line of sight from the viewer through it into the scene, and intersects that line of sight with

Computer Graphics. Fig. 2 Stages of tracing a ray. (a) Traversing a spatial data structure to find likely candidate elements for intersection. (b) Intersecting an element. (c) Shading the intersection. (d) Spawning secondary rays for reflection, refraction, and shadowing

the scene's geometry. For curved (non-polygonal) surfaces this intersection is a numerical root-finding solver. The intersection point can yield further ray tracing of shadow, reflection, refraction, and other rays to find further illumination from the light sources. This process can be trivially parallelized over the pixels for SIMD processing, but can lead to load imbalance since some pixels miss the scene entirely while others display complex illumination requiring many recursive ray intersections (Fig. 2).

Scenes are often complex, and require complex spatial data structures to efficiently determine which scene elements are intersected by which rays to avoid an expensive all-pairs ray scene intersection. Especially for meshed scenes, ray intersection becomes a spatial database query, using hierarchical or grid structures to organize the scene. When parallelized, this structure needs to be shared or distributed among the processors. When the scene is dynamic, then this structure needs to be updated or reconstructed, which itself can rely on parallel speedups.

The intersection of a pair of rays passing through neighboring pixels often share the same computation and can benefit from spatial coherence and accelerated vector processing. However, the rays they spawn to measure secondary illumination are rarely coherent and their computation can diverge precluding efficient vector processing. Some approaches seek to cache secondary rays into coherent bundles that can be intersected more efficiently, though the expense of the caching and reordering often outweighs the reward of the parallelism speedup.

The GPU, designed for parallel rasterization-based rendering, can be reprogrammed for parallel ray tracing. One approach created a pair of texture images

where each pixel corresponds to a single ray. One texture image's RGB values were the XYZ coordinates of the anchor (origin) of each ray, and a second texture image's RGB values were the XYZ coordinates of the ray directions. Then a single screen-filling quad would be rendered, whose vertices shared the same attribute data, in this case the nine values corresponding to the three coordinates of the three vertices of the triangle. As the screen-filling quad is rasterized, the attribute data is reproduced across each pixel, and when combined with the texture data provided each pixel's shader with access to the quad's triangle and the pixel's ray, allowing it to compute a ray intersection it could report back as the pixel's color and z-value. While it leverages full speed SIMD GPU computation of ray-triangle intersections, this approach requires a lot of CPU communication to coordinate spatial data structures, shading, and spawning new rays.

Ray tracing can be performed completely in SIMD on the GPU by treating the process as a state machine. The process of tracing a ray can be decomposed into four states: (1) traversing a spatial data structure to find which elements might intersect a ray, (2) intersecting the ray with elements, (3) shading the resulting intersection, and (4) spawning new rays to recursively determine illumination. Since the GPU is a SIMD processor (actually a collection of independent SIMD processors) each ray's process must wait until all of the other rays' processors finish the current state before any of them can move to the next state.

Micropolygons

Yet a third rendering approach, called micropolygon rendering, subdivides scene elements in 3-D into small "micropolygons" that each project to about the size of

a pixel and thus do not need to be rasterized. Micropolygons allow surface geometry to be displaced to more easily model embossed surface detail, and since each micropolygon projects to such a small pixel neighborhood, they can more easily be rendered in parallel.

Micropolygons led to the concept of the programmable “shader,” in an application specific little language called Renderman, that led to the vertex and pixel shaders of the modern GPU. The Renderman Shading Language succeeded because it contained a small collection of powerful high-level operators and data structures devoted specifically to the narrow task of illuminating and texturing surfaces. It inspired parallel GPU shader programming languages including Cg, GLSL, and HLSL, which are in comparison less elegant but sought to broaden the scope of GPU programming, eventually to CUDA, OpenCL, and other GPGPU programming frameworks and domain-specific languages for parallel programming.

Bibliographical Notes and Further Reading

Applications of general scientific computing methods to specific problems in graphics can be found throughout the history of computer graphics literature. Some key examples of these are the Metropolis method for Monte Carlo sampling of light paths [1] and solving a symmetric positive definite matrix to find the equilibrium of light in a closed room [2]. Researchers have framed a number of graphics problems, such as seamlessly copying a portion of one image to another [3] or tiling a surface with quadrilaterals [4], as a Poisson partial differential equation, which opened a floodgate of “gradient domain” methods in graphics, solved largely interactively or in real-time by parallel matrix solvers. The GraphCut network optimization method can be used to stitch pixel swatches into an image [5]. Both radiosity [6] and radial basis function surface reconstruction [7] have been accelerated by treating them as N-body problems.

Planar Voronoi diagrams were computed with early parallel graphics hardware by depth-buffered rasterization of cones extending from the data points [8], and a Mandelbrot set could be computed by repeated image operations, called multipass programming [9].

Parallel ray tracing often suffers from memory management issues, especially when reorganizing rays into coherent bundles [10]. This plagued the ray engine which used the GPU to intersect rays and the CPU to manage ray coherence [11], while simpler geometry coherence structures, such as a grid, could be implemented on the GPU in a state-based system [12] suffered from excessive waiting that can be improved through better scheduling [13].

The micropolygon approach was pioneered by Pixar as the REYES (Render Everything You Ever Saw) architecture [14] that formed the basis for the parallel Pixar Image Computer, which could process each micropolygon independently in parallel. This lead to the development of programmable shaders and Renderman [15].

Definition

Concurrent Collections (CnC) is a parallel programming model, with an execution semantics that is influenced by dynamic dataflow, stream-processing, and

tuple spaces. The three main constructs in the CnC programming model are *step collections*, *data collections*, and *control collections*. A step collection corresponds to a computation, and its instances correspond to invocations of that computation that consume and produce data items. A data collection corresponds to a set of *data items*, indexed by *item tags* that can be accessed via *put* and *get* operations; once put, data items cannot be overwritten and are required to be *immutable*. A control collection corresponds to a *factory* [9] for step instances. A put operation on a control collection with a *control tag* results in the *prescription* (creation) of step instances from one or more step collections with that tag passed as an input argument. These collections and their relationships are defined statically as a CnC *graph* in which a node corresponds to a step, data or item collection, and a directed edge corresponds to a put, get, or prescribe operation.

Discussion

Introduction

Parallel computing has become firmly established since the 1980s as the primary means of achieving high performance from supercomputers. Concurrent Collections (CnC) was developed to address the need for making parallel programming accessible to nonprofessional programmers. One approach that has historically addressed this problem is the creation of *domain-specific languages* (DSLs) that hide the details of parallelism when programming for a specific application domain.

In contrast, CnC is a model for adding parallelism to any host language (which is typically serial and may be a DSL). In this approach, the parallel implementation details of the application are hidden from the domain expert, but are instead addressed separately by users (and tools) that serve the role of *tuning experts*. The basic concepts of CnC are widely applicable. Its premise is that domain experts can identify the intrinsic *data dependences* and *control dependences* in their application (irrespective of lower-level implementation choices). This identification of dependences is achieved by specifying a CnC *graph* for their application. Parallelism is implicit in a CnC graph. A CnC graph has a deterministic semantics, in that all executions are guaranteed to produce the same output state for the same

input. This deterministic semantics and the separation of concerns between the domain and tuning experts are the primary characteristics that differentiate CnC from other parallel programming models.

CnC Specification Graph

The three main constructs in a CnC specification graph are *step collections*, *data collections*, and *control collections*. These collections and their relationships are defined statically. But for each static collection, a set of dynamic *instances* is created as the program executes.

A step collection corresponds to a specific computation, and its instances correspond to invocations of that computation with different input arguments. A control collection is said to *control* a step collection – adding an instance to the control collection *prescribes* one or more step instances i.e., causes the step instances to eventually execute when their inputs become available. The invoked step may continue execution by adding instances to other control collections, and so on.

Steps also dynamically read (*get*) and write (*put*) data instances. The execution order of step instances is constrained only by their producer and consumer relationships, including control relations. A complete CnC specification is a graph where the nodes can be either step, data, or control collections, and the edges represent *producer*, *consumer*, and *control* relationships.

A whole CnC program includes the specification, the step code and the environment. Step code implements the computations within individual graph nodes, whereas the *environment* is the external user code that invokes and interacts with the CnC graph while it executes. The environment can produce data and control instances. It can consume data instances and use control instances to prescribe conditional execution.

Collections Indexed by Tags

Within each collection, control, data, and step instances are each identified by a unique *tag*. In most CnC implementations, tags may be of any data type that supports an equality test and hash function. Typically, tags have a specific meaning within the application. For example, they may be tuples of integers modeling an iteration space (i.e., the iterations of a nested loop structure). Tags can also be points in non-grid spaces – nodes in a tree, in an irregular mesh, elements of a set, etc. Collections use tags as follows:

- A step begins execution with one input argument – the tag indexing that step instance. The tag argument contains the information necessary to compute the tags of all the step's input and output data. For example, in a stencil computation a tag “*i, j*” would be used to access data at positions “*i+1, j+1*”, “*i-1, j-i*”, and so on. In a CnC specification file, a step collection is written (*foo*) and the components of its tag indices can optionally be documented, as in (*foo: row, col*).
- Putting a tag into a control collection will cause the corresponding steps (in all controlled step collections) to eventually execute when their inputs become available. A control collection *C* is denoted as *<C>* or as *<C : x, y, z>*, where *x, y, z* comprise the tag. Instances of a control collection contain no information *except* their tag, so the word “tag” is often used synonymously with “control instance.”
- A data collection is an associative container indexed by tags. The contents indexed by a tag *i*, once written, cannot be overwritten (dynamic single assignment). The immutability of entries within a data collection, along with other features, provides determinism. In a specification file a data collection is referred to with square-bracket syntax: [*x:i, j*].

Using the above syntax, together with *:* and → for denoting prescription and production/consumption relations, we can write CnC specifications that describe CnC graphs. For example, below is an example snippet of a CnC specification showing all of the syntax.

```
// control relationship: myCtrl
    prescribes instances of myStep
<myCtrl> :: (myStep);
// myStep gets items from myData, and
    puts tags in myCtrl and items in
    myData
[myData] → (myStep) → <myCtrl>,
[myData];
```

Further, in addition to describing the graph structure, we might choose to use the CnC specification to document the relationship between tag indices:

```
[myData: i] → (myStep: i) → <myCtrl:
    i+1>, [myData: i+1];
```

Model Execution

During execution, the state of a CnC program is defined by *attributes* of step, data, and control instances. (These attributes are not directly visible to the CnC programmer.) Data instances and control instances each have an attribute *Avail*, which has the value *true* if and only if a put operation has been performed on it. A data instance also has a *Value* attribute representing the value assigned to it where *Avail* is true. When the set of all data instances to be consumed by a step instance and the control instance that prescribes a step instance have *Avail* attribute value *true*, then the value of the step instance attribute *Enabled* is set to *true*. A step instance has an attribute *Done*, which has the value *true* if and only if all of its put operations have been performed.

Instances acquire attribute values monotonically during execution. For example, once an attribute assumes the value *true*, it remains *true* unless an execution error occurs, in which case all attribute values become undefined. Once the *Value* attribute of a data instance has been set to a value through a put operation, assigning it a subsequent value through another put operation produces an execution error, by the single assignment rule. The monotonic assumption of attribute values simplifies program understanding, formulating and understanding the program semantics, and is necessary for deterministic execution.

Given a complete CnC specification, the tuning expert maps the specification to a specific target architecture, creating an efficient schedule. This is quite different from the more common approach of embedding

parallel constructs within serial code. Tag functions provide a tuning expert with additional information needed to map the application to a parallel architecture, and for static analysis, they provide information needed to optimize distribution and scheduling of the application.

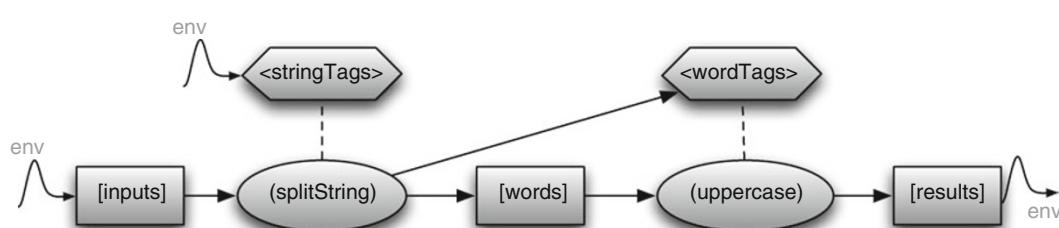

Example

The following simple example illustrates the task and data parallel capabilities of CnC. This application takes a set (or stream) of strings as input. Each string is split into words (separated by spaces). Each word then passes through a second phase of processing that, in this case, puts it in uppercase form.

```
<stringTags> :: (splitString); // step 1
<wordTags>   :: (uppercaseWord); // step 2
// The environment produces initial inputs
// and retrieves results:
env → <stringTags>, [inputs];
env ← [results];
// Here are the producer/consumer relations
// for both steps:
[inputs] → (splitString) → <wordTags>,
[words]; 
[words]   → (uppercaseWord) → [results];
```

The above text corresponds directly to the graph in Fig. 1. Note that separate strings in [input] can be processed independently (data parallelism), and, further, the (splitString) and (uppercase) steps may operate simultaneously (task parallelism).

The only keyword in the CnC specification language is env, which refers to the *environment* – the world outside CnC, for example, other threads or processes

Concurrent Collections Programming Model. Fig. 1 A CnC graph as described by a CnC specification. By convention, in the graphical notation specific shapes correspond to control, data, and step collections. Dotted edges represent prescription (control/step relations), and arrows represent production and consumption of data. Squiggly edges represent communication with the environment (the program outside of CnC)

```

// The execute method "fires" when a tag is available.
// The context c represents the CnC graph containin item and tag collections.
int splitString::execute(const int & t, partStr_context & c ) const
{
    // Get input string
    string in;
    c.input.get(t, in);

    // Use C++ standard template library to extract words:
    istringstream iss(in);
    vector<string> words;
    copy(istream_iterator<string>(iss),
          istream_iterator<string>(),
          back_inserter<vector<string> >(words));

    // Finally, put words into an output item collection:
    for(int i=0; i < words.size(); i++) {
        pair<int,int> wtag(t,i);
        c.wordTags.put( wtag );
        c.words.put( wtag, words[i] );
    }
    return CnC::CNC_Success;
}

// Convert word to upper case form:
int uppercaseWord::execute(const pair<int,int> & t, partStr_context & c ) const
{
    string word;
    c.words.get(t, word);
    strUpper(word);
    c.results.put(t, word);
    return CnC::CNC_Success;
}

int main()
{
    partStr_context c;
    for(...)

        c.input.put(t, string); // Provide initial inputs
        c.wait();               // Wait for all steps to finish
        ...                     // Print results
}

```

Concurrent Collections Programming Model. Fig. 2 C++ code implementing steps and environment. Together with a CnC specification file the above forms a complete application

written in a serial language. The strings passed into CnC from the environment are placed into [inputs] using any unique identifier as a tag. The elements of [inputs] may be provided in any order or in parallel. Each string, when split, produces an arbitrary number of words. These per-string outputs can be numbered 1 through N – a pair containing this number and the original string ID serves as a globally unique tag for all output words. Thus, in the specification we could annotate the collections with tag components indicating the

pair structure of word tags: e.g., (uppercaseWord: stringID, wordNum).

[Figure 2](#) contains C++ code implementing the steps splitString and uppercase. The step implementations, specification file, and code for the environment together make up a complete CnC application. Current implementations of CnC vary as to whether the specification file is required, can be constructed graphically, or can be conveyed in the host language code itself through an API.

Mapping to Target Platforms

There is wide latitude in mapping CnC to different platforms. For each there are several issues to be addressed: grain size, mapping data instances to memory locations, steps to processing elements, and scheduling steps within a processing element. A number of distinct implementations are possible for both distributed and shared memory target platforms, including static, dynamic, or a hybrid of static/dynamic systems with respect to the above choices.

The way an application is mapped will determine its execution time, memory, power, latency, and bandwidth utilization on a target platform. The mappings are specified as part of the static translation and compilation as well as dynamic scheduling of a CnC program. In dynamic run-time systems, the mappings are influenced through scheduling strategies, such as LIFO, FIFO, work-stealing, or priority-based.

Implementations of CnC typically provide a translator and a run-time system. The translator uses a CnC specification to generate code for a run-time system API in the target language. As of the writing of this entry, there are known CnC implementations for C++ (based on Intel's Threading Building Blocks), Java (based on Java Concurrency Utilities), .NET (based on .NET Task Parallel Library), and Haskell.

Step Execution and Data Puts and Gets: There is much leeway in CnC implementation, but in all implementations, step prescription involves creation of an internal data structure representing the step to be executed. Parallel tasks can be spawned eagerly upon prescription, or delayed until the data needed by the task is ready. The `get` operations on a data collection could be blocking (in cases when the task executing the step is to be spawned before all the inputs for the step are available) or non-blocking (the run-time system guarantees that the data is available when `get` is executed). Both the C++ and Java implementations have a rollback and replay policy, which aborts the step performing a `get` on an unavailable data item and puts the step in a separate list associated with the failed `get`. When a corresponding `put` is executed, all the steps in a list waiting on that item are restarted. The Java implementation also has a “delayed async” policy [1], which requires the user or the translator to provide a boolean `ready()` method that evaluates to *true* once all the inputs required by the step are available. Only when `ready()` for a given step

evaluates to *true* does the Java implementation spawn a task to execute the step.

Initialization and Shutdown: All implementations require some code for initialization of the CnC graph: creating step objects and a graph object, as well as performing the initial `puts` into the data and control collections.

In the C++ implementation, ensuring that all the steps in the graph have finished execution is done by calling the `run()` method on the graph object, which blocks until all runnable steps in the program have completed. In the Java implementation, ensuring that all the steps in the graph have completed is done by enclosing all the control collection `puts` from the environment in a Habanero-Java finish construct [14], which ensures that all transitively spawned tasks have completed.

Safety properties: In addition to the differences between step implementation languages, different CnC implementations enforce the CnC graph properties differently. All implementations perform run-time system checks of the single assignment rule, while the Java and .NET implementations also enforce tag immutability. Finally, CnC guarantees determinism as long as steps are themselves deterministic – a contract strictly enforceable only in Haskell.

Memory reuse: Another aspect of CnC run-time systems is garbage collection. Unless the run-time system at some point deletes the items that were put, the memory usage will continue to increase. Managed run-time systems such as Java or .NET will not solve this problem, since an item collection retains pointers to all instances. Recovering memory used by data instances is a separate problem from traditional garbage collection. There are two approaches identified thus far to determine when data instances are dead and can safely be released (without breaking determinism). First, [8] introduces a declarative *slicing annotation* for CnC that can be transformed into a reference counting procedure for memory management. Second, the C++ implementation provides a mechanism for specifying *use counts* for data instances, which are discarded after their last use. Irrespective of which of these mechanisms is used, data collections can be released after a graph has finished running. Frequently, an application uses CnC for finite computations inside a serial outer loop, thereby reclaiming all memory between iterations.

Related Work

Table 1 is used to guide the discussion in this section. This table classifies programming models according to their attributes in three dimensions: *Declarative*, *Deterministic*, and *Efficient*. A few representative examples are included for each distinct set of attributes. The reader can extrapolate this discussion to other programming models with similar attributes in these three dimensions.

A number of lower-level programming models in use today – e.g., Intel TBB [18], .Net Task Parallel Library [19], Cilk, OpenMP [3], Nvidia CUDA, Java Concurrency [17] – are non-declarative, nondeterministic, and efficient. Here a programming model is considered to be efficient if there are known implementations that deliver competitive performance for a reasonably broad set of programs. Deterministic Parallel Java [7] is an interesting variant of Java; it includes a subset that is provably deterministic, as well

as constructs that explicitly indicate when determinism cannot be guaranteed for certain code regions, which is why it contains a “hybrid” entry in the *Deterministic* column.

The next three languages in the table – High Performance Fortran (HPF) [15], X10 [6], Linda [10] – contain hybrid combinations of imperative and declarative programming in different ways. HPF combines a declarative language for data distribution and data parallelism with imperative (procedural) statements, X10 contains a functional subset that supports declarative parallelism, and Linda is a coordination language in which a thread’s interactions with the tuple space is declarative. Linda was a major influence on the CnC design. CnC shares two important properties with Linda: both are coordination languages that specify computations and communications via a tuple/tag namespace, and both create new computations by adding new tuples/tags to the namespace. However, CnC also differs from Linda in many ways. For example, an `in()` operation in Linda atomically removes the tuple from the tuple space, but a CnC `get()` operation does not remove the item from the collection. This is a key reason why Linda programs can be nondeterministic in general, and why CnC programs are provably deterministic. Further, there is no separation between tags and values in a Linda tuple; instead, the choice of tag is implicit in the use of wildcards. In CnC, there is a separation between tags and values, and control tags are first class constructs like data items.

The last four programming models in the table are both declarative and deterministic. Asynchronous Sequential Processes [2] is a recent model with a clean semantics, but without any efficient implementations. In contrast, the remaining three entries are efficient as well. StreamIt [12, 13] is representative of a modern streaming language, and LabVIEW [20] is representative of a modern dataflow language. Both streaming and dataflow languages have had major influence on the CnC design. The CnC semantic model is based on dataflow in that steps are functional and execution can proceed whenever data is ready.

However, CnC differs from dataflow in some key ways. The use of control tags elevates control to a first-class construct in CnC. In addition, item collections allow more general indexing (as in a tuple space) compared to dataflow arrays (I-structures). CnC is like

Concurrent Collections Programming

Model. Table 1 Comparison of several parallel programming models

Parallel prog. model	Declarative	Deterministic	Efficient
Intel TBB [18]	No	No	Yes
.Net Task Par. Lib.	No	No	Yes
Cilk	No	No	Yes
OpenMP [3]	No	No	Yes
CUDA	No	No	Yes
Java Concurrency [17]	No	No	Yes
Det. Parallel Java [7]	No	Hybrid	Yes
High Perf. Fortran [15]	Hybrid	No	Yes
X10 [6]	Hybrid	No	Yes
Linda [10]	Hybrid	No	Yes

StreamIt [12]	Yes	Yes	Yes
LabVIEW [20]	Yes	Yes	Yes
CnC	Yes	Yes	Yes

streaming in that the internals of a step are not visible from the graph that describes their connectivity, thereby establishing an isolation among steps. A producer step in a streaming model need not know its consumers; it just needs to know which buffers (collections) to perform read and write operations on. However, CnC differs from streaming in that put and get operations need not be performed in FIFO order, and (as mentioned above) control is a first-class construct in CnC. Further, CnC's dynamic put/get operations on data and control collections serves as a general model that can be used to express many kinds of applications that would not be considered to be dataflow or streaming applications.

Future Directions

Future work on the CnC model will focus on incorporating more power in the specification language (module abstraction, libraries of patterns) and integration with persistent data models.

Combinations of static/dynamic treatment of scheduling and step/data distribution will continue to be explored. Run-time strategies, such as for reducing overhead for finer-grained parallelism and for memory management, will be developed.

Static graph analysis will play a role in performance optimization in the future.

Bibliographic Notes and Further Reading

The basic principles behind the Concurrent Collections programming model are outlined in [4]. The model is built on past work done at Hewlett Packard Labs on TStreams, described in [16].

A technique is presented in [8] for memory management of data items with lifetimes that are longer than a single computation step.

[5] is a pioneering paper in dataflow languages. For a description of coordination languages and their use, see [11].

Many members of the Concurrent Collections community gathered at workshops held in 2009 (<http://habanero.rice.edu/cnc09>) and 2010 (<http://cnc10.rice.edu/cnc10>).

the term “CML” refers to a specific language implementation, it is also used to refer to implementations of its language primitives in other systems.

Discussion

Concurrent ML Basics

Concurrent ML was designed with the goal of supporting high-level concurrent programming. Its design was originally motivated by the idea that user-interface software should be concurrent and that message passing was the best way to construct such concurrent programs [5, 30, 38]. Its basic concurrency features were heavily influenced by earlier message-passing designs, including Hoare's *Communicating Sequential Processes* [20] and Cardelli's Amber language [6]. Applications of CML include a multithreaded GUI toolkit [18], a distributed tuple-space implementation [37], and a system for implementing partitioned applications in a distributed setting [40].

Because CML is embedded in SML, SML specifications are used to introduce CML's features and the code examples are also written in SML. For readers who are unfamiliar with SML syntax, this paragraph provides a brief description of SML specification and type syntax. Specifications in SML are declarations that appear in the signature of a module and are used to describe the types, values, etc., defined by the module. For example, the `output` function has the specification

```
val output : (outstream * string)
           -> unit
```

which specifies that `output` is a function that takes a pair of arguments, an `outstream` and a `string`, and returns the `unit` value. `Unit` is the type with only one value (written as “`()`”). The symbol “`*`” is the product type constructor and the symbol “`->`” is the function type constructor. Lastly, SML is a polymorphic language, which means that specifications can have universally qualified type variables. For example:

```
type 'a vector
val length : 'a vector -> int
```

is the specification of the abstract vector type constructor and its `length` function. The identifier “`'a`” is an SML type variable. The `vector` type constructor can

Definition

Concurrent ML (CML) is a higher-order concurrent language embedded in the sequential language Standard ML (SML). CML's basic programming model consists of dynamically created threads that communicate via message passing over dynamically created channels. CML also provides *first-class synchronous operations*, called event values, which support user-defined synchronization and communication abstractions. While

be applied to other types to construct arbitrary vector types, such as “int vector” and “int vector vector” (note that type-constructor application is *postfix*). The `length` function will work on any of these vector types, since it is polymorphic.

New threads are created in CML using the `spawn` function, which has the following SML value specification:

```
val spawn : (unit -> unit)
    -> thread_id
```

Because SML is a *strict* functional language, the argument to `spawn` must be encapsulated in a unit to unit function or thunk. The `spawn` function creates a new thread to evaluate its argument and returns the new thread’s ID. CML threads communicate over typed channels that have the following signature:

```
type 'a chan
val channel : unit -> 'a chan
val recv : 'a chan -> 'a
val send : ('a chan * 'a) -> unit
```

Message passing is synchronous: both the `recv` and `send` operation are blocking. The model is distributed in that threads only interact via messages, but it is usually implemented in shared memory and is quite efficient. In addition to channels, CML provides other communication mechanisms, such as asynchronous channels and synchronous variables. The semantics of these mechanisms is defined in terms of the channel and thread operations, but their implementation is more efficient.

As an illustration of these basic primitives, the following code creates a simple producer/consumer thread pair, which communicate over a shared channel:

```
let val ch = channel ()
  fun producer () = (
    send (ch, produce ());
    producer ())
  fun consumer () = (
    consume (recv ch);
    consumer ())
in
  spawn producer;
  spawn consumer
end
```

This code illustrates a couple of idioms that CML inherits from SML. The first is the use of tail-recursion to define threads that loop for ever. The second is the use of lexical scoping to limit access to channels. In this case, the channel `ch` is visible to both the producer and consumer threads, but not outside the scope of the let binding.

First-Class Synchronous Operations

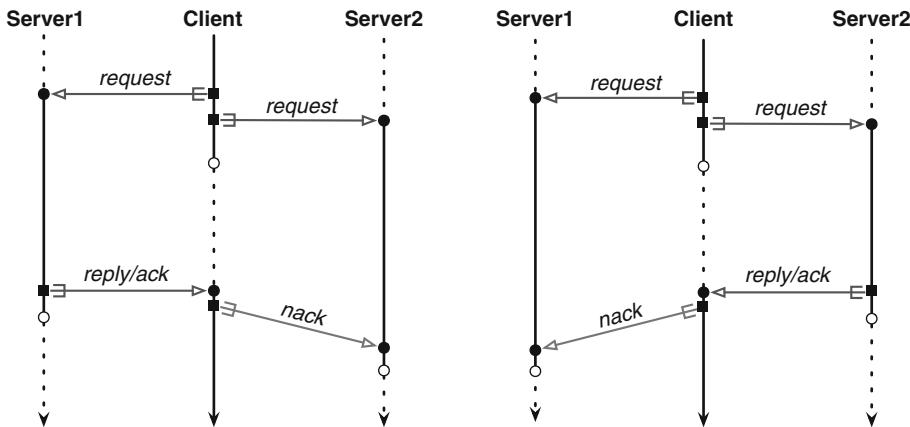

The distinguishing feature of CML is its support for *first-class synchronous operations*. Much the same way that higher-order languages support first-class function values, CML supports first-class synchronization values. This design is motivated by two observations:

1. Most interprocess interactions involve multiple messages
2. Processes need to interact with multiple partners

For example, consider a typical client–server protocol. The client sends a request message to the server and then waits for a reply. But suppose that the client wants to request a result from two different servers, accepting whichever reply it receives first? In that case, the protocol must include a *negative acknowledgment* mechanism for the case where the client wishes to abort the protocol. [Figure 1](#) illustrates the two possible outcomes of this scenario. This example assumes the existence of an asynchronous mechanism for transmitting the negative acknowledgments.

The client-side code for this interaction might look something like the following pseudo-CML code, where each server has its own request channel (`reqCh1` and `reqCh2`) and the requests consist of a triple of the request message, a private reply channel, and a signal variable for aborting the transaction:

```
let val replCh1 = channel()
  val nack1 = cvar()
  val replCh2 = channel()
  val nack2 = cvar()
in
(* send requests to the servers *)
  send (reqCh1,
    (req1, replCh1, nack1));
  send (reqCh2,
    (req2, replCh2, nack2));
(* wait for a reply from one of
 * the servers *)
```

Concurrent ML. Fig. 1 Interacting with two servers

```

selectRecv [
  (rep1Ch1, fn repl1 => (
    set nack2; act1 repl1)),
  (rep1Ch2, fn repl2 => (
    set nack1; act2 repl2))
]
end

```

This example uses two additional concurrency features that are not part of CML, but which can be easily definable in CML. The “cvars” are unit-valued write-once synchronous variables that are used to implement the asynchronous negative acknowledgements, and the `selectRecv` function implements a nondeterministic choice of reading from a list of channels paired with message handlers. As can be seen from this code, the interactions with the two servers are quite entangled. The situation would become even more complicated if a third server were added. Furthermore, the client and server sides of the protocol are split apart, which makes changes to the protocol more difficult to implement.

The traditional mechanism of procedural abstraction is not appropriate in this situation, because it hides away the synchronous aspect of the operations and does not handle the negative acknowledgments.

CML solves this problem by introducing a new abstraction mechanism called *first-class synchronous operations*. It defines a type of abstract values, called events, that represent synchronous operations, such as receiving a message on a channel or a timeout.

`type 'a event`

An event value represents a potential computation with latent communication and synchronization effects. Its type argument specifies the type of the result when a thread synchronized on the event, which is done using the following operator:

`val sync : 'a event -> 'a`

Base-event constructors create event values for the channel communication primitives.

```

val recvEvt : 'a chan -> 'a event
val sendEvt : 'a chan * 'a
      -> unit event

```

Note that these functions are *pure* – they define event values but have no side effects themselves. They also satisfy the obvious equations:

$$\begin{aligned} \text{sync} \circ \text{recvEvt} &= \text{recv} \\ \text{sync} \circ \text{sendEvt} &= \text{send} \end{aligned}$$

The power of events comes from the combinators that CML provides for building more complicated values. The first of these is the `wrap` combinator, which takes an event value and a post-synchronization action and returns a new event that will apply the action after synchronization. It has the type

```

val wrap : ('a event * ('a -> 'b))
      -> 'b event

```

and satisfies the equation

$$\text{sync}(\text{wrap}(ev, f)) = f(\text{sync } ev)$$

for any event value ev and function f that are well typed for the context.

The second combinator is `choose`, which takes a list of event values and returns a new event that represents the nondeterministic choice of the events in the list. It has the type

```
val choose : 'a event list  
      -> 'a event
```

Note that all of the events in the list must have the same result type, but one can use `wrap` to convert between types as necessary. The `sync` operator and `wrap` and `choose` combinators define the *PML subset* of CML, which is named after the first language to support first-class synchronization [34]. Full CML adds two event-generator combinators, which are used to define pre-synchronization operations. The first of these is the `guard` combinator, which takes a event-valued function and returns an event value that will evaluate the function at synchronization time and then synchronize on its result. It has the type

```
val guard : (unit -> 'a event)  
      -> 'a event
```

and satisfies the equation

$$\text{sync}(\text{guard } f) = \text{sync}(f())$$

for any function f that is well typed for the context. Typically the `guard` combinator is used to package up operations, such as initiating a transaction with a server, that should be done before synchronization. As long as the operations in the function are idempotent, `guard` is sufficient, but when they are not, some additional mechanism is required for aborting the transaction. The final event combinator provides this mechanism:

```
val withNack :  
      (unit event -> 'a event)  
      -> 'a event
```

Like `guard`, its argument is a function that is evaluated at synchronization time to produce an event value, which is then synchronized on. What is different is that the function is passed an event-valued argument, which is a negative-acknowledgment event that is used to signal when some other event in the synchronization is chosen instead.

A more modular interface to the servers in the client–server example from above can be implemented using CML’s abstraction mechanisms. Using event values, one can define an abstract interface that hides the details of the client–server protocol from the client:

```
type server  
val rpcEvt : (server * req)  
      -> repl event
```

With this interface, the client-side code has a clear separation of concerns between the interactions with the two servers.

```
sync (  
  choose [  
    wrap (rpcEvt server1,  
          fn repl1 => act1 repl1),  
    wrap (rpcEvt server2,  
          fn repl2 => act2 repl2)  
  ] )
```

The implementation of this interface is straightforward using CML’s event combinators. The server type is represented by a request channel that takes a triple of the request message, a private reply channel, and a negative-acknowledgment event that signals when the transaction should be aborted.

```
type req_msg =  
  (req * repl chan * unit event)  
type server = reqmsg chan
```

The `rpcEvt` function is implemented using the `withNack` combinator.

```
fun rpcEvt (serverCh, req) =  
  withNack (fn nackEvt => let  
    val replCh = channel ()  
    in  
      send (serverCh,  
            (req, replCh, nackEvt));  
      recvEvt replCh  
    end)
```

Modularity is supported by defining the `rpcEvt` function in the module that implements the service and only exposing the abstract interface to clients.

Event values also provide a uniform framework for incorporating other types of synchronous operations into the language. For example, synchronizing on thread termination is supported by the combinator

```
val joinEvt : thread_id
    -> unit event
```

and timeouts are supported by

```
val timeOutEvt : time -> unit event
```

System services, such as I/O and system-process management, are also modeled as event-valued operations.

Events can also be used to implement many of the high-level concurrency mechanisms that have been defined over the years, including Ada's rendezvous mechanisms [12], Multilisp's futures [19], asynchronous RPCs (or promises) [25], Linda-style distributed tuple spaces [7], and the Join-calculus communication mechanisms [17]. Many of these implementations are described in the definitive description of CML: *Concurrent Programming in ML* [37].

Semantics and Analysis

Since its earliest days, CML has been the subject of research on the semantics of concurrent languages and on program analyses for concurrent programs [3, 36].

Because CML provides a mechanism for implementing communication and synchronization abstractions, one might ask what expressiveness limits are there on these abstractions? The answer is that it depends on the underlying communication primitives. In the case of CML, which provides synchronous communication with output guards (i.e., `sendEvt`), communication mechanisms that require two-way common knowledge can be implemented, but it is not possible to define a three-way synchronization mechanism [28]. If CML were based on asynchronous message passing (i.e., non-blocking send) or did not have output guards, then even two-way common knowledge would be impossible to achieve.

The problem of program analysis for CML has also been studied by a number of researchers. Nielson and Nielson developed an effects-based analysis for detecting when programs written in a subset of CML have *finite topology* and thus can be mapped onto a finite processor network [27]. Debbabi *et al.* developed a

type-based control-flow analysis for a CML subset [10], but did not propose any applications for their analysis. Colby developed an abstract-interpretation for a subset of CML that is based on a semantics that uses control paths (i.e., an execution trace) to identify threads. Unlike using spawn points to identify threads (as in [21]), control paths distinguish multiple threads created at the same spawn point, which is a necessary condition to understand the topology of a program. Reppy and Xiao developed an analysis for CML that can be used to specialize channel primitives for better performance in a parallel implementation of CML [32]. For example, if a channel is only used for point-to-point communication, then it can be implemented using fixed storage and an atomic swap instruction.

Implementations

The idea of awarding first-class status to synchronous operations was first implemented as part of the PML language [34], which was the metalanguage for the Pegasus system designed at Bell Laboratories [38]. These ideas were then reimplemented as Concurrent ML on top of the Standard ML of New Jersey system (SML/NJ) [1] and released in the autumn of 1990. As discussed above, CML extended the PML design with two important combinators: `guard` and a precursor to `withNack` called `wrapAbort` [35]. These primitives greatly increased the expressiveness of the mechanism. CML continues to be distributed as part of SML/NJ.

CML's implementation uses SML/NJ's heap-allocated first-class continuations to implement threads [2]. This implementation strategy has three important advantages: The implementation is written in a high-level language (SML), threads are extremely lightweight in both space and time, and threads are garbage collected. CML is preemptively scheduled, but, like most of the user-space threading libraries developed in the 1980s and 1990s, it does not support multiprocessors (the main reason for this lack of multiprocessor support is because the underlying SML/NJ system does not support multiprocessors). Because the main motivation for CML was the use of concurrency as a programming idiom, and not parallelism, the lack of multiprocessor support was not a major concern. More recently, there has been an interest in parallel implementations of the

CML primitives. Reppy and Xiao developed an *optimistic concurrency* algorithm for the asymmetric subset of CML (i.e., CML without output guards) [33]. This algorithm was later extended to include support for the full range of CML primitives and has been implemented both as part of the Manticore system [16] and as a library in C# [31].

In addition to the SML/NJ implementation, the CML design has been ported to a number of other systems and languages, including other implementations of SML, other dialects of ML, other functional languages, such as Haskell and Scheme, and other high-level languages, such as Java.

- MLton is a whole-program optimizing compiler for Standard ML, which has its own implementation of the CML primitives [26]. Like the SML/NJ version, it multiplexes CML threads onto a single system thread and supports preemptive scheduling. Its implementation of threads is stack based, so they are somewhat heavier than the SML/NJ version and are not garbage collected. This implementation is being used by Jagannathan and his students to explore concurrent language design [41].
- One of the earliest re-implementations of CML was in the OCaml system, which is another dialect of ML [24].
- There have been two implementations of CML's primitives in Haskell [8, 39]; both implemented using the primitives of Concurrent Haskell [29]. These implementations support multiprocessors, since the underlying Concurrent Haskell implementation runs on multiprocessors.
- The PLT-Scheme system implements CML-style concurrency with an additional mechanism, called *kill-safe abstractions*, to support safe asynchronous termination of threads [15]. The Scheme 48 system also supports CML-style concurrency [22].
- Outside of the world of functional languages, the CML primitives have been reimplemented in Java [11] and C# [31].

Derivatives

CML has also served as the basis for further research into language mechanisms for concurrency. One of the first examples is Krumvieda's *Distributed ML* language

[9, 23], which combined the Isis model of atomic multicast [4] with CML's events.

More recently, researchers have been exploring the marriage of software transactions with CML's events. Donnelly and Fluet generalized the idea of events to allow protocols that involve multiple synchronization points [13]. They defined a new combinator

```
val thenEvt :
  'a event * ('a -> 'b event)
  -> 'b event
```

with the semantics that the expression *thenEvt evf* defines an event value, which synchronizes on *ev*, passes the result to *f*, and then synchronizes on the result of *f*. The key feature of this combinator is the synchronization is *transactional*; i.e., either all the synchronizations occur or none. Donnelly and Fluet's design was implemented in Haskell, but it has been adapted to ML by Effinger-Dean, Kehrt, and Grossman [14]. A related idea is the notion of *stabilizers*, which are a checkpointing mechanism for CML programs [41].

Definition

Congestion appears in an interconnection network when intense traffic clogs any number of internal network paths, thus slowing down traffic flowing. Congestion management refers to any strategy focused on avoiding, reducing, or eliminating network congestion and/or its negative impact on network performance.

Discussion

Introduction

Congestion is a phenomenon that may dramatically degrade network performance. Congestion situations may actually appear in both computer communication networks (like the Internet) and interconnection networks of parallel computing systems. In the former, packet dropping is allowed ("lossy" networks), thus congestion is not a critical problem as congested packets can be discarded. Nevertheless, congestion should be avoided because dropped packets have consumed

bandwidth, thus wasting it, and packet retransmissions significantly increase individual packet latency. In the latter, on the contrary, packets usually can not be discarded ("lossless" networks) due to the prohibitive delay in detection mechanisms and retransmissions for current parallel applications. Moreover, the designers of interconnection networks for modern parallel systems try to use as few network components as possible, due to their high cost and power consumption, but this increases link utilization, thus making congestion situations more likely to happen. Even when interconnection networks are overdimensioned, the actions taken by power management mechanisms tend to bring the network close to saturation, with identical consequences.

Therefore, in modern, high-performance parallel computing systems, thorough strategies should be used in order to solve the problems related to congestion situations that may arise in the network interconnecting processing or storage nodes. In fact, congestion management is one of the most important issues that high-performance interconnect designers face nowadays, always trying to guarantee a certain network performance level, even in congestion situations. The following sections offer an overview of the congestion phenomenon, its effects on network performance and the most common approaches to deal with congestion in parallel computing systems.

Congestion in Interconnection Networks

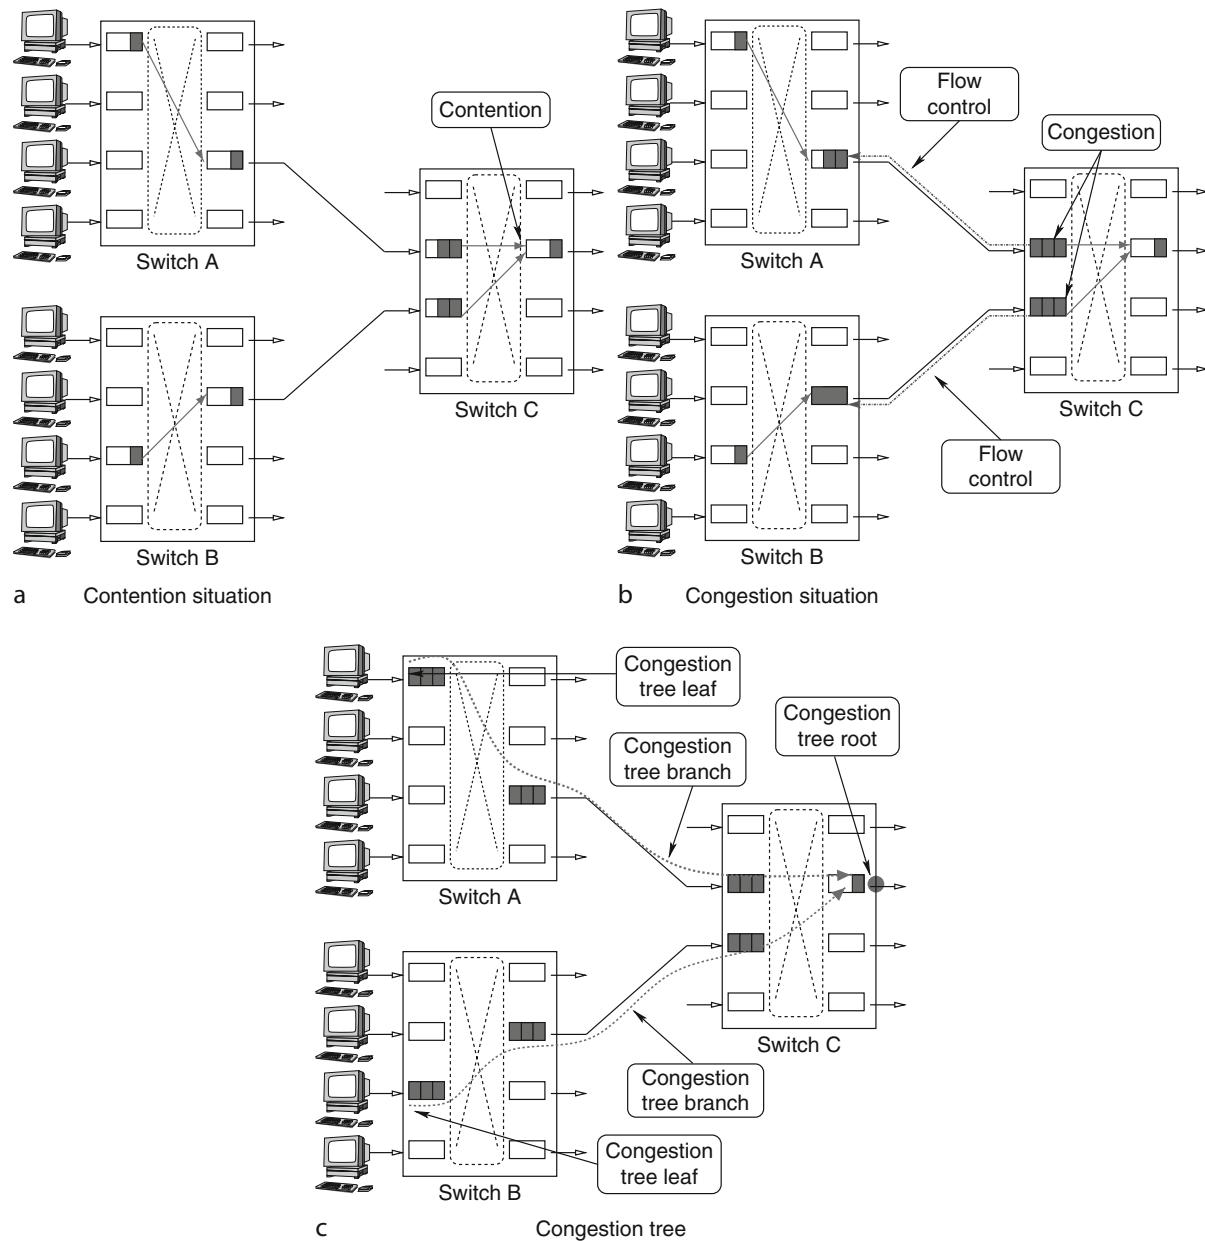

As mentioned above, congestion may appear under conditions of intense traffic in the network, when some of its internal paths, or sections of paths, become jammed. However, this idea is just the most basic definition of that phenomenon, while any study of the main congestion management strategies requires a deeper, previous analysis of both the congestion formation process and its consequences.

Congestion Basics

The immediate cause of congestion situations in interconnection networks is contention, which happens when several flows of packets crossing the network simultaneously request access to some network resource (typically, a switch output port). If the internal

speedup of switches (the maximum speed at which packets can be forwarded from input to output ports, relative to link speed) is not enough for granting several requests at the same time, the access to the requested output port will be granted to only one packet, while the rest must wait. [Figure 1a](#) shows a contention situation caused by two incoming flows requesting the same

output port at Switch C. In this example, it is assumed that switch speedup is 1. Note that the example (and the following ones) shows switches with buffers (queues) at both input and output ports, but it could be easily adapted to switches with other queue schemes. Note also that the requested output port may be connected to an end node or to another switch.

Congestion Management. Fig. 1 Contention and congestion in switches of an interconnection network

When contention persists over time, congestion appears. In these situations, the buffers containing the blocked packets will be filled and the flow control, in lossless networks, will prevent other switches (or end nodes) from sending packets to the congested ports. Although flow control is essential to avoid discarding packets, it will rapidly propagate congestion to other switches, as packets stored at some of their ports will also be blocked. [Figure 1b](#) shows a congestion situation whose origin is the contention situation shown in [Fig. 1a](#). In this example, it is assumed that the network is a lossless one (so, packets are not discarded when buffers are full), and also that the sources of the contending flows continuously inject packets into the network. These flows contributing to congestion are usually referred to as “congested flows.” Note also that packet-level flow control is assumed, but a similar situation could be easily imagined for networks using flow control at other levels (flit-level, for instance).

In this way, congestion may progressively spread through the network, even reaching the sources of congested flow packets. The whole of the network resources affected by the spreading of congestion is commonly known as a “congestion tree.” In a congestion tree, the “root” is the point where the congested flows finally meet, the “branches” are series of consecutive congested points along any path followed by congested flows, and the “leaves” are the points at the extreme of each branch. [Figure 1c](#) shows the final congestion tree that is formed from the congestion situation shown in the previous examples.

Note that the congestion tree shown in [Fig. 1c](#) is a very simple example, since congestion trees may exhibit very complex dynamics. In fact, congestion trees may actually evolve in very different ways, depending on traffic patterns, routing schemes, and switch architecture, as shown in [9]. For example, a congestion tree may grow from leaves to root and vice versa. Also, several congestion trees may grow independently and later merge, and it is even possible that some trees completely overlap while being independent.

Congestion Impact on Network Performance

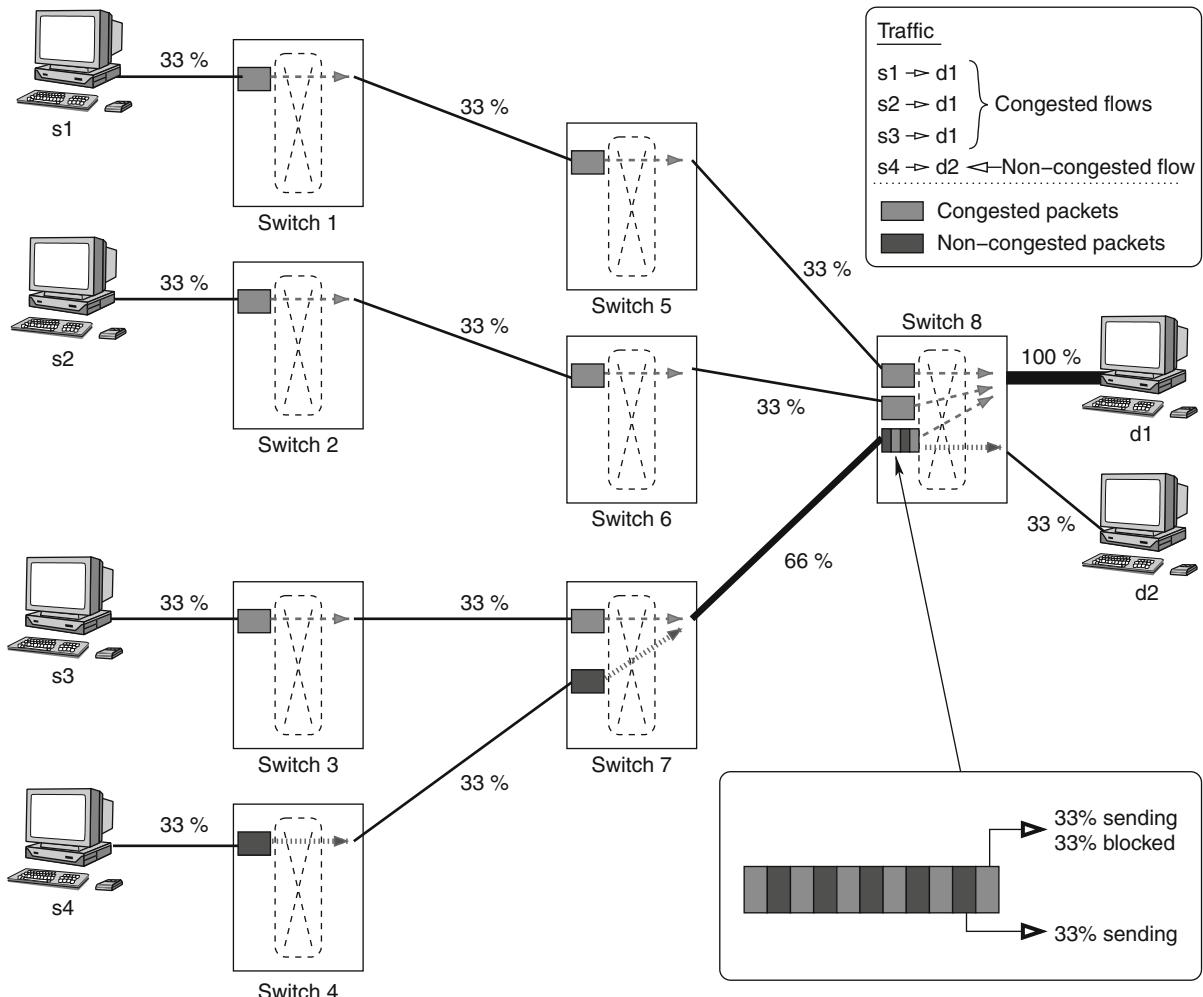

It is a well-known fact that the presence of congestion trees in a network may dramatically degrade network performance. Specifically, it has been exhaustively

reported that congestion leads to a decrease in network throughput and to an increase in packet latency. However, if the simple congestion tree described in the previous example is considered, it is not obvious that it could produce these effects in the network. Note that, in fact, the congested output port in the example could forward packets at maximum rate, and congested packets advance at the maximum possible speed for that specific traffic load. Thus, if the presence of congestion trees does not directly imply any negative effect, which is the actual cause of network performance degradation under congestion situations?

The answer to the previous question is that congested flows are actually dangerous when they share network resources (buffers, links) with other, non-congested flows. In these cases, the final effect is non-congested flows advancing at the same speed as congested ones, thereby increasing the latency of non-congested packets and decreasing overall network throughput.

[Figure 2](#) shows an example of this “real” negative effect of congestion trees. In this example, it is assumed that four sending end nodes (sources s1, s2, s3, and s4) inject packets at the maximum speed allowed by the network at any time, while there exist two receiving end nodes (destinations d1 and d2). As can be seen, three sources (s1, s2, and s3) inject packets addressed to the same destination (d1), forming a congestion tree whose root is at the output port leading to d1. Although there exists another flow in the network (from s4 to d2), it is a non-congested flow, since packets belonging to this flow do not request to cross the root of the tree. Since the three congested flows that create the tree meet at Switch 8, they must share the bandwidth of the link that connects the root point to d1. Therefore, assuming a fair arbitration from the switch scheduler, each congested flow will cross Switch 8 at a speed equal to one third (33%) of the maximum link rate. Moreover, due to the spreading of congestion by means of flow control, all the packets along the congestion tree branches will advance at the same speed, and finally even the sources of these packets will be forced to slow injection until this rate. The figure indicates link utilization percentages when the network reaches this “stable” state.

Note that the utilization of the link that connects the hot-spot destination (d1) to the network is maximum (100%), so it is not possible to improve network

Congestion Management. Fig. 2 Congestion tree causing Head-Of-Line (HOL) blocking to a non-congested flow

throughput at this point. In fact, network throughput would be the maximum if only congested flows exist. As mentioned above, this means that the mere existence of the congestion tree does not justify by itself the network throughput degradation observed in congested networks. On the contrary, note that the link leading to d_2 is used only at 33% of the maximum link rate. However, there is no contention for this link, since only one flow requests to access it. So, why is not this link used at full rate? This is because the non-congested flow requesting this link follows a path partially affected by the congestion tree, in such a way that packets belonging to the non-congested flow share a link and a queue with congested flow packets. Due to this sharing, non-congested flow packets advance at the same speed

as the congested flow ones. Note that, without this interaction between congested and non-congested packets, the link leading to d_2 would be used at maximum link rate.

Therefore, the cause of network performance degradation associated to congestion is that packets belonging to congested flows may prevent other flows from advancing at the injection rate, even if they belong to non-congested flows. Actually, this effect is a generalization of the phenomenon known as Head-Of-Line (HOL) blocking, which, in general, happens whenever a packet ahead of a First In, First Off (FIFO) queue blocks, preventing the rest of packets in the same queue from advancing. In fact, congested packets may produce HOL blocking to non-congested ones in any network point

where both types of packets share network resources. Of course, the wider the congestion tree, the greater the probability of HOL blocking caused by congested packets.

In conclusion, the performance degradation (throughput decreases, latency increases) that networks suffer in the presence of congestion trees is due to the HOL blocking that congested flows cause to non-congested ones when they share network resources. As explained in the following, some congestion management strategies are based on that principle, while others deal with congestion without explicitly considering HOL blocking.

Congestion Management Strategies

As mentioned in the introduction, congestion management is currently an essential issue in the design of the interconnection network of modern parallel computing systems. In fact, it has been a popular research topic for many years, thus existing many approaches to solve the problems related to congestion. The most relevant of these approaches are analyzed below. As several specific strategies that differ in some aspects or details may share the same basic approach, different strategies may appear in the following grouped into the same category, although independently described when necessary. Note, however, that taxonomies of congestion management techniques different than the one shown here are perfectly possible. Note also that some of the strategies described below are currently obsolete or unfeasible in modern interconnect technologies, but they have been considered in order to offer a wide overview of both past and present strategies.

Packet Dropping

This approach, as it has already been explained, consists in discarding packets when congestion occurs. Ideally, the discarded packets should be those actually contributing to congestion, i.e., packets belonging to congested flows. Obviously, if congested packets are discarded, congestion trees would disappear or even would never form, depending on the criteria for detecting congestion. Thus, theoretically, this approach would straightforwardly solve the problems congestion may produce.

However, packet dropping presents some drawbacks that make it not suitable for current high-performance

interconnection networks. First, it is quite difficult to implement this strategy without discarding packets belonging to non-congested flows. For instance, in a queue shared by congested and non-congested packets, instead of just emptying the buffer at once, it would be necessary to perform some kind of “selective discarding” in the usual FIFO queues, thus introducing significant complexity and probably an additional delay. Second, and more important, for most parallel applications packets that are discarded must be retransmitted, thus increasing final packet latency. Note that in these cases non-congested packets may experience a delay similar (or even worse) to the one they suffer in the presence of congestion trees; thus, this approach may produce the same effect that the phenomenon it tries to avoid!

Summing up, the congestion detection and packet dropping processes, and the associated re-transmissions may lead to some packets experiencing a very high latency, which may have a direct impact on application execution time in a parallel computer. In particular, parallel applications with Quality of Service (QoS) requirements would be very sensitive to this effect. For that reason, this congestion management approach is invalid for the interconnection networks of current parallel computing systems. In fact, modern high-performance interconnect technologies do not allow packet dropping (they are “lossless” networks). However, packet dropping is allowed in other environments (for instance, computer networks like the Internet) where latency requirements are not strict at all.

Network Overdimensioning

Overdimensioning the network consists in using many more network components than the minimum required for connecting all the system end nodes, with the aim of making the network to operate well below the saturation point, thus keeping low link utilization and thus reducing congestion probability. Obviously, a network offering much more bandwidth than the required by the applications is unlikely to suffer congestion situations.

This was a valid approach for parallel systems some time ago, when network utilization in parallel machines and clusters was low. However, overdimensioned networks are becoming inappropriate for current parallel systems due to cost and power consumption constraints. On the one hand, current interconnect

components are very expensive when compared to processors. Thus, the network represents a high percentage of the total system cost. On the other hand, as VLSI technology advances and link speed increases, interconnects are consuming an increasing fraction of the total system power. Moreover, current high-speed links require continuous pulse transmission in order to keep both ends synchronized, even when no data are being transmitted. As a consequence, link power consumption is almost independent of link utilization. Note that dynamic frequency/voltage scaling techniques could be used in order to reduce power consumption, but unfortunately the efficiency of these proposals is not completely satisfactory due to their slow response against traffic variations and the suboptimal frequency/voltage settings during transitions. Anyway, even if these techniques were more efficient, they would not solve the cost problem.

Therefore, a trend in current network design is to reduce the number of networks components with the aim of reducing both system cost and power consumption. Obviously, if the system computational power must be maintained, then the only ways to reduce the number of network components are to increase the number of end nodes attached to each switch (note that most current interconnect technologies allow that) or to use a more suitable network topology. However, any of these solutions lead to a higher level of link utilization, thereby driving the network to work closer to its saturation point, and thus increasing congestion probability.

Summing up, overdimensioning the network is practically unfeasible in current parallel systems, which in fact are prone to suffer congestion situations due to the low number of components used to build their interconnection networks, thus requiring specific, efficient congestion management mechanisms.

Avoidance-Based Strategies

This category includes all the techniques based on planning the use of network resources, in order to find a schedule, which guarantees that congestion never appears. Following this schedule, the network resources required by each data transmission are reserved before starting it, thus avoiding congestion situations. Some of these techniques are software-based, while others are hardware-oriented.

Note that these strategies need to know in advance both the resource requirements of each transmission and the occupancy of network resources, in order to obtain the optimal resource reservation schedule. However, this knowledge is not always available. Besides, resource reservation incurs significant overhead. Thus, this kind of technique is not suitable for general-purpose congestion management. In fact, these strategies are strongly related to QoS provision, and most of them have been proposed in that sense, thereby only implicitly addressing congestion. An example of these strategies is the one proposed in [15].

Prevention-Based Strategies

Prevention-based strategies control the traffic in such a way that congestion trees should not happen. In general, decisions are made “on the fly,” based on limiting or modifying routes (or memory accesses) with the aim of preventing the appearance of congestion situations, as proposed in [11].

Like avoidance-based strategies, prevention-based techniques need a knowledge of network status in order to obtain the optimal traffic schedule. Consequently, their drawbacks are basically the same as the aforementioned ones for the former category. Analogously, these techniques can also be software-based or hardware-oriented.

Note that the differences between avoidance-based and prevention-based strategies are quite subtle, and, in fact, in some taxonomies both types are grouped into the same category. In this case, all these strategies are usually referred to as “proactive” strategies, because they all try to solve congestion before it appears.

Reactive Techniques

Reactive (or detection-based) techniques are based on detecting the appearance of congestion, in order to activate some control mechanism that should eliminate any possible congestion tree in the network. Note that in this case, in contrast with the two previous approaches, congestion situations are actually allowed to happen, assuming that the control mechanism will finally solve the problem.

This basic approach has been followed by many proposals, which mainly differ in two aspects: the congestion detection criteria and the mechanism in

charge of eliminating congestion. Regarding congestion detection, some feedback information is usually required. For instance, some proposals locally measure the occupancy of buffers in the switches, while other techniques (especially in multiprocessor systems) monitor the amount of memory access requests.

Regarding congestion elimination mechanisms, most of them involve notifying the end nodes of the congestion so that they throttle the injection of packets or they cease (or reduce) memory access requests. Depending on which end nodes receive congestion notifications, reactive techniques can be divided into three subcategories:

1. Congestion notifications are broadcast to all the end nodes.
2. Notifications are sent only to end nodes contributing to congestion.
3. Notifications are sent only to end nodes attached to the switch where congestion is detected.

It is obvious that if the first (broadcast) notification policy is implemented, a large fraction of the offered network bandwidth is consumed for sending notifications, thus inefficiently using network resources. Another serious drawback, common to the first and second notification policies, is the lack of scalability, as in these cases reaction time is directly proportional to the distance from the point where congestion is detected to the traffic sources. Therefore, if network size and/or link bandwidth increase, the effective delay between congestion detection and reaction increases linearly. Note that during this time, a high number of packets contributing to congestion could be injected, in such a way that, by the time congestion notifications reach the sources, big congestion trees may have already been formed. All that leads to slow response and the typical oscillations that arise in closed-loop control systems with delays in the feedback loop, thus the first two notification policies may be not appropriate for many networks, especially for those with long round trip times (RTTs). The third notification policy (used, for instance in [2]), however, does not present the described scalability problems, but, unfortunately, it fails if the sources contributing to congestion are not attached to the switch where congestion is detected. As this is perfectly possible, the efficacy of the third policy would vary depending on congestion

trees' shape (which, as mentioned above, depends on several factors).

HOL Blocking Elimination Techniques

While the aforementioned strategies try to eliminate, reduce, or delay congestion itself, other techniques focus on eliminating the actual cause of performance degradation under congestion situations: The HOL blocking. In fact, note that, if the HOL blocking produced by congested packets is eliminated, congestion becomes harmless. Most of the existing HOL blocking elimination proposals are based on having different queues at each switch port, in order to separately store packets belonging to different flows, thus lowering HOL blocking probability. Note that congestion trees would not be eliminated but isolated as much as possible, in order to avoid interaction with non-congested flows. This is the common basic approach followed by several techniques which, on the other hand, differ in many aspects, basically in the number of queues required, in the policy for mapping packets to queues, and in queue management.

For instance, a well-known HOL blocking elimination technique is Virtual Output Queues (VOQs) [3], which requires at each port as many queues as destinations in the network. This scheme allows that, at each port, all the packets addressed to a specific destination are exclusively stored in the queue assigned to that destination, and never share that queue with packets addressed to other destinations, thus completely eliminating HOL blocking. However, as the number of queues per port grows with the number of destinations, this scheme does not scale with network size, becoming unfeasible in medium or large networks (note that each queue requires a minimum silicon area to be implemented).

In order to overcome this problem, a variation of this scheme uses as many queues at each port as output ports in the switch [1], and each incoming packet is stored in the queue assigned to its output port. This scheme is usually referred to as VOQ at switch level (VOQsw), in contrast to the former scheme, that may be named as VOQ at network level (VOQnet). VOQsw scales with network size, and it eliminates HOL blocking in a switch if it is directly caused by packets contending for output ports in the same switch. On the contrary, in switches affected by congestion

“spreading” from other switches, VOQsw cannot guarantee that congested packets do not share queues with non-congested packets, thus VOQsw eliminates just partially HOL blocking. The Dynamically Allocated Multi-Queues (DAMQs) technique [14] uses the same queue scheme, although in this case the size of queues may dynamically vary when required. Virtual Channels [4] may also reduce HOL blocking at the switch level but do not eliminate it.

Another scalable solution is the Destination-Based Buffer Management (DBBM) strategy [13]. This proposal also uses a reduced set of queues at each port, but in this case packets are assigned to queues according to a modulo-mapping function: a packet with destination D is stored in the queue whose number is $D \bmod N$, where N is the number of queues in a port. As a result, a set of nonconsecutive destinations are assigned to each queue, thus packets addressed to a congested destination produce HOL blocking only to packets addressed to destinations in the same set. Dynamic Switch Buffer Management (DSBM) also assigns sets of destinations to queues, but in this case it assigns depending on queue occupancy. Note that these solutions, as VOQsw, eliminate HOL blocking just partially, as congested packets are allowed to share queues with non-congested ones.

In general, for all the aforementioned HOL blocking elimination techniques, the greater the number of queues per port, the more HOL blocking is eliminated. This is because congested packets are not explicitly identified, and consequently the probability of isolating them grows with the number of queues. Moreover, note that packets are assigned to queues following “static” criteria, independently of network status.

By contrast, other solutions detect congestion in order to explicitly identify congested packets, later isolating them in dynamically allocated queues. Note that these queues would only store packets belonging to congested flows (i.e., those packets that could produce HOL blocking), and if these flows vanish, the corresponding queues could be deallocated and later reallocated for new congested flows. In this way, these techniques are able to eliminate HOL blocking without relying on an unaffordable number of queues, thereby achieving scalability. In that sense, the solution proposed in [12] for the ATLAS I assigns queues to isolate packets addressed to congested end nodes. However, in many cases congestion arises inside the network, thus in these cases

this solution would not accurately detect congestion and it would not efficiently eliminate HOL blocking. On the contrary, other proposals dynamically assign queues to isolate packets addressed to congested points, either inside the network or end nodes. This is the case for the Regional Explicit Congestion Notification (RECN) [6] and the Flow-Based Implicit Congestion Management (FBICM) [7] techniques, which probably achieve the most effective HOL blocking elimination that can be obtained with a reduced set of queues. RECN has been proposed for technologies using source routing, while FBICM for deterministic distributed routing networks. Note that both strategies require control memories at ports in order to keep track of congestion information and to manage the dynamic queues (specifically, CAM memories are used). Additionally, special control messages exchanging congestion information between switch ports are necessary. Summing up, these two strategies are very effective and scalable, but their implementation is not simple.

Other Approaches

Other strategies that may help to alleviate congestion or delay its appearance are the use of fully adaptive routing [5] or load balancing techniques [8]. In order to be actually effective against congestion, these strategies should take into account network status for making routing decisions, as the technique proposed for Networks-on-Chip (NoCs) in [10] does. Note, however, that these techniques delay the appearance of congestion, but cannot avoid network performance degradation if congestion is reached (especially under heavy traffic loads). Moreover, adaptive routing may cause out-of-order packet delivery, which is unacceptable for some parallel applications.

Future Directions

Despite many proposals for solving the problems related to congestion in interconnection networks, congestion management can be considered still an open issue. On the one hand, some solutions cannot guarantee that network performance will not suffer a significant degradation in congestion situations. On the other hand, other solutions minimize the impact of congestion but are difficult to implement because they either consume too many network resources, or require expensive additional resources, or increase switch complexity. As concerns about network components’ cost and

power consumption are not likely to disappear, cost-effective approaches will probably be the most popular ones in the future.

In that sense, as mentioned above, the strategies currently offering the best relationship among efficacy, feasibility, and scalability are probably the ones based on eliminating HOL blocking, especially those that dynamically assign queues to isolate congested packets. Therefore, it make sense that future proposals about congestion management should try, at least, to improve the efficacy and/or cost-effectiveness of such strategies, although it does not necessarily imply they should follow the same approach to solve the problems related to congestion. In particular, in some emerging technologies like NoCs, where silicon area and power consumption constraints are quite strong, most existing solutions are not suitable at all, thus new approaches should be proposed to deal with congestion in these environments.

Bibliographic Notes and Further Reading

As can be drawn from the number and diversity of the aforementioned strategies, there is a huge research body in the congestion management area (although, as mentioned above, not all the strategies are suitable for the interconnection networks of modern parallel systems). Moreover, new proposals focused on or related to congestion are not currently infrequent in journals and conferences. Of course, this is a consequence of both the serious impact of congestion situations in network performance and the aforementioned difficulties for achieving a truly efficient congestion management. Taking all that into account, most of the references included below in the bibliography are just a small selection from a vast number of works proposing strategies to solve the problems related to congestion. Note, however, that there exist few studies, like the one shown in [9], devoted to the complex dynamics of the congestion phenomenon in interconnection networks.

Connection Machine

GUY L. STEELE JR.
Oracle Labs, Burlington, MA, USA

Definition

The term “Connection Machine” refers to massively parallel supercomputers manufactured by Thinking Machines Corporation. The CM-1 (1985) was a purely SIMD architecture intended for artificial intelligence (AI) applications; 65,536 single-bit processors were connected by a hypercube network. The CM-2 (1987) added 32-bit-wide floating-point coprocessors and set performance records for numerical applications. The CM-5 (1991) was MIMD, using Sun Microsystems SPARC processors connected by a fat-tree network to drive proprietary SIMD floating-point coprocessors. The first TOP500 Supercomputer List (June 1993) showed that the four fastest supercomputers were CM-5 systems, and 25 of the top 100 were either CM-2 or CM-5 systems.

Discussion

Origins

Influential predecessors of the initial Connection Machine architecture include the Illiac IV, the ICL Distributed Array Processor (DAP), and the Goodyear Massively Parallel Processor (MPP). Certain other early designs also merit discussion.

While the Illiac IV [3, 7] never met its original design goals, it was for a time the world’s fastest supercomputer and used to solve important real-world scientific problems, and so it may be regarded as the first successful parallel supercomputer. Several designers and implementors who developed language compilers for the Illiac IV later developed similar compilers for the Connection Machine. The Illiac IV had a SIMD architecture, with a central control unit that issued instructions to many processing elements – 256 as originally

designed, though only one “quadrant” of 64 processors was delivered to NASA. (The first Connection Machines had a similar SIMD architecture, though with thousands of processors rather than dozens, and were likewise divided into quadrants.) The processing elements of the Illiac IV were connected into a square two-dimensional grid such that each processing element could communicate with its four nearest neighbors.

There is an engineering trade-off between the processing element size and the total number of processing elements. Each Illiac IV processing element was a full-fledged floating-point unit. In contrast, many other early parallel machine designs were SIMD architectures with much larger numbers of processing elements, each just 1 bit wide, all simultaneously executing an instruction stream broadcast by a central controller.

As early as 1958, Unger proposed a SIMD design with 1-bit processors having only a few bits of state apiece, for purposes of “spatial problems” such as visual pattern recognition. This design was never constructed, but was simulated on a (conventionally sequential) IBM 704 computer [60]. The network connecting the processors was a two-dimensional, eight-nearest-neighbors grid, but for some purposes interprocessor links could be “enabled” or “disabled” and then data could be transferred between distant processors in one step through chains of enabled links. Unger (correctly) envisioned the need for such a machine to have many hundreds of processors in order to be useful, and commented “this means thousands of memory elements and tens of thousands of gate inputs in the matrix alone. These are alarming figures ... However, progress in the components field is such that it is reasonable to hope that within a few years there may be available manufacturing processes whereby entire blocks of logical circuitry could be constructed in one unit.... While the author has specifically discussed a computer based on a rectangular matrix of modules using one-bit registers, it might be worthwhile to consider other arrangements. Possible variations include matrices in three or more dimensions, registers enlarged to handle multi-bit words, and polar co-ordinate arrays.”

The SOLOMON computer [19, 48] was designed to connect up to 2,048 processors into a 32×64 two-dimensional, four-nearest-neighbors grid though smaller sizes such as 32×32 or even 32×8 were envisioned (and apparently the only hardware actually

constructed was a demonstration system much smaller than this).

The Illiac III [35] was designed for visual pattern recognition and had multiple independent computational units, one of which was a Pattern Articulation Unit containing 1,024 SIMD processors arranged as a 32×32 two-dimensional, eight-nearest-neighbors grid.

The Staran [4] had multiple array modules of 256 processors each and a rather complex communication network [5] capable of permuting 256 bits in many ways.

The ICL DAP [39] had 4,096 processors connected into a 64×64 two-dimensional, four-nearest-neighbors grid.

The Goodyear MPP [6] had 16,384 processors connected into a 128×128 two-dimensional, four-nearest-neighbors grid.

Supercomputer projects whose gestation was roughly contemporaneous with that of the first Connection Machine designs include the NYU Ultracomputer [18], a MIMD architecture with a “fetch-and-add” network; NON-VON [17, 43], with thousands of 1-bit processors connected into a complete binary tree, intended to process massive quantities of data kept on secondary storage; and the Caltech Cosmic Cube [40], with 64 conventional microprocessors connected by a six-dimensional hypercube network (however, the notion of connecting thousands of processors using a hypercube network goes back at least to 1963 [49]).

Many of the software techniques, such as bit-serial arithmetic, developed and used on earlier massively parallel machines with 1-bit processors were directly applicable to the Connection Machine. The Connection Machine model CM-1 was distinguished from these predecessors by its inclusion of a hypercube network that provided much faster communication between distant processing elements and much greater overall network bandwidth (and by being the first massively parallel architecture to be put into commercial production, with multiple copies sold to multiple customers). The Connection Machine model CM-2 introduced hardware floating-point coprocessors that allowed it to be programmed in some ways more like the Illiac IV than like the Goodyear MPP. The Connection Machine model CM-5 represented a radical departure, with an entirely new architecture that was MIMD, used conventional microprocessors (optionally augmented with vector coprocessors), and had a network topology that

was not a hypercube; in some ways it resembled the NYU Ultracomputer.

Connection Machine Model CM-1

A full Connection Machine model CM-1 consisted of $2^{16} = 65,536$ processors [59], each having:

- An arithmetic-logic unit (ALU) and associated latches
- $2^{12} = 4K$ bits of bit-addressable local memory
- Eight 1-bit flag registers
- Router interface
- NEWS grid interface

Each ALU was an almost trivial piece of circuitry: a 3-input, 2-output logic element that could compute any two Boolean functions of three inputs. The functions were specified by two 8-bit truth tables, so in effect the ALU consisted simply of two 1-of-8 selectors controlled by the three input bits. The three inputs were any two bits from local memory and any of the eight flags; of the two outputs, one was written back to memory and one was written to a specified flag. Finally, the entire operation was conditional on yet another specified flag; if its value was 0, then the two results were not written after all.

Using this ALU, all data processing was carried out bit-serially within each processor. One of the original inspirations for the Connection Machine was Scott Fahlman’s PhD work on semantic networks and computation within such networks via marker propagation. Fahlman himself had sketched an idea for a hardware implementation [16]. W. Daniel “Danny” Hillis refined these ideas in his own PhD work at MIT [21], and in particular designed a more efficient and more easily controlled network for connecting the processors [22]. Each processor might then represent one node in a semantic network and contain the addresses of a moderate number of other processors; the network could then be used to propagate markers, each consisting of a single bit or a small number of bits, among the processors. The CM-1 ALU design was, however, adequate to implement a full adder, and so it was reasonably convenient to implement addition and subtraction in a bit-serial fashion, and then multiplication, division, and all other arithmetic operations of interest.

Consider, for example, conditional addition of two signed integers, each k bits long. The following steps

were carried out simultaneously within each hardware processor. First a bit was loaded from memory into a flag bit to control whether the results of the addition should be stored for that processor. Next a second hardware flag was cleared for use as a carry bit. Next came k iterations of an ALU operation that read one bit of each operand from memory as well as the carry bit from the hardware flag, computed the sum (a three-way exclusive OR) and carry-out (a three-input majority function), and stored the sum back into memory and the carry-out back into the hardware flag. These iterations started with the least significant bits of the operands and proceeded toward the most significant bits. The sum could replace one of the input operands or be stored into a third area of memory. The last of the k iterations stored the carry-out into a third hardware flag rather than the second one; a further computation that compared the second and third flags (the carry-outs from the last two iterations) could then determine whether integer overflow occurred.

This bit-serial strategy was not original with the Connection Machine; earlier machines that performed all arithmetic in bit-serial fashion include the Goodyear MPP supercomputer [6] and the Digital Equipment Corporation PDP-8/S minicomputer [13]. The CM-1 could perform one ALU iteration for integer addition in about half a microsecond; taking instruction decoding and initialization overheads into account, a 32-bit integer add required about 21 μ s. But with 2^{16} processors performing such additions simultaneously, this produced an aggregate rate of 2,500 MIPS (i.e., 2.5 billion 32-bit integer additions per second). By way of comparison, the earlier Cray-1 vector supercomputer (1975) had a peak speed of 160 MFLOPS when performing multiply-add operations on 64-bit floating-point operands [9], and the initial model of the Cray X-MP (1984) had a peak speed of 210 MFLOPS per CPU, where a system could have up to two (1982) or four (1984) CPUs [10, 11]. While no one expected the bit-serial arithmetic of the CM-1 to outperform Cray supercomputers on floating-point computation, it was clear that the CM-1 could be competitive for integer computations and perhaps supremely successful for marker propagation algorithms.

(It is instructive, however, to do a back-of-the-envelope calculation for the speed of floating-point arithmetic carried out on such a bit-serial processor. For

floating-point addition, the input significands must be aligned and the output sum must be normalized; for m -bit significands, the cost is roughly $m[\log_2 m]$ ALU cycles. The addition itself requires m ALU cycles. For 32-bit floating-point operands with $m = 24$, this comes to about 250 ALU cycles; for 64-bit operands with $m = 53$, it is about 700 ALU cycles. For floating-point multiplication, the cost is roughly m^2 ALU cycles, plus integer addition of the exponents, plus a 1-bit normalization step. For 32-bit floating-point operands with $m = 24$, this comes to about 650 ALU cycles; for 64-bit operands with $m = 53$, it is about 2,900 ALU cycles. If an ALU cycle is about half a microsecond, and one assumes a mix of floating-point operations that is half adds and half multiplies, then the estimated speed is roughly 275 MFLOPS for 32-bit operations and 73 MFLOPS for 64-bit operands – not quite Cray-1 class, but still fast enough to be interesting.)

The real innovation in the Connection Machine was its *router*, which passed message packets bit-serially among processors. While the network is often described as a 16-dimensional hypercube, it should be noted that the processors were packaged 16 to a chip. The $2^{12} = 4,096$ chips were connected by a 12-dimensional hypercube of actual physical wires, and additional multiplexing was done on-chip. Routing of data among chips made use of some of the same hardware flags and memory paths as the ALU operations. Each processor that needed to send a message (possibly all of them) would first load 16 bits from memory, one at a time, representing the address of a destination processor, and then n bits of data to be sent. The router on each chip could accept up to four messages at a time from processors on that chip, and would respond to each sending processor with a bit saying whether its message had been accepted; processors whose messages were not accepted on this routing cycle would try again on the next routing cycle.

Message bits traversed the hypercube in pipelined fashion; at each of 12 steps, each accepted message would have the opportunity to traverse one of the 12 hypercube dimensions. (A message would need to traverse a wire along a given dimension if and only if the address of the destination processor differed in that bit position from the address of the originating processor.) After those 12 steps had processed the 12-bit destination address in each message, data bits would follow the address bits serially along the paths that had been

established through the hypercube. As data bits arrived at a destination processor, they were then stored one at a time. For sufficiently long messages, on each routing iteration a bit would be loaded from memory to be sent out and a newly arrived bit (from an earlier position in the message) would be stored back into memory; toward the end of the process, the final steps would simply store the last arriving bits.

Two or more messages might compete for the same hypercube wire, in which case one message would get the use of the wire, and the others would not. These others would still have the opportunity to traverse other hypercube dimensions, but would not reach their destinations during the current routing cycle; instead, they would be stored into temporary buffers within the memory of whatever processors they had managed to arrive at, and then forwarded by another round of routing. A more subtle point is that, at each of the 12 dimension steps, each router had to be prepared to accept a message on the incoming dimension wire. Therefore, if the router buffers on some chip were all full and *none* of those messages needed to traverse the outgoing dimension wire, then one message was chosen and sent out on that dimension anyway – and therefore that particular message would be unable to reach its destination in the current routing cycle – just to make sure that a buffer would be free to accept an incoming message (this move was called *desperation routing*). Software would then repeat the routing process – forwarding messages that had not reached their destinations because of wire competition or desperation routing, and accepting messages that had not been previously accepted – until all messages eventually reached their destinations [20, 22].

The router allowed any processor to establish a data connection with any other processor with reasonable speed and efficiency – from this idea came the very name “Connection Machine.” Compare this to the Illiac IV [3, 7] or the Goodyear MPP [6], each of which connected processors in a two-dimensional grid, each processor able to communicate directly with only its four nearest neighbors: Transferring data to a distant processor could take quite a long time. On the other hand, it was also clear that a two-dimensional grid could be particularly attractive and efficient for certain applications such as image processing. Therefore the CM-1 had a second network, completely independent from

the hypercube, called the NEWS (North/East/West/-South) network, that allowed a processor to pass a single data bit to any of four nearest neighbors without the overhead of first loading a destination address.

Instructions were provided to the 65,536 processors from a central source through a two-step process. The CM-1 was not a stand-alone system, but a coprocessor that was always attached to a front-end computer (a Symbolics 3600 Lisp Machine). Programs running within the front-end computer would issue instructions, one at a time, to the Connection Machine. These instructions constituted an abstract architecture that supported integer and floating-point arithmetic, other operations on multi-bit operands, message-passing, reduction operations such as finding the sum or maximum of a collection of values, and most importantly *virtual processors*, by which the memory of each hardware processor was split into m regions, and each hardware processor was time-sliced so as to simulate m processors. By the time of the CM-2, this instruction set had been given a name: Paris, for PARallel Instruction Set. Paris instructions sent from the front-end processor arrived at a microcoded *sequencer* within the Connection Machine. Two networks (over and above the hypercube and the NEWS network) connected the sequencer to the Connection Machine processors: A *broadcast network* allowed SIMD *nanoinstructions* to be sent from the sequencer to the processors, and a *combining* network took a 1-bit signal from every processor and delivered the logical OR of these 65,536 signals to the sequencer. Finally, the sequencer had the ability to read or write any 32-bit word within the memory of any Connection Machine processor.

A single CM-1 nanoinstruction specified one sub-cycle of an ALU or router operation. A nanoinstruction contained a 3-bit operation code, a 3-bit flag number, a 12-bit memory address, and one 8-bit truth table for the Connection Machine ALU. As an example, the basic ALU iteration for the integer add operation described above would consist of three nanoinstructions:

- LOADA: read memory operand A, read flag operand, latch one truth table
- LOADB: read memory operand B, read conditional flag, latch other truth table
- STORE: store one result bit in memory, store other result bit in flag

The nominal clock speed of the CM-1 was 6 MHz [59], so such an ALU cycle would take about half a microsecond.

In order to allow large machines to be shared among multiple users and to allow a range of machine sizes to be offered for sale, there was actually one sequencer for every 16,384 processors. A 4×4 crossbar switch called the *nexus* allowed up to four front-end computers to be connected to a single CM-1 system, and such a system could consist of 1, 2, or 4 *quadrants*. These quadrants could be dynamically assigned to front-end processors for their use. If a front-end processor were assigned more than one quadrant, then Paris instructions issued by that front-end processor were broadcast by the nexus to multiple sequencers, and in all other ways the ganged quadrants were made to behave as if under the control of a single sequencer.

The cabinetry of the CM-1 (which was also used for the CM-2) had a striking physical design: It looked like a “cube of cubes” that was 56 inches on a side and was intended to evoke the hypercube topology of the router network (see Fig. 1). Each of the eight subcubes was about 26 by 26 by 26 in. and contained 16 vertically oriented printed circuit boards connected by a large square backplane. Each printed circuit board

held 32 processor chips of 16 processors each and had 32 red light-emitting diodes mounted on the edge opposite the backplane connectors [23, p. 110]. These lights were visible through translucent panels on the front and back of the cabinet; thus 2,048 lights were visible on the front and 2,048 on the back. These lights could be used for diagnostic reporting purposes, but also served to give the cabinet a visual “wow factor” intended to communicate to spectators that there was a lot going on inside that otherwise static-looking black cabinet [52]. (Indeed, software was eventually written specifically to produce good-looking patterns for still photos and for video recording.) The cabinet could be physically split apart into four quadrants (each consisting of two vertically stacked subcubes) for shipping, and systems were offered in three sizes, consisting of one, two, or four quadrants.

Most software for the CM-1 was coded in *Lisp, which was a package of functions that extended Symbolics Zetalisp to provide access to the Connection Machine. If the sequencer was instructed to simulate some number n of virtual processors, then *Lisp allowed the user to allocate certain data structures within the CM-1 that behaved like vectors of length n that could perform various elementwise operations simultaneously on all elements, as well as finding the largest or smallest value, the sum of all values, permuting the elements according to a vector of indices, and so on. A more elaborate dialect of Lisp called Connection Machine Lisp (CM-Lisp) was also designed and prototyped, but never became a full-fledged product. Both were aimed at supporting the programming of data parallel algorithms [24].

One example of an artificial intelligence application explored on the CM-1 was memory-based reasoning [51]. Examples of non-AI applications implemented on the CM-1 include circuit simulation [61], ray-tracing [12], and free-text search [50].

Connection Machine Model CM-2

The CM-2 was a fairly compatible revision of the CM-1 architecture and design [53, 54, 59]. A full Connection Machine model CM-2 similarly consisted of $2^{16} = 65,536$ processors, each consisting of:

- An arithmetic-logic unit (ALU) and associated latches

Connection Machine. Fig. 1 Connection Machine model CM-2 with DataVault and graphic display

- $2^{16} = 64\text{ K}$ (and later $2^{18} = 256\text{ K}$) bits of bit-addressable local memory
- Four (rather than eight) 1-bit flag registers
- Router interface
- NEWS grid interface
- I/O interface
- Floating-point accelerator interface
- Improved error-detection circuitry, including single-error correction, double-error detection (SECDED) for memory

The four biggest changes in the CM-2 hardware from the CM-1 were the floating-point accelerators, the NEWS grid implementation, in-router combining of messages, and the I/O interface. The CM-2 also had a slightly higher clock rate, 7 MHz [36].

A CM-2 could be built with or without floating-point accelerators: For every 32 Connection Machine processors (i.e., for every pair of Connection Machine processor chips) there was a proprietary custom interface chip and an off-the-shelf floating-point coprocessor chip (the Weitek WTL3132, and later the Weitek WTL3164 [36]). The main task of the custom interface chip was to transpose 32×32 bit matrices. Each of the 32 Connection Machine processors in a group would supply a 32-bit operand, one bit at a time, to the floating-point interface chip; thus, in 32 Connection Machine ALU cycles, 32 complete operands could be transferred to the interface chip, with bit j of each of 32 operands being transferred during cycle j . The interface chip would then present complete 32-bit operands, one at a time, to the floating-point coprocessor. The floating-point coprocessor had multiple registers, so operands might reside within the coprocessor while multiple floating-point operations were performed. Eventually results would be transferred from the coprocessor, one at a time, back to the interface chip, which would then transfer the results simultaneously to the 32 Connection Machine processors, one bit at a time to each. With careful microprogramming of the Connection Machine sequencer, these steps were pipelined so that operand transfer was overlapped with the floating-point operations. Later floating-point coprocessor chips also supported 64-bit floating-point operations; the process was much the same, with each operand transferred from chip to chip as two 32-bit portions. A full CM-2 system

with floating-point accelerators would contain 2,048 floating-point coprocessor chips.

The CM-1 had a separate hardware grid for its NEWS network; in the CM-2, circuitry was added to the processor chips to use the hypercube wires for NEWS connections. It was already well known that a two-dimensional grid (or, more generally, a grid of any dimension) could be embedded in a hypercube, and that all processors could be part of such a grid if the length of each axis of the grid were a power of two. This implementation strategy reduced the hardware cost of the CM-2 while increasing its flexibility to efficiently support three-dimensional grids (useful for physical simulations [42]) and four-dimensional grids (useful for QCD calculations [2]). The CM-2 NEWS interface also included features to assist the computation of parallel prefix operations along any axis of a multidimensional grid.

In the CM-2 router, as in the CM-1 router, if two or more messages were competing for use of the same hypercube wire, then one was chosen to get use of the wire. However, if any of the other competing messages had the same destination address, then the CM-2 router could *combine* them with the chosen one, rather than simply denying them use of the wire during that routing step. Messages could be combined in any of four ways: bitwise OR, choosing the largest (unsigned) value, (unsigned) integer addition, or simply choosing one arbitrarily (thereby discarding the others). (Software could also get the effect of bitwise AND or choosing the smallest value by exploiting De Morgan's laws.) The CM-1 combined messages in all the same ways, but only at the destination processor, by using its ALU as messages were received; in-router combining allowed the CM-2 to provide the same functionality with greater efficiency. The CM-2 router also had a way to fetch messages from, rather than send messages to, other processors: Request messages were routed in the usual manner, with a special kind of in-router combining operation, and then the router was run "backwards" to return data to the requesting processor – wherever in-router combining had occurred in the forward direction, the returned data was replicated in the backward direction (in effect, the forward operation constructed a set of "broadcast trees," one tree for each distinct fetch target).

The I/O interface was originally planned for the CM-1 but not implemented. In the CM-2, the I/O interface provided wide datapaths that connected directly to the Connection Machine processors, allowing high-bandwidth transfers between Connection Machine memory and peripheral devices. Each CM-2 subcube backplane provided two I/O channels, and each channel could accommodate either a framebuffer card or an I/O controller card. The 8,192 processors in each subcube were divided into two banks of 4,096 processors, that is, 256 processor chips, each having one I/O line, so I/O transfers to or from the processors consisted of 256-bit words. The graphic display framebuffer card drove a 19-inch color CRT monitor (typically $1,280 \times 1,024$ pixels), using either 8-bit or full 24-bit color, and supported data transfer from the Connection Machine processors at 40 megabytes per second. The CM I/O controller, on the other hand, multiplexed each 256-bit word into four 64-bit words for transmission on the CM I/O bus.

Two devices were initially offered by Thinking Machines Corporation for connection to the CM I/O bus: the DataVault and a VME I/O interface. The DataVault was the first commercially available RAID disk system; it supported data transfers of 25 megabytes per second, and four could be driven simultaneously by the four quadrants of a full CM-2 system. Each DataVault could hold either 42 or 84 off-the-shelf disk drives, thereby providing either 10 G bytes or 20 G bytes of data storage. Each group of 42 drives was treated as 32 for data, seven for error correction and detection, and three “hot spares.” The VME I/O interface allowed a computer with a VME bus (which might or might not also be in use as a front-end computer) to be connected to the CM I/O interface.

Each CM-2 sequencer had four times as much microcode memory as in the CM-1. The Paris instruction set, which was implemented by sequencer microcode, was greatly expanded for the CM-2. Arithmetic operations included integer and floating-point arithmetic, transcendental and trigonometric functions (including hyperbolic functions and their inverses), bitwise logical operations, interprocessor message sends with combining, multidimensional nearest-neighbor NEWS communication, global reduction operations (such as computing the logical OR of one bit from

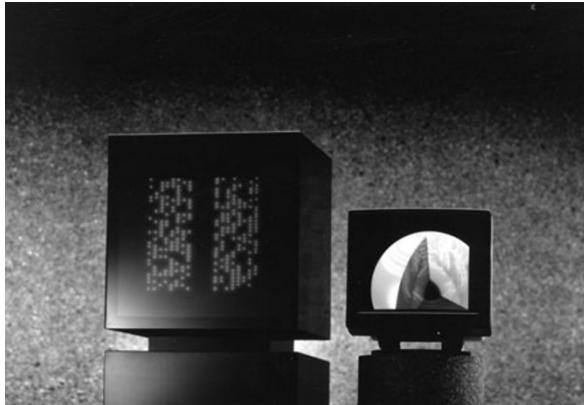

every processor, or the floating-point sum of one value from every processor), and reduction and parallel prefix operations along any axis of a multidimensional array. Every virtual processor had four flags: a carry bit, an overflow bit, a test bit (to receive the result of comparison operations), and a context bit (which if 0 suppressed storing of results for most Paris operations). Paris supported multiple virtual processor sets simultaneously within a single program; each virtual processor set could have a different NEWS configuration, and interprocessor message sends could be used to transfer data between virtual processors in different virtual processor sets. Within each virtual processor set, Paris supported dynamic memory allocation of *fields*, where a field was simply number number of consecutive bits at the same address within each virtual processor in a virtual processor set. Paris supported both stack (“push” and “pop”) and heap (analogous to “malloc” and “free”) allocation and deallocation of fields.

With the CM-2, Thinking Machines offered a choice of front-end bus interfaces, so that either a Symbolics 3600 Lisp Machine or a Digital Equipment Corporation VAX computer could be used as a front-end processor (indeed, a single CM-2 system might have both kinds of front end attached to its nexus crossbar). A VAX front end was required to execute programs written in C* or Connection Machine Fortran; either kind of front end could execute programs written in *Lisp or CM-Lisp.

The cabinetry of the CM-2 was essentially identical to that of the CM-1 (see Fig. 1). At one point, Danny Hillis investigated the possibility of making the lights blue rather than red, but discovered that while blue LEDs had just become available, their relatively high cost and short lifetime at that time made them impractical for use in the CM-2.

The DataVault cabinet was another striking example of industrial design: Rather than being rectilinear, the cabinet had a gentle curve that made it look rather like an information desk or a bartender’s station (Fig. 1). The intent was that a Connection Machine cabinet might be encircled by up to half a dozen DataVault cabinets separated by access paths.

By 1989, a version of the CM-2 called the CM-2a was offered in a smaller cabinet, approximately one eighth the size of the original CM-1/CM-2 cabinet: 26 by 26

Connection Machine. Fig. 2 Connection Machine model CM-2a with graphic display

by 43 in., consisting of a single CM-2 subcube standing on a pedestal that contained power supplies and cooling fans (see Fig. 2). The CM-2a could be populated with either 4,096 or 8,192 Connection Machine processors (and optionally with the same floating-point accelerators used in the CM-2). Three choices of front-end processor for the CM-2 and CM-2a were now available: Symbolics 3600, DEC VAX, and Sun Microsystems Sun-4/200 series. The CM-Lisp language proved to be difficult to implement in its full generality and by 1989 was no longer emphasized in Thinking Machines literature; *Lisp, C*, and Connection Machine Fortran all enjoyed continued support.

A revised version of the CM-2, with a faster clock rate and larger memory, might have become the CM-3, but was eventually shipped under the name CM-200, to emphasize continuity with the CM-2 product line. There was no CM-4 product, though that number was sometimes used to refer to a follow-on SIMD machine design that was discarded early on in favor of what became the CM-5.

The fastest CM-2 systems ever listed in a TOP500 list were two 65,536-processor machines, one at Brandeis University and one at Florida State University [58, June 1993, ranked #37 and #38]; the theoretical aggregate peak performance of each was 14 gigaflops, and the reported peak LINPACK performance was 5.2 gigaflops. The fastest CM-200 systems ever listed in a TOP500 list were two 65,536-processor machines, both at Los Alamos National Laboratory [58, June 1993, ranked #23 and #24]; the theoretical aggregate peak performance of each was 20 gigaflops,

and the reported peak LINPACK performance was 9.8 gigaflops.

The 1989 Gordon Bell prize for absolute computer performance was won by a seismic modeling application running on the CM-200 that achieved sustained performance of 6 GFLOPS [14]. The same application was further improved by use of a “stencil compiler” [8] that compiled a subroutine written in Connection Machine Fortran into application-specific microcode that could be downloaded into the sequencer; it earned a 1990 Gordon Bell Prize honorable mention for improving the performance of this application to over 14 GFLOPS [15, 36].

A variety of other scientific applications were implemented on the CM-2 [44].

Connection Machine Model CM-5

The CM-5 was designed to be upward-compatible with CM-2 software, but its hardware architecture represented a radical break in nearly every aspect [25, 56]. Rather than using proprietary 1-bit SIMD processors controlled by a proprietary sequencer, it used off-the-shelf RISC processors (SuperSPARC I chips from Sun Microsystems), thus supporting MIMD programming as well as the data-parallel style of programming. The original plan was for the CM-5 to be a purely MIMD machine, but the performance of SuperSPARC I chips turned out to be lower than predicted by the historical SPARC technology curve; in order to provide competitive numerical performance, Thinking Machines made a late design change that added proprietary floating-point vector coprocessor chips. As a result, although MIMD programming could be exploited for some purposes, the best performance on the CM-5 was attained only by using the same data-parallel programming model that had been used on the CM-1 and CM-2.

Rather than using a hypercube network to connect these processors, and separate I/O busses to connect processors to I/O devices, the CM-5 used a fat-tree network [29] to which processors and I/O devices were attached on an equal footing [31, 32, 56]. One of the (quite plausible) goals of the CM-5 architecture was to allow eventual scaling to teraflop performance [30, 32, 37], thus allowing systems to be offered in a software-compatible range of sizes spanning more than three orders of magnitude [27]. The choice of fat-tree over hypercube made this vision possible because the fat-tree, unlike the hypercube, could be made larger

without increasing the number of wires connected to each processor. The fat-tree also had the advantage that the number of processors need not be an exact power of two.

The fat-tree network was actually used to connect three type of nodes: ordinary processing nodes (perhaps having vector coprocessors), usually present in large numbers; a handful of control processor nodes, each of which ran an enhanced version of UNIX and could fulfill the role of a CM-2 front-end processor; and a modest number of I/O nodes, which were almost identical to processor nodes but had conventional I/O interfaces instead of vector coprocessor chips.

User-mode code on the SPARC could access the fat-tree network interface directly, but had to use virtual addresses to identify destinations; the CM-5 fat-tree network then provided virtual address translation. In this way the processors of a CM-5 system could be divided into groups called *partitions*, with each partition assigned to a different user task and each task protected against interference from other tasks. Privileged (supervisor) code on the SPARC could send messages using either virtual or physical (absolute) addresses to identify destinations. Typically the operating system would dedicate one control processor to manage each partition.

A high-bandwidth I/O device was typically connected to the CM-5 by striping a wide bus across a set of I/O node processors that together formed a partition; typically the operating system would dedicate one control processor to each I/O partition to manage its I/O requests. Yet another advantage of the fat-tree structure was that if partitions were allocated appropriately, then network traffic within a partition never interfered (competed for network resources) with traffic in any other partition, nor with traffic between two other partitions (thus I/O activity by one user task would not interfere with computation by another user task).

The 65,536-way logical-OR signaling network in the CM-1 and CM-2 was replaced in the CM-5 with a more comprehensive *control network*. This was a tree structure that paralleled the fat-tree *data network* but did not become fatter near the root of the tree. The CM-5 control network provided these facilities:

- Broadcasting: Any processor could inject a message into the control network, and a copy of that message

would be delivered to all processors in the partition. Each broadcast message could be from 1 to 15 32-bit words in length. There were actually three distinct broadcast facilities: user-mode, supervisor-mode, and interrupt. Supervisor-mode and interrupt broadcasts were privileged operations. An interrupt broadcast could cause every processor in the partition to receive either an interrupt or a hard-reset signal.

- Combining: Each processor could (asynchronously) inject a message into the control network; after every processor in the partition had done so, a result would be delivered to each processor. Four different combining modes were supported: global reduction, parallel prefix, parallel suffix, and router-done (which was simply a specialized logical-OR reduction intended to assist processors in cooperatively determining whether a bulk data-network transmission phase had been completed). The combining operation for the first three modes could be bitwise OR, bitwise XOR, signed maximum, signed integer addition, or unsigned integer addition. (Software could also get the effect of bitwise AND, signed minimum, unsigned maximum, or unsigned minimum by exploiting De Morgan's laws or related techniques.) Each message could be 32 to 128 bits long.
- Global bit: As in the CM-1 and CM-2, each processor could provide one bit, but the logical OR of these bits was delivered to all CM-5 processors in the partition rather than to a sequencer. In the CM-5, there were actually three global-bit interfaces: user-mode synchronous, user-mode asynchronous, and supervisor-mode asynchronous.

The CM-5 also included a third network, the diagnostic network, that was invisible to application programmers but allowed the system to self-monitor for hardware failures and to isolate failed components. This was based on then-emerging standards for on-chip testing and connection-control circuitry using a serial interface that required only a few extra pins per chip, but the CM-5 implementation was notable for using a tree-structured network to allow testing of thousands of chips in parallel. The CM-5 diagnostic network could also diagnose itself by using chips higher in the tree to test chips lower in the tree [38, 56].

A CM-5 processor node *without* vector coprocessors consisted of a 64-bit memory bus connecting three

chips: the RISC processor chip, a network interface chip that connected to the control network and data network [57], and a memory interface that could manage from one to four memory chips of 8 MB each. A CM-5 processor node *with* vector coprocessors consisted of a 64-bit memory bus connecting six chips: the RISC processor chip, a network interface chip, and four vector coprocessor chips, each of which also served as a memory interface that could manage from one to four memory chips of 8 MB each. Thus a processor node without vector coprocessors could have up to 32 MB of memory, but a processor node with vector coprocessors could have up to 128 MB of memory.

In 1991, each vector coprocessor had a peak memory bandwidth of 128 MB/s, 32 megaflops of peak 64-bit floating-point performance, and 32 mega-ops peak 64-bit integer performance [38]. (By 1993, these figures had been increased to 160 MB/s, 40 megaflops, and 40 mega-ops [56].) The RISC microprocessor could issue instructions to individual vector units or to all four at once. Each vector unit had 64 64-bit registers (which were also addressable as 128 32-bit registers), a 16-bit vector mask, and a 4-bit vector length register. Each vector instruction could process up to 16 sets of operands. Each register vector operand was specified by a 7-bit starting register number and a 7-bit stride; the first element for that vector operand was taken from the starting register; that register number was then repeatedly incremented by the given stride to produce register numbers containing succeeding elements of the vector operand. A large stride had the same effect as a small negative stride, so vector operands could be processed in reverse order. Each vector coprocessor provided addition, multiplication, memory load/store, indirect register addressing, indirect memory addressing, and population count (counting the 1-bits in a word). Each vector-unit instruction could specify at least one arithmetic operation and an independent memory operation, allowing pipelining of operands from memory and results to memory while computation was taking place internal to the coprocessor. Single-cycle multiply-add and multiply-subtract operations were supported, as well as the fairly unusual combination of an integer multiply (high or low part) followed by a bitwise Boolean operation – by choosing the high or low part of the multiply and using an appropriate power of 2 as the multiplier, the programmer could get the effect of

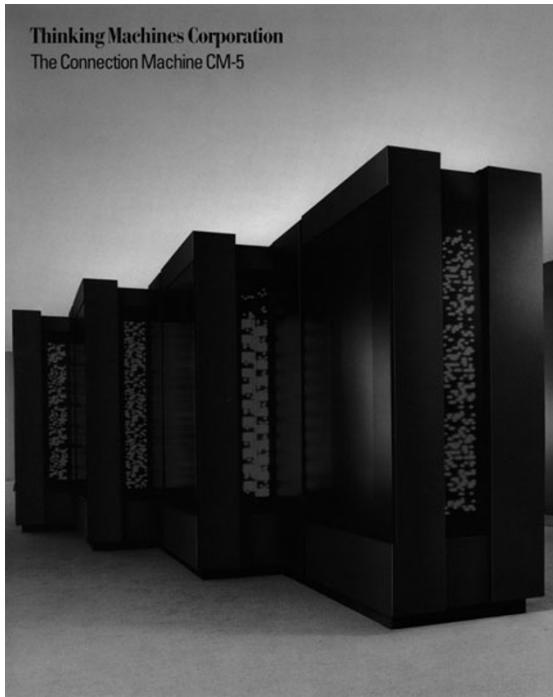

various shift-and-mask or shift-and-XOR operations in a single cycle.

The CM-5 had an option to integrate a massively parallel disk array (called SDA, or Scalable Disk Array) into the CM-5 processor cabinets: One form of CM-5 I/O node consisted of the usual RISC processor and CM-5 network interface chip, a data buffer, four SCSI-2 controllers, and eight 3.5-in. hard disk drives. Another form of CM-5 I/O node was similar but had no disk drives and just two SCSI-2 controllers; these nodes were connected to tape drives mounted in a separate cabinet (called ITS, the Integrated Tape System). A CM5-HIPPI interface allowed the CM-5 to be connected to an industry-standard HIPPI (High Performance Parallel Interface) bus; a CM-HIPPI interface was also offered for CM-2 and CM-200 systems, allowing different generations of Connection Machine systems to communicate at high speed with each other or to share I/O devices. Yet another form of CM-5 I/O node was a CM I/O bus adapter, which allowed use of CM-2 peripherals, such as the DataVault, on CM-5 systems.

The CM-5, like the CM-2 and CM-200, supported the *Lisp, C*, and Connection Machine Fortran languages, as well as CMSSL (the Connection Machine Scientific Software Library [26]) and the Prism programming environment [55, 56]. Prism was notable for using graphics-intensive visualization techniques to display debugging data for thousands of processors [45, 46] and for being one of the software products that survived the dissolution of Thinking Machines Corporation [47].

The operating system for the CM-5, which ran in the control processors, was an enhanced version of UNIX called CMOST, for “Connection Machine Operating SysTem” [28, 56]. (The more obvious acronym “CMOS” was passed over because it was, and still is, in wide use to denote the integrated-circuit technology “Complementary Metal-Oxide-Semiconductor.”) This operating system eventually included a “scalable file system” that extended supported file sizes from 32-bit integers to 64-bit integers [34].

The cabinetry of the CM-5 was quite different from that of the CM-1 and CM-2 but no less striking; multiple 7-foot-tall, oblong cabinets, each of which could hold up to 256 processors, were connected in groups of five in a staggered “lightning bolt” arrangement that allowed one end of each cabinet to display a large rectangular panel

Connection Machine. Fig. 3 Four cabinets of a Connection Machine model CM-5

of the red LEDs that had become the signature look of the Connection Machine series (see Fig. 3). These LEDs were not, however, mounted on the processor boards, and each cabinet had a panel of lights, no matter whether the cabinet contained processors, storage modules, fat-tree nodes, I/O interfaces, or a mixture. (The fact that the lights were now physically separated from the processors made it less costly to exploit their eerie look in the 1993 movie *Jurassic Park*; CM-5 cabinets – with the blinking red lights but without processors [1] – were featured in the “control room” scenes, the phrase “Connection Machine” was used in a bit of dialogue, and the Thinking Machines Corporation logo appeared prominently in the credits.)

The central cabinet in each group of five could contain fat-tree nodes sufficient to connect the other four cabinets to each other and to other lightning bolts. CM-5 systems with more than four processor cabinets were arranged on the machine room floor as parallel lightning bolts with their central cabinets connected by overhead cable bridges, each several feet wide, that supported the numerous physical fat-tree connections between the five-cabinet groups.

The fastest CM-5 system ever listed in a TOP500 list was a 1,056-processor machine at Los Alamos National Laboratory [58, June 1993, ranked #1]; each processor node was rated at 128 megaflops, for a theoretical aggregate peak performance of 135 gigaflops, and the reported peak LINPACK performance was 59.7 gigaflops.

Examples of scientific applications implemented on the CM-5 include computational fluid mechanics [41] and a solution of the Boltzmann equation [33] that was measured as running at 60.7 gigaflops.

[CM fortran](#)

Definition

Connection Machine Fortran is a data-parallel version of Fortran developed around 1987 for Connection Machine supercomputers manufactured by Thinking Machines Corporation. It consists essentially of Fortran 77 augmented by array-processing features that had been proposed for Fortran 8x (and were eventually adopted as part of the Fortran 90 and Fortran 95 standards), additional data-parallel intrinsic functions (such as for parallel prefix operations), and data distribution directives. It was one of the parallel Fortran projects that contributed several noteworthy features to the design of High Performance Fortran.

Discussion

Connection Machine Fortran (also called CM Fortran) was developed and implemented for the CM-2 and CM-5 models of Connection Machine supercomputer. The language was specified by Thinking Machines Corporation but was initially implemented under contract by Compass, Inc. [1]. (That well-known compiler company, also known as Massachusetts Computer Associates, had previously implemented a Fortran compiler for the Goodyear MPP [2].)

Of the four programming languages (*Lisp, C*, CM Fortran, and CM-Lisp) provided by Thinking Machines Corporation for Connection Machine Systems, CM Fortran was perhaps the most conventional, adhering as closely as possible to existing Fortran standards or projected future standards, and yet also the most influential, because of its contributions to High Performance Fortran.

The version as of April 1987 was described [3] as including all of Fortran 77 as defined by ANSI standard X3.9-1978, as well as two sets of extensions: those defined by MIL-STD-1753 [4] (principally intrinsic functions for bit manipulation, the DO WHILE statement, the END DO statement, and the

IMPLICIT NONE statement), and a subset of features proposed in the draft ANSI Fortran 8x standard (draft S8, version 103), including some features described in that draft as “removed extensions.” The Fortran 8x features adopted by CM Fortran included array-valued expressions and elemental functions; other intrinsic functions such as reduction operations (such as SUM, PRODUCT, MAXVAL, MAXLOC, ANY, and ALL), dot product (DOTPROD), and matrix multiplication (MATMUL); array constructor expressions; array sections and vector-valued subscripts; masked array assignment (the WHERE statement and WHERE construct); and the FORALL statement and FORALL construct, which are somewhat like a DO loop, but possibly having more than one index variable, that executes its body (a single statement or a block of statements) in a data-parallel fashion for all possible combinations of values of its index variables simultaneously – and if a logical mask expression is also included, then only combinations of index values for which the mask expression is true are used. For example, assume that A and B are arrays of shape 100×100 ; then the FORALL construct

```
FORALL (I=1:100, J=1:100, I .NE. J)
  A(I,J) = 0.0
  B(I,J) = C(I,J)
  C(I,J) = C(J,I)
END FORALL
```

first sets all the off-diagonal elements of A to 0.0, and only then copies the off-diagonal elements of C into corresponding positions of B, and only after that transposes (the off-diagonal elements of) the array C.

It is noteworthy that the FORALL statement and construct were among the “removed extensions” in the Fortran 8x draft and were not incorporated into the Fortran 90 standard; that the FORALL statement and construct were adopted as part of High Performance Fortran [5, pp 170–184]; and that as a result of experience with High Performance Fortran, the FORALL statement and construct were included in the Fortran 95 standard. However, though the FORALL statement and construct were described as part of CM Fortran as early as April 1987 [3], they were not yet implemented in CM Fortran as of February 1990 [6, page 83] (see also [7, p 7]). They do appear to have been implemented by mid-1992 (an internal design document for implementing FORALL [8] is dated November 1991, and published

release notes dated October 1992 refer to an “enhancement” to FORALL that generates parallel code for more cases than in “previous releases” [9, p 13]). Over the next 2 years, additional enhancements and optimizations for FORALL were introduced for the both CM-5 and the CM-200 [10–13].

By September 1989, a set of compiler directives had been added to CM Fortran [14, pp 365–386]. Following the practice of Fortran compilers for other supercomputers such as the Cray series, CM Fortran directives took the form of structured comments – in this case, exploiting the fact that both Fortran comments and the abbreviation “CMF” for Connection Machine Fortran begin with the letter “C”. The two directives of greatest historical and technical interest were the LAYOUT and ALIGN directives. The LAYOUT directive specified how a Fortran array should be laid out across Connection Machine processors; for example,

```
DIMENSION A(64, 64, 64, 100)
CMF$ LAYOUT A(:SEND, :NEWS, :NEWS, :SERIAL)
```

specified that the four-dimensional array A should be laid out in such a way that elements whose indices differed only in the last axis should reside in the same virtual processor, and that the other three axes should be distributed across virtual processors in such a way that the processor numbering along the first axis corresponded to the Connection Machine router’s “send address” ordering, and the processor numbering along the second and third axes corresponded to the Connection Machine’s NEWS grid ordering (which amounted to a Gray encoding of some portion of the router address). The ALIGN directive specified that the layout of one array should be determined by the layout of another array, so as to maintain minimum communications cost between corresponding elements. For example,

```
DIMENSION A(64,64,64,100),B(64,64,64),C(64)
CMF$ ALIGN B(I,J,K) WITH A(I,J,K,1)
CMF$ ALIGN C(M) WITH B(M,M,M)
```

causes array B to be aligned with (and therefore allocated in the same virtual processors as) a slice of array A, and causes array C to be aligned with the main space diagonal of array B. Such directives allowed for explicit programmer control over array allocation decisions that had previously been made automatically by an optimization phase in the CM Fortran compiler [1, 15–18].

These layout and alignment directives were eventually adopted, with some modifications and contributions from other parallel Fortran projects [19] (notably Fortran D [20–22] and Vienna Fortran [23, 24]), into High Performance Fortran [5, pp 91–119].

As implemented for the Connection Machine model CM-2, CM Fortran did not have intrinsic functions for scan (parallel prefix and parallel suffix) operations; instead, there was a utility library that allowed CM Fortran programs to invoke individual instructions from the PARIS (Connection Machine PARallel Instruction Set), including instructions that performed scan operations. With the introduction of the model CM-5, a CM Fortran Utility Library was introduced that provided a more abstract interface to certain computational and communications facilities that could be supported on both the CM-2 and CM-5. This library included scan operations with names such as CMF_SCAN_ADD and supported segmented scan operations [25, pp 74–77]. It also included a group of operations labeled “scatters with combining,” with names such as CMF_SEND_ADD [25, pp 85–86]. These library functions were the direct predecessors of intrinsic functions such as SUM_PREFIX, SUM_SUFFIX, and SUM_SCATTER in High Performance Fortran [5, pp 301–303].

By 1993, Thinking Machines Corporation in collaboration with Applied Parallel Research had produced a parallelizing translator from Fortran 77 to CM Fortran called CMAX [26].

Figure 1 shows an early (1987) example of a CM Fortran program that identifies prime numbers less than 100,000 by the method of the Sieve of Eratosthenes, taken (with one minor correction) from [3]. This program is written in what is now entirely conventional Fortran, except that the expression [1:N] would have to be written [I, I=1, N]. Because Fortran arrays normally use 1-origin indexing (rather than the 0-origin indexing provided by such languages as C, Java, and Common Lisp), the parameter N used to specify array length is defined to be 99999 rather than 100000. The first three assignment statements set every element of array PRIME to false, every element of array CANDIDATE to true, and the first element of CANDIDATE to false. While CM Fortran did have a DO WHILE statement, this example happens to use a statement label 20 and a conditional

```

SUBROUTINE FINDPRIMES(PRIME)
PARAMETER (N = 99999)
LOGICAL PRIME(N), CANDIDATE(N)
PRIME = .FALSE.
CANDIDATE = .TRUE.
CANDIDATE(1) = .FALSE.
20 NEXTPRIME = MINLOC([1:N], CANDIDATE)
PRIME(NEXTPRIME) = .TRUE.
FORALL (I = 1:N, MOD(I,NEXTPRIME) .EQ. 0) CANDIDATE(I) = .FALSE.
IF (ANY(CANDIDATE)) GO TO 20
RETURN
END

```

Connection Machine Fortran. Fig.1 Example Connection Machine Fortran program for identifying prime numbers

GO TO statement to implement the loop. The standard Fortran intrinsic function MINLOC is used to find the index of the smallest value between 1 and N for which the array CANDIDATE has a true value. This index is then used to determine which element of PRIME to set to true. The FORALL statement processes all elements of CANDIDATE in parallel, setting to false those elements for which the expression MOD(I, NEXTPRIME) .EQ. 0 is true. The standard Fortran intrinsic function ANY returns true if any element of its array argument is true; thus the loop is repeated if any candidate remains. Note that both MINLOC and ANY are reduction operations at heart.

from S-expressions to S-expressions, and special syntax for performing elementwise operations, reductions, and permutations on these data structures.

Discussion

Of the four programming languages (*Lisp, C*, CM Fortran, and CM-Lisp) provided by Thinking Machines Corporation for Connection Machine Systems, CM-Lisp was the most radical in design (requiring the use of non-ASCII characters in its notation, and introducing an associative data structure indexed by non-numeric values) and the most difficult to implement (requiring automatic garbage collection of parallel data structures). Danny Hillis used it in his book about the Connection Machine [4] to explain how he imagined programming a massively parallel supercomputer intended for nonnumerical applications in a data parallel style [5]. While it was featured along with the other three languages in the earliest *Connection Machine Technical Summary* [10], it was dropped from all later versions [11, 12], and Thinking Machines never offered a complete parallel implementation as a commercial product.

CM-Lisp consists of Common Lisp augmented with an extra data structure, the *xapping*, essentially an unordered set of ordered index-value pairs suitable for parallel processing, where each element of each pair may be any CM-Lisp data structure and the index of each pair must be unique within that xapping. Here is the CM-Lisp notation for a xapping that maps names of colors to numbers:

```
{red→14 green→3 purple→93 blue→3.5}
```

For the common and useful special case that the indices are consecutive integers starting from zero, the xapping is also called a *xector*, and a square-bracket notation may be used:

```
[banana apple pear kumquat]
```

is simply an alternate notation for

```
{0→banana 1→apple 2→pear 3→kumquat}
```

A distinctive feature of CM-Lisp is that xappings could be conceptually infinite by having a *default value* considered to be associated with every index not explicitly mentioned:

```
{red→14 green→3 purple→93 blue→3.5 →0}
```

Definition

Connection Machine Lisp (CM-Lisp) is a data-parallel version of Lisp developed around 1987 for Connection Machine supercomputers manufactured by Thinking Machines Corporation. Unlike the *Lisp language, it drew no sharp distinction between front-end data and parallel data, and provided for parallel processing of S-expressions, not just numbers and bit fields. CM-Lisp introduced an aggregate data type called a *xapping*, which was essentially a (not necessarily finite) map

is a xapping that has a pair $x \rightarrow 0$ for every possible CM-Lisp data structure x other than red, green, purple, and blue.

CM-Lisp also adds three notations for parallel processing. The α notation allows elementwise parallel processing; if two or more xappings are processed by an α -expression, then corresponding values are combined by matching up their indices (a process that can be regarded as a simple form of database join operation – simple because no input xapping will have multiple pairs with the same index, and therefore no output xapping will have multiple pairs with the same index). As a simple example, if x names the xapping

```
{red→14 green→3 purple→93 blue→3.5}
```

and y names the xapping

```
{red→4 yellow→5 green→6}
```

then the expression $\alpha (+ \cdot x (* 2 \cdot y))$ produces the value

```
{red→22 green→15}
```

The character “ α ” indicates that the following expression is to be executed “in parallel, as many copies as needed”; the character “ \cdot ” in effect says, “but not this part – just evaluate it once and use the value” (i.e., the following expression should be evaluated just once and is expected to produce a xapping). Thus, in the expression $\alpha (+ \cdot x (* 2 \cdot y))$, there will be many copies of the addition operation $+$ and the multiplication operation $*$, and also of the constant 2, but x and y already have parallel values. For every possible index, the result xapping will have a pair with that index if and only if *all* input xappings have a pair with that index. This use of the α and \cdot characters is syntactically reminiscent of (and intentionally modeled on) the backquote notation of Common Lisp [8, 9], in which the backquote character “`” indicates that a copy should be made of the following data structure, and the comma character “,” in effect says, “but not here – just evaluate it and use the value.”

The second notation uses the character β as a reduction functional: If f is a function of two arguments, then βf is a function that, when given a xapping x as an argument, will use f to combine the values of all the pairs in x pairwise, repeatedly, until a single value results. Thus

$\beta +$ is a function that will sum all the values in a xapping, and $\beta \max$ will return the largest value in a xapping.

The third notation uses the same character β (in an overloaded fashion) as a permutation functional that, in an abstract sense, describes what the Connection Machine router does when passing messages from processor to processor. If f is a function of two arguments, then βf is a function that, when given two xappings x and y as arguments, matches up pairs by their indices just as the α notation does; if x contains a pair $p \rightarrow q$ and y contains a pair $p \rightarrow r$, then the result will contain a pair $q \rightarrow r$. If one regards xapping indices as naming Connection processors (or, to turn it around, if one thinks of a xapping as having a Connection Machine processor associated with each pair), then this describes the action of processor p sending to processor q a message containing the value r . If x happens to contain more than one pair whose value is q , then multiple processors will send messages to the same processor q , in which case the function f is used to combine those values into a single value so as to produce a single pair in the result with index q . (This is why the same character β is used to notate two different operations: In the most general case, they each involve reduction of multiple values to a single value).

The design of CM-Lisp attempts to be completely general in giving meaning to every possible Common Lisp operation when α is applied to it. This leads to a rather intricate theory of control flow and function application that can be described either by a metacircular interpreter or algebraic relationships between α and such Lisp constructs as lambda and if [7].

Figure 1 shows an early (1987) example of a Connection Machine Lisp program that identifies prime numbers less than 100,000 by the method of the Sieve of Eratosthenes, taken (with minor alterations) from [10]. The function `find-primes` takes an argument n indicating the number of integers to be tested; for this example, it should be called as `(find-primes 100000)`. The function `make-xector` makes a `xector` (a xapping whose indices happen to be consecutive integers starting from 0); thus the local variable `candidate` is bound to a xector of length n whose elements are all initially `t` (true), and the local variable `primes` is bound to a xector of length n whose elements are all initially `nil` (false). The function `iota`

```
(defun find-primes (n)
  (let ((candidate (make-xector n :initial-element t))
        (primes (make-xector n :initial-element nil)))
    (value (iota n)))
  (asetf candidate ' [nil nil])
  (do ((next-prime (position t candidate) (position t candidate)))
      ((null next-prime) primes)
    (setf (xref primes next-prime) t)
    α(setf •candidate
          (and •candidate
               (not (zerop (mod •value next-prime)))))))
```

Connection Machine Lisp. Fig. 1 Example Connection Machine Lisp program for identifying prime numbers

creates a xector that maps integers to themselves; thus the local variable `value` is bound to a xector such that element k has value k , for $0 \leq k < n$. The construction `asetf` indicates that `setf` is to be used as many times as needed; the second argument is a xector `[nil nil]` of length 2, and so at most two `setf` operations will be performed (fewer if n is 0 or 1). The effect is to set elements 0 and 1 (if they exist) of the xector in variable `primes` to `nil`. The `do` loop is a conventional Common Lisp `do` loop; it binds, initializes, and steps the variable `next-prime` repeatedly, executing the body in between, until the test expression `(null next-prime)` is true, at which point the result expression `primes` is evaluated and its result is returned. The function `position` is the conventional Common Lisp sequence function `position`, overloaded to process xectors (and implemented using parallel techniques); it returns the index of the leftmost element (i.e., the element of smallest index) whose value matches the given value (in this case `t`), but returns `nil` if no element of the xector matches. Each time that `next-prime` is not `nil`, the two body expressions are executed. The function `xref` is analogous to Common Lisp `aref`, but indexes a xapping rather than an array; thus the expression `(setf (xref primes next-prime) t)` sets one element of the xector `primes`, namely the one selected by the index `next-prime`, to `t`. (One could select many elements in parallel, thereby producing a new xapping or updating many elements of an existing xapping, by using `α` with `xref` in an expression such as `α (xref primes •indices)`). With elements of a xapping spread across

many Connection Machine virtual processors, this construction would perform interprocessor communication.) The second expression in the body of the `do` loop updates elements of the `candidate` xector; because the operands `candidate` and `value` are each preceded by a bullet character “`•`,” they are treated as already parallel; on the other hand, the operand `next-prime` has no bullet in front of it and therefore is automatically replicated (broadcast to all virtual processors). This expression uses the conventional (and idiomatic) Common Lisp special form `and`, but it could (equally idiomatically) have been written using `when`:

```
α (when •candidate
      (setf •candidate
            (not (zerop (mod •value
                           next-prime)))))
```

Either version has the effect of inactivating virtual processors for which `candidate` has the value `nil`, then executing the expression `(not (zerop (mod •value next-prime)))` on whatever virtual processors remain active, then reactivating virtual processors disabled in the first step.

By 1987 there was a working implementation of CM-Lisp that included a garbage collector and a compiler, but it restricted the values of xappings stored within Connection Machine processors to be integers, floating-point numbers, or characters, and did not yet support the execution of nested `α` expressions in parallel [13]. Programming languages whose designs were influenced by experience with CM-Lisp include Paralation Lisp [6], which was by design less abstract than CM-Lisp so

as to admit an efficient compiled implementation [1], and NESL [2], which successfully implemented nested parallel execution of data-parallel operations on nested vectors of differing size [3].

Definition

The Control Data 6600 computer, regarded by many as the world's first supercomputer, was designed by Seymour Cray and James Thornton, introduced in 1964, and featured an instruction issue rate of 10 MHz, with overlapped, out-of-order instruction execution in multiple functional units and interleaved memory banks. A unique "scoreboard" unit controlled instruction issue and execution so as to match the behavior of traditional, sequential execution.

Discussion

Introduction

The state of the art in scientific computing, immediately prior to the Control Data 6600, was represented by the Univac LARC, introduced in 1960, with 20K–96K 48-bit words of core memory, a 4-μs floating-point add time, an 8-μs floating-point multiply time, and a 28-μs floating-point divide time. The LARC was closely followed, in 1961, by the IBM 7030 (also called Stretch), with 16 K–128 K 64-bit words of core memory, a 1.4-μs floating-point add time, a 2.5-μs floating-point multiply time, and a 9-μs floating-point divide time. The IBM 7030 executed 1.2 million instructions per second (MIPS), on average, and occupied 2,000 ft² of floor space.

Three years later, the Control Data 6600 computer offered 64K–128K 60-bit words of core memory, a 0.4-μs floating-point add time, a 0.8-μs floating-point multiply time, and a 2.9-μs floating-point divide time. Its execution rate averaged 3 MIPS, 2.5 times faster than the IBM 7030, but occupied only 200 ft² of floor space.

Architecture

The CDC 6600 instruction-set architecture had several features common to Cray's machines, including:

- A load-store architecture
- Several register types
- An absence of condition-codes
- Three-address instruction formats
- Word-only access to memory
- Non-standard arithmetic
- Delegation of input-output and overhead functions to peripheral processors

These architectural features were chosen to allow Cray's characteristically aggressive clocking, with multiple cycles required, even for simple instructions.

Load-Store Architecture

Load-store architectures require operands to be loaded into registers before they can be operated on, and results must be explicitly stored to memory. With explicit load instructions, support for overlapped instruction execution, and with a sufficient number of registers, it is often possible to schedule long-latency memory loads of operands in advance of their use, so that a computation is not delayed by the access latency. With explicit store instructions, memory bandwidth is only used to save desired intermediate results.

The CDC 6600 was a load-store architecture, but it had no pure load or store instructions. Rather, loads were initiated when one of a subset of address registers was written, and stores were initiated when one of a different subset of address registers was written.

Register Sets

The registers of the CDC 6600 included a set of eight address registers (A registers), a set of eight index registers (B registers, with B0 holding the constant zero), and a set of computation registers (X registers). The A and B registers were 18 bits in length, large enough to address the entire, 128K word memory space. Loop indices and other housekeeping variables could, also, be represented with 18 bits of precision. The X registers were 60 bits in length, and were used to hold fixed-point and floating-point operands.

Loading and storing of registers was through an unusual mechanism; an instruction that wrote to one of registers A1 through A5 caused the corresponding register X1 through X5 to be loaded from memory at the address in the corresponding A register. An instruction that wrote to either A6 or A7 caused the contents of either X6 or X7 to be stored at the address in the corresponding A register. Registers A0 and X0 did not have this behavior.

In addition to the general-purpose A, B, and X registers, the CDC 6600 had an 18-bit program counter, an 18-bit base register for all memory accesses, an 18-bit field-length register for all memory accesses, an exit-enable register, as well as a pair of base and field-length registers for Extended Core Storage accesses.

The program counter could only point to a 60-bit location in memory, even though up to four instructions could be packed into a memory location. This necessitated that every branch target was to the instruction encoded in the high 15 or 30 bits of the destination word.

The base and field-length registers allowed program and data relocation within the memory space of the CDC 6600, supporting efficient sharing of the computer by multiple programs. Other than this linear relocation, no other address translation was performed by the CDC 6600.

The exit-enable register encoded the conditions that could cause a program to exit, and included address-out-of-range, operand-out-of-range, and indefinite-operand conditions. Upon program exit, this register field held the actual conditions at the time of program exit.

All of the registers of the CDC 6600 were saved (and restored) in a 16-word block of memory by the Exchange Jump operation.

Branch Condition Encoding

Conditional branches in the CDC 6600 were based on the states of specified registers (or pairs of registers), rather than the state of a single, condition-code register. Branch conditions include the zero, negative, in-range, and indefinite status of any X register, as well as equality and inequality relations between arbitrary pairs of B registers.

In common computer architectures, a single condition-code register is usually implicitly set by the last arithmetic or logical operation, and sometimes by the last load operation, as well. Typically, it encodes if the last result was zero, was negative, caused a carry-out, or caused an arithmetic overflow. For an implementation with strictly sequential execution, condition codes cause few performance penalties, although determination of a zero result often requires an additional cycle after an arithmetic result is available.

When instruction execution is overlapped, however, the implicitly set, single-condition-code register requires that the condition-setting instruction immediately precede its conditional branch. If branches are not based on the state of a single condition code, useful instructions can often be inserted between a long-executing instruction and the branch depending on its result.

Other approaches to branch conditions include conditional writing the of the condition code (for example, in the Sun SPARC architectures), or multiple condition codes (for example, in the IBM Power and PowerPC architectures). These approaches both require additional opcode space to specify the condition-writing behavior.

Three-Address Instruction Format

Most of the CDC 6600 instructions specified three registers, two source registers, and a destination register. Although requiring a larger instruction word than a two-address instruction format (where the destination register is, also, one of the source registers), a three-address instruction format does not require an extra instruction to move a result. This is particularly helpful when registers are not completely symmetrical, as was the case with the CDC 6600's loadable registers X1-X5 and storable registers X6 and X7.

The opcode field implicitly encoded the type of registers addressed by the instruction, so that each register specifier field was only three bits in length, for a total of nine bits for the three operands, leaving six bits for an opcode in the 15-bit instruction format. A longer, 30-bit instruction format included a 15-bit constant field that was combined with one 3-bit register-specifier field to form an 18-bit constant for branch targets or immediate operands. Note that the 18-bit branch target addressed

a 60-bit word; branches were always to the most significant 15 or 30 bits of the destination addresses. The 15-bit and 30-bit instruction formats are shown below.

Memory Access Sizes

Loads and stores in the CDC 6600 always moved 60 bits; there was no direct architectural support for accessing smaller operands. Furthermore, loads only targeted registers X1-X5, and only registers X6 and X7 could be stored. Loading an operand into an A or B register required a load to an X register, followed by a move to the desired register. If other than the low 18 bits of the memory word were desired, the X register could be shifted, with a separate instruction, before moving the new, low 18 bits of its contents to the desired A or B register.

The advantages to such inconvenient restrictions were that the distribution networks between memory and the registers could be highly optimized and that fewer load and store opcodes were required. These advantages were minor, however, and the architectural trade-off reflects Cray's philosophy that ease of programming was far less important than speed of execution.

Number Representations

Integer arithmetic in the CDC 6600 was performed using a 1's-complement representation, in which arithmetic negation, like logical negation, required inverting each bit of the input operation. Two disadvantages of the 1's-complement representation were that additions and subtractions required that the carry-out from the sum be added into the least-significant bit of the sum (an end-around carry), and that there were two representations for zero (in octal, for 18-bit values, $+0 = 000000$, $-0 = 777777$), although the CDC 6600 fixed-point add units never produced a negative-zero result.

Floating-point numbers in the CDC 6600 had a 1-bit sign, an 11-bit binary exponent (biased by 1,024), and a 48-bit coefficient with the radix point to the right of the least significant bit. Both the exponent and the coefficient were represented as 1's complement numbers. The radix point on the right allowed easy conversion of integers to floating-point values. In addition to finite values, the floating point format encoded positive and

negative infinity (that might be generated via arithmetic overflow or division by zero), as well as indefinite values (that might be generated by dividing zero by zero, or by adding positive infinity to negative infinity). These exceptional results could be tested by branch instructions.

The CDC 6600's floating point representation differed from all other computer families, most notably differing from that of the IBM 360, with its hexadecimal exponent, and sign-and-magnitude fraction. At the time of its introduction, this mattered little, but, over time, the ubiquity of the 360 and 370 architectures meant that most of a growing collection of carefully crafted numerical routines could not be used by programmers of the CDC 6600 and its successor machines.

Peripheral Processors

The central processor of the CDC 6600 was dedicated to computation; input-output operations, job scheduling, and other "overhead" operations were delegated to a set of ten peripheral processors, or PPUs. Although implemented in the same technology as the central processor, and housed within the same cabinet, each of the PPUs executed at a fraction of the central processor's speed and had a very different instruction set architecture, along with its own, private memory.

These PPUs were connected to the computer system's input-output devices and controlled them directly. The PPUs interfaced to the central processor via the system memory. The PPUs could interrupt the central processor by using the Exchange Jump operation, which simultaneously saved the current central processor program context to memory and loaded a new context from memory. In one sense, the central processor was a compute-server slave to the collection of PPUs. In a different sense, the central processor was the star performer, freed from mundane responsibilities by its entourage of support processors.

Instruction Set Listing

The instruction set of the CDC 6600 central processor is listed below. Octal notation is used to represent the six-bit opcodes; where three-digit opcodes are specified, they indicate that the i-field of the instruction further expand the opcode. The value jk is the 6-bit constant formed by the j- and k-fields.

00	Stop
01	Return Jump to K
013	Central Processor-initiated Exchange Jump (special hardware option)
02	Goto K + Bi
030	Goto K if Xj is zero
031	Goto K if Xj is not zero
032	Goto K if Xj is positive
033	Goto K if Xj is negative
034	Goto K if Xj is in range (not infinite)
035	Goto K if Xj is out of range (infinite)
036	Goto K if Xj is definite
037	Goto K if Xj is indefinite (similar to IEEE NaN)
04	Goto K if Bi == Bj
05	Goto K if Bi != Bj
06	Goto K if Bi >= Bj
07	Goto K if Bi < Bj
10	Transmit Xj to Xi
11	Logical Product (AND) of Xj and Xk to Xi
12	Logical Sum (OR) of Xj and Xk to Xi
13	Logical Difference (XOR) of Xj and Xk to Xi
14	Transmit not Xk to Xi
15	Logical Product of Xj and not Xk to Xi
16	Logical Sum of Xj and not Xk to Xi
17	Logical Difference of Xj and not Xk to Xi
20	Rotate Xi left jk places
21	Shift Xi right jk places (with sign-extension)
22	Shift Xi nominally left Bj places (right if Bj negative)
23	Shift Xi nominally right Bj places (left if Bj negative)
24	Normalize Xk to Xi and Bj
25	Round and normalize Xk to Xi and Bj
26	Unpack Xk to Xi and Bj
27	Pack Xk and Bj to Xi
30	Floating point sum of Xj and Xk to Xi
31	Floating point difference of Xj and Xk to Xi
32	Floating double sum of Xj and Xk to Xi
33	Floating double difference of Xj and Xk to Xi
34	Rounded floating point sum of Xj and Xk to Xi
35	Rounded floating point difference of Xj and Xk to Xi
36	Integer sum of Xj and Xk to Xi
37	Integer difference of Xj and Xk to Xi
40	Floating point product of Xj and Xk to Xi
41	Rounded floating point product of Xj and Xk to Xi

42	Floating double product of Xj and Xk to Xi
43	Form jk mask in Xi
44	Floating point divide Xj by Xk to Xi
45	Rounded floating point divide Xj by Xk to Xi
46	Nop
47	Sum of 1's (population count) in Xk to Xi
50	Sum of Aj and K to Ai (load or store Xi if i != 0)
51	Sum of Bj and K to Ai (load or store Xi if i != 0)
52	Sum of Xj and K to Ai (load or store Xi if i != 0)
53	Sum of Xj and Bk to Ai (load or store Xi if i != 0)
54	Sum of Aj and Bk to Ai (load or store Xi if i != 0)
55	Difference of Aj and Bk to Ai (load or store Xi if i != 0)
56	Sum of Bj and Bk to Ai (load or store Xi if i != 0)

Implementation Technology

The resistor-transistor logic gates of the CDC 6600 were packaged in “cordwood” modules, approximately $2.5'' \times 2.5'' \times 0.8''$ in size, in which pairs of circuit boards were connected by resistors between the boards. With the silicon transistors on the inside, wiring traces on the outside, off-module wiring on one edge, power and mechanical connections to a cooling plate on the opposite edge, each module implemented a high-density, serviceable logical element.

The core memory used by the CDC 6600 was packaged in blocks, approximately $6'' \times 6'' \times 2.5''$, each

holding 4,096, 12-bit subwords, with five memory modules making up a bank of 4,096, 60-bit words. A fully populated CDC 6600 had 32 interleaved banks of memory; each bank had an access time of 800 ns and cycle time of 1,000 ns, and a different bank could be accessed every 100 ns.

Memory reads to core memory were destructive, so that, following a read, the data had to be written back or it would be lost. This characteristic was exploited by the Exchange Jump operation, which saved the current 16-word program context, while simultaneously loading a new program context.

Implementation Features

The major implementation features of the CDC 6600 were its:

- Ten functional units capable of overlapped execution
- An Instruction Stack for caching instructions in loops
- A Scoreboard unit to manage the overlapped and out-of-order instruction execution

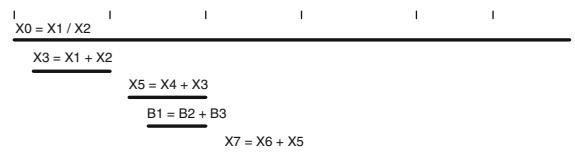

Functional Units

Functional units of the CDC 6600 included:

- A 60-bit Boolean unit (3 cycles)
- A 60-bit shift unit (3 cycles)
- A 60-bit fixed (integer) add unit (3 cycles)
- A 60-bit floating point add unit (4 cycles)
- Two 60-bit floating point multiply units (10 cycles)
- A 60-bit floating point divide unit (29 cycles or 8 cycles)
- Two 18-bit increment (short integer) units (3–11 cycles)
- An 18-bit branch unit (8–15 cycles)

These functional units all required multiple cycles to execute, as indicated, but they were not pipelined; they could only process one set of operands at a time. Two multiply units were provided, because multiplies are relatively common in scientific programming, but slow to execute. Two increment units were, also, provided, because their operations, which included load and store operations, were very common.

One clock cycle was the minimum time required to issue a new instruction, so it was possible, with care, for a program to keep multiple functional units busy simultaneously. Furthermore, differing execution times could cause instructions to complete out of program order. For example, a divide, followed by a series of adds could finish after all of the following adds finished. In the figure below, the divide issues and begins execution in cycle 0, completing in cycle 29. The following floating-point add (to X3) issues and begins execution in cycle 1, completing in cycle 5. The next add (to X5) cannot issue until cycle 6 because the add unit is busy; its input operand is available, so it executes in cycle 6 and completes in cycle 10. The next instruction, an 18-bit add (to B1), issues and begins execution in cycle 7, completing in cycle 10. The final add (to X7) issues and executes in cycle 11, when the add unit is not busy, completing in cycle 15.

The floating point add and multiply units supported both single and double precision arithmetic, but required two instructions to return the more and less significant parts of a double-precision result.

Conversions between integer and floating point operands used the shift unit, sometimes requiring two instructions to complete a conversion.

The divide unit executed floating point divides, as well as a population-count instruction (which counted the number of 1-bits in a word) and a no-operation (nop) instruction. Because of the branch-target restrictions, nop instructions were very common in CDC 6600 programs.

Most branch instructions, besides requiring the branch unit, also required the use of an increment unit or the fixed-point add unit for operand comparison or testing.

Instruction Stack

Instructions for the CDC 6600 were cached in an 8-word instruction buffer (called the Instruction Stack), so up to 32 instructions could be held in fast-access

storage, although loops were limited to, at most, 26 instructions, plus one branch, if they were to remain in the Instruction Stack.

Scoreboard Unit

The Scoreboard Unit enforced sequential execution semantics, while allowing instructions to execute and complete out of program order. For this discussion, an instruction *issues* when it is decoded and sent to a functional unit for eventual execution, an instruction *executes* when it has received all of its operands and begins the specified operation, and it *completes* when it writes its final result(s) to a memory location or to one or more registers. Instructions in the CDC 6600 always issued in program order, although they often executed and completed out of order.

Because the CDC 6600 functional units were not pipelined, a functional unit remained busy from the time an instruction was issued to it until one cycle after that instruction completed. A result register remained busy from the time its instruction issued until it completed.

During the issue process, each instruction was decoded and its required functional unit(s) and destination register(s) were determined. If a required functional unit was unavailable, or if the destination register was busy, issuing stalled until all were available. These were called first-order conflicts by the designers of the CDC 6600. Once the first-order conflicts disappeared, the instruction was sent to the required functional unit(s), along with the source and destination register specifiers. This enabled the issue process for the following instruction to begin.

If all required input registers were available, execution began; otherwise, the functional unit waited for them to become available. Unavailability of input registers was called a second-order conflict; this tied up a functional unit, but allowed other instructions to continue executing.

Execution proceeded and, one cycle before the result was ready, the functional unit signaled that it was ready to release its result to the destination register. If all release datapaths were busy, or if one or more previously issued instructions had not yet used the older value in the destination register, completion stalled. Inability to write a result was called a third-order conflict; like a second-order conflict, it tied up the functional unit, but

did not affect the execution of instructions that did not depend on the uncompleted instruction.

The Scoreboard Unit operated on state information associated with the functional units and the registers. With each functional unit (FU) was associated:

- F_m – function to be performed by the unit (e.g., integer add, integer subtract)
- F_i – the destination register for the result
- F_j – the first source register for the function
- F_k – the second source register for the function
- Q_j – the functional unit producing the result in F_j
- Q_k – the functional unit producing the result in F_k
- RF_j – a bit indicating that F_j was ready
- RF_k – a bit indicating that F_k was ready
- XS – a bit indicating that the FU had begun execution
- RQ – a signal indicating that the FU was requesting to release its result
- RL – a signal indicating that the FU was releasing its result
- AC[] – a set of bits indicating that registers F_j and F_k had not been read

Also, copies of the current input operands were kept within each functional unit.

With each register r in {A0-A7, B0-B7, X0-X7}, was associated QR, the functional unit or memory read storage channel that would, eventually, write its data, or an indication that the register had its data. With each register r was associated AC, or All Clear, indicating that no functional unit reading that register had started execution.

The issue process can be described by the following algorithm, operating on each instruction p in succession:

1. Decode instruction p to determine the functional unit FUp, F_m, F_i, F_j, and F_k.
2. Use F_j and F_k to look up values for Q_j, Q_k in QR[].
3. While FUp is busy or register F_i is busy, stall.
4. Send F_m, F_i, F_j, F_k, Q_j, Q_k to FUp.
5. If F_j is not waiting for a FU result, set RF_j and transmit register F_j to FUp, otherwise clear RF_j.
6. If F_k is not waiting for a FU result, set RF_k and transmit register F_k to FUp, otherwise clear RF_k.
7. Clear AC[FUp][F_j] and AC[FUp][F_k].
8. Set QR[F_i] to FUp.

Notes on the issue process:

- Steps 2 and 3 depend on step 1, but can execute during the same processor cycle as step 1.
- Step 3 could repeat for many cycles, given a long chain of instruction dependencies.
- Once Step 3 is past, Steps 4, 5, 6, 7, and 8 can proceed in parallel.

The execute process can be described by the following algorithm, operating in each functional unit in parallel:

1. If RF_j is clear and RL[Q_j] is active, load operand j with the result on the release datapath and set RF_j.
2. If RF_k is clear and RL[Q_k] is active, load operand k with the result on the release datapath and set RF_k.
3. If RF_j is set and RF_k is set, start execution, set AC[F_j] and AC[F_k], and set XS.

Notes on the execute process:

- Steps 1 and 2 execute in parallel.
- The release datapaths for operand j and operand k are either independent, or RL[Q_j] and RL[Q_k] are asserted on different cycles, so no release datapath conflicts can occur.

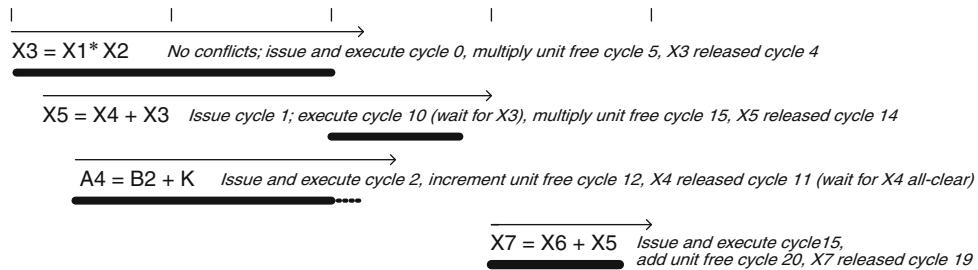

The result release process can be described by the following algorithm:

1. One cycle before completing its operation, a functional unit asserts RQ.
2. If any AC[*][F_i], for all relevant functional units, is clear, delay the grant.
3. If a functional unit of higher priority for the release datapath is asserting RQ, delay the grant.
4. Otherwise, grant the release request.
5. The following cycle, the functional unit asserts RL and writes its result onto the release datapath to the appropriate register.

6	3	3	18
Opcode	i	j	K

Control Data 6600. Fig. 1 Issue and execute timing example for dependent and independent instructions

Control Data 6600. Fig. 2

Notes on the release process:

- Because the RQ signal is sent one cycle early, there is time to detect release conflicts and, if there are none, the release can be granted without delaying the functional unit.
- Any other functional units waiting for the result can select it from the release datapath, saving a register read.

A simple example illustrates some of the scoreboard functions. Assume that all four instructions have been loaded into the Instruction Stack. The multiply to X3 has no conflicts, so it issues and begins execution in cycle 0. The multiplier remains busy through cycle 11 (indicated by the light arrow), and execution runs from cycle 0 through cycle 10 (indicated by the bold line please see Fig. 2).

The add to X5 issues in cycle 1 because both X5 and the adder are free. However, the operand X3 is not available until cycle 10, when the add begins to execute. The adder releases X5 in cycle 14 and the unit becomes free in cycle 15.

The 18-bit add to A4 (causing a load to X4) issues in cycle 2 because X4, while an input operand to a previous, uncompleted instruction, was copied into the add unit at cycle 1. The release of X4 is delayed until after X4 receives the all-clear signal (in cycle 10, when the add started execution). X4 is released in cycle 11 and the increment unit becomes free in cycle 12.

Issuing of the add to X7 stalls from cycle 4 until cycle 15, when the add unit becomes free. X5 is available by then so execution also begins in cycle 15, releasing X7 in cycle 19, and freeing the adder in cycle 20.

The scoreboard unit enforced the serial dependency of X3 -> X5 -> X7, allowed the load to X4 proceed in parallel, but prevented the load to X4 from completing

before the add to X5 began. Sequential execution would have required an additional eight cycles to complete.

For all its apparent complexity, the Scoreboard Unit required fewer gates than the average functional unit in the CDC 6600 [5]; nevertheless, this was the only computer to use such a unit. A more complex algorithm, the Tomasulo algorithm, used in the IBM 360 Model 91, provided faster execution for poorly scheduled and register-allocated code [6]. A simpler algorithm, which only tracked pending writes to registers, was used in Cray's later, pipelined machines, allowed faster instruction issuing and, with good instruction scheduling and register allocation, allowed instruction execution as fast as did the Scoreboard Unit of the CDC 6600.

Derivative Machines

The Control Data 6400 employed the same technology as the CDC 6600, but only supported sequential execution of instructions in a single, non-pipelined execution unit. In the Control Data 6500, two 6400 central processors shared a single, interleaved memory system.

In 1969, the Control Data 7600 succeeded the CDC 6600 as the fastest computer in the world. It executed the same instruction set in multiple, fully pipelined, functional units, with an instruction issue rate of 36 MHz.

Definition

During the creation and conception of a new car model, safety engineers from automotive industry perform crash simulation, in order to evaluate the level of safety of a car and its occupants. During a car crash, the kinetic energy of the car, $E = 1/2M.v^2$, that the vehicle has

before impact, is transformed into deformation energy. Crash simulation indicates the capability of the material used for the design, to absorb this energy and protect the occupant. Most important results are the deceleration felt by the occupants, which must fall below threshold values fixed in legal car safety regulations [1]. To ensure driver safety during a car crash, and meet the regulations in order to get the official approval and homologation of a new car model for road services, car manufacturers need to perform crash tests. Race cars need also to meet requirements specified by the FIA, “Fédération Internationale de l’Automobile” [2]. Safety regulations require several physical crash tests that must be performed on a new model. These tests are extremely expensive; to reduce the number of physical crash tests, and also the product development lead time and costs, engineers need to carry out a range of virtual tests, or crash simulations, using crash codes. These codes are based on explicit finite element method well suited for analyzing nonlinear dynamic response of structures. The ability of crash codes is to effectively handle material nonlinearity, and nonlinear behavior such as contact. To perform a crash simulation in a reasonable time scale, safety engineers use High-Performance Computing (HPC) that allows to perform several crash simulation, during a day, from frontal crash to components impact simulation. Nowadays, automotive industry relies heavily on simulations; by using simulation, the number of real test crash is reduced, but computer simulations cannot fully replace the crash test, since a crash test is required in the final stage of development to validate numerical results. Simulations are compared to test data using high-speed camera for visualization, and accelerometers that are placed at different locations on the dummy. Before the first prototype is built, a new car model goes through thousands of computer simulations, crash and components system impact simulations. When engineers conduct the physical crash tests, the model has already achieved a high standard performance through computer simulations. In automotive industry, car crash simulation is the most computer time-consuming task, thus the need to use parallel computing. With adoption of HPC technology, new systems can perform crash simulations using clusters, an assembly of several computers running in parallel, “parallel computing,” that can achieve a speed that is proportional to the number of CPU's in the parallel

system. In a crash simulation, the most critical part of the parallel simulation is the contact handling, new contact search algorithms based on bucket sort have been developed that lead to better scalability. A detailed description of the performance of contact algorithm is described in [3].

Discussion

To ensure driver safety during a car crash, impact structures are designed and optimized to absorb the kinetic energy during the crash, and limit decelerations acting on parts of human body like knees and necks. Decelerations values have to meet safety requirements specified by government regulations. To meet product development schedule of new car models, it is necessary to use parallel processing for crash simulation. Vector processing has been in use from the beginning of practical crash simulation. Vector processing which permits the performance of several calculations simultaneously was introduced as an extension to serial processor [4], to reduce computer time for crash simulation. Vector processing techniques, first developed for supercomputers for high-performance applications, were commonly used in crash simulation in the 1980s and 1990s.

HPC remained expensive and limited because of single CPU system. In recent years, multiple CPUs and multiple cores have offered increase of multiple performance and lower cost for crash simulation and other engineering simulation tasks. Later, in order to extend execution of data parallel processing constructs as DO loop, IF loop analysis, and nested loops in the Fortran language, SMP (Shared Memory Processing) version of crash code has been developed.

In the SMP technology, multiple CPUs share same memory. Since CPUs are accessing shared memory simultaneously, data supplied from memory to CPUs is likely to be slow, when the number of CPUs increases, which limits the number of CPUs that can be used efficiently. However, it has been observed that the scalability of the SMP version of crash codes was observed to stop at eight processors [3]. To overcome this problem, and solve the limitation of shared memory processing, the MPP (Massive Parallel Processing) version of crash codes has been developed, which uses distributed memory. In MPP, each small group of CPUs has its own memory, and CPUs are interconnected via a high-speed

networking system. MPP version of crash codes as LS-DYNA and other crash codes has been performing with scalability up to hundred and even thousands of processors; however, it has been observed that interconnected speed is a significant limiting factor in the scalability of MPP performance [3].

When using the MPP version, prior to computer processing, domain decomposition needs to be performed to divide the problem. In domain decomposition, the model is decomposed into subdomains; each subdomain is processed by a CPU and uses the memory dedicated to that CPU.

Current compilers are not yet capable of automatically translating an SMP version of a crash code that runs on shared memory into an MPP version that runs efficiently on distributed memory. MPP requires a certain amount of development that needs to be performed jointly by developers from computer and software development companies.

Several computer companies, such as Fujitsu in Japan which has been involved from the beginning in the vectorization and parallelization of crash simulation codes, first started developing SMP version of crash codes using OpenMP language, and then moved to MPP using MPI library (Message Passing Interface). Today, most engineering simulations are performed on Quad core or more powerful CPUs.

Few years ago, simple simulation events, such as a small model using a few dozen elements and representing an event that lasts 100 ms, required a day or more on a vector supercomputer to complete. Today, by using low-cost parallel computing, safety engineers can model large-scale crash car to car simulation with airbags and occupants in just a few hours. Nowadays, all car companies have incorporated parallel computing into their car design.

Historical Performance Trends

The primary goal of crash simulation is to improve safety for human occupants and evaluate design improvements to enable vehicles to score well on crash tests performed by regulatory and insurance agencies. In order to improve the accuracy of crash test safety analysis and to represent vehicle geometry more accurately, the number of finite elements in analysis models has been continuously increasing.

Crash safety numerical simulation is performed primarily by explicit time marching, in which the entire evolution of a crash from initial impact to final resting state, about a tenth of a second, is calculated in steps of about 1ms. During crash simulation, different parts of the car get in contact with themselves and each other, this can be handled by using contact algorithms. Contact analysis is an important feature in crash simulation, and continuing research for efficient parallelization of contact algorithms is still ongoing. A detail description of the performance of contact algorithm is described in [5]. Crash simulation is performed using finite difference method for time integration, and Finite element method FEM, for space discretization [6]. Deformations, velocities, and forces on all relevant parts of the vehicle and of dummies simulating the danger of injury to human occupants are calculated at each time step. To simulate a crash and occupant safety, crash analysis software, including LS-DYNA, PAM-CRASH, and other commercial and academic codes, must be able to handle large deformation, material nonlinearity, and complex contact conditions among multiple components [7]. The software must be able to simulate different type of car crash events, as frontal, side, and rear impact.

In the early 1990s, crash simulation would typically be performed on Symmetrical Multi-Processor supercomputers, with 36,000 elements considered a large model. In year 2001, several car manufacturers had adopted MPI cluster computing [8] for crash simulation, using CPUs such as AMD Athlon K7 [9], Intel Xeon DP, or Itanium. At that time, high-speed

Interconnect system did not support more than 24 CPUs efficiently, thus a simulation with 500,000 elements would be the most detailed, suitable for overnight completion.

Also, by that year, the detail and computational cost of a useful practical analysis far exceeded the Dodge Neon benchmark (535,000 elements), the only benchmark quoted the first year. This detail of the car crash model of the benchmark is fully described in the next section, (elements number, nodes number, etc.). The benchmark has been completed on several commercial analysis codes of similar nature, all available for parallel computing. For this car model, we compare the performance of high-end dual CPU technical workstations quoted in 2003 against a consumer product single CPU quad core desktop of 2009. From Tables 1 and 2, we observe that not only the performance has been improved by a factor of six, the computer system in Table 1 is five times more expensive than the computer used in Table 2. Consequently, cost and performance of minimum parallel computing platforms for crash simulation each improved by more than a factor of 6 over 6 years time.

These quotations are for the SMP (OpenMP) single node threaded analysis, at least in the case where that information was provided in the submission.

Tables 3 and 4 compare MPP performance cluster results quoted in 2003 and 2009, using IBM and Intel CPUs; Table 3 represents the highest performance reported in that year. From these tables, we can conclude that for clusters, performance has been increasing at least by a factor of 4 between the years 2003 and 2009.

In 2009, much larger clusters could be purchased for the price of clusters quoted in 2003.

As reported in TopCrunch [10], a project initiated to track the aggregate performance trends of high-performance computer systems and engineering software [10], InfiniBand™ adapters and switches had proven cost-effective for cluster communication, and substantial improvements in simulation cost and

performance are demonstrated. In the TopCrunch report, the car2car benchmark model using close to six million elements (5,800,000 elements) was introduced in 2006 to represent better the detail of simulation required in practice at that time.

In Tables 5 and 6, we compare the performance of realistic size models for clusters installed in 2006 and 2009. In these two tables, it is shown that in 3 years time,

computational performance doubled, while cutting the number of cluster nodes in half, using the same total number of CPU cores.

In the performance quotations referred in [Tables 1–6](#), an increasing number of cores has accounted for a major part of enhanced performance. This trend may be expected to continue.

Recent development in parallel computing combines both SMP and MPP technologies, called hybrid OpenMP/MP. The hybrid model may see increased usage as the number of cores within shared memory nodes increases, as it should moderate growth of memory size and communications load with increasing number of threads.

Practical Benefit of Improved Parallel Computation

In 2003, only a few passenger vehicles, aimed toward the safety conscious market segments, had been designed by the aid of crash simulation, and achieved good ratings on various governmental and insurance industry tests. By 2009, all vehicles marketed internationally had published crash survival ratings, most of them substantially improved, while the required tests had become more comprehensive. Cost-effective parallel computing enabled this degree of success in product introductions.

CPU vendors like to tell how, if the automotive industry had made progress equivalent to the computing industry, we would all be driving vehicles faster and safer than bullet trains at less than the price of a single train ride. In fact, the safety record of current vehicles has improved by several times in less than a decade, due directly to the success of their manufacturers in computational design and product improvement, with no adverse impact on consumer acceptability.

For the simulations, the models have been improved and details taken into consideration by increasing the number of elements in the model.

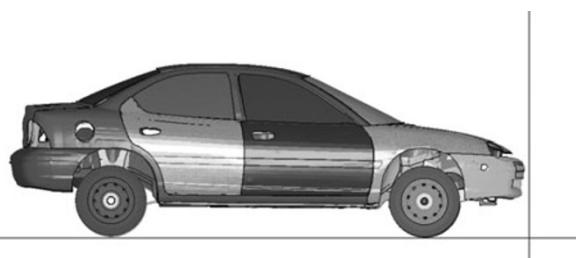

- 1986: First model had 3,439 elements
- 1990: 1.5×10^4 – 2.00×10^4 elements
- 1995: 5.0×10^4 – 10.0×10^4 elements
- 2000: 10×10^4 – 25.0×10^4 elements
- 2005: 1.0×10^6 – 1.50×10^6 elements

In the near future, in order to have an accurate model, the number of elements in a full scale crash will

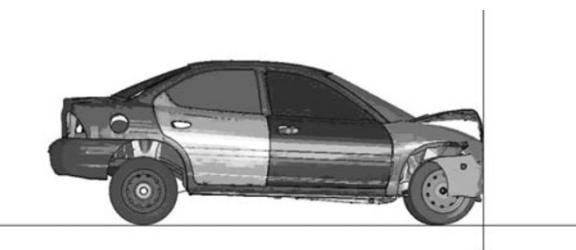

exceed ten million elements. All current simulations performed on clusters.

Description of the Dodge Neon Benchmark

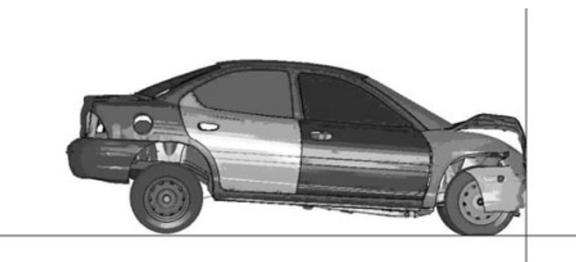

The first test case illustrated here is a vehicle crash-worthiness application of vehicle impacting into a rigid barrier. The digitized vehicle model, a Dodge Neon, is developed by the National Crash Analysis Center at the George Washington University. The model is developed through reverse engineering process that involves systematic disassembly of the physical vehicle to finite element model of each and every part in the vehicle. The geometry data for each part is converted to an FE (finite element) mesh and carefully reassembled with the appropriate consideration of connections and constraints between elements to create a full vehicle FE model. A series of material level characterization tests,

Crash Simulation. Fig. 1 Car deformation at time $t = 0$ ms

Crash Simulation. Fig. 2 Car deformation at time $t = 40$ ms

Crash Simulation. Fig. 3 Car deformation at time $t = 80$ ms

on coupons extracted from various locations of the vehicle, are performed to gather the required input for the material models in FE program. The fully assembled model of the vehicle consisting of 535,070 elements is shown below with model statistics listed.

Number of components	324
Number of nodes	291,206
Number of shells	532,077
Number of beams	73
Number of solids	2,920
Number of elements	535,070

Run have been performed using LS-DYNA MPP version. The following pictures show the car deformation at time $t = 0$, $t = 40$ ms, and $t = 80$ ms (Figs. 1–3).

Definition

This entry describes the hardware and software architecture of the CRAY T3E Massively Parallel Processor (MPP), a landmark supercomputer system that became the first commercially successful MPP, and the first to be used in production data centers around the world. It discusses the historical context leading to the development of the T3E and its predecessor system, the CRAY T3D, and the significance of the T3E to the computational science and engineering community.

Overview

The Transition from Vector Systems to Massively Parallel Systems

In 1976, the first CRAY-1 supercomputer was shipped to Los Alamos National Laboratory, setting a new benchmark for general purpose supercomputing. Although Cray Research was a very small company with less than 100 employees at the time, Seymour Cray and a small team had already started down what would turn out to be a rather difficult path to design a successful follow-on product, the CRAY-2. The success of the single-processor CRAY-1 came from a combination of high-performance chip and packaging technology together with an effective streaming vector architecture. Operations achieved a large parallel speedup, provided that long sequences of data could stream through highly segmented “vector pipes” consisting of special vector pipeline registers feeding highly segmented functional units. This architecture was a natural fit for many

problems that simulate extensive n-dimensional computational space. However, successful speed-ups did require management of an extra layer of architectural complexity – the efficient loading and unloading of the vector registers from, and to, main memory.

Seymour Cray always saw simplicity as a mark of architectural elegance. So for the new project, he naturally began to think about alternatives to the vector registers. Perhaps these registers could be eliminated and performance could be more than made up by a large number of CPUs sharing a common memory space. (In current parlance multiple integrated CPUs are now usually called “cores.”) So it was that the first iteration of the CRAY-2 design would have up to 64 scalar “M” processors, each handing off intermediate 64-bit results to similar processors throughout a shared-memory architecture. I/O work would be managed by a cluster of 16-bit “A” processors also connected to this shared-memory system. Significant architectural and detailed logic designs for the “M” and “A” processors were completed, and both an experimental operating system and a Fortran compiler were running in a simulated environment.

Then one day this entire phase of the CRAY-2 work came to an abrupt halt. It had become apparent after consultation with users of the CRAY-1 that there were huge challenges to effectively program the proposed CRAY-2 for anything but the most regularly organized problems. Memory management and data coherence issues were unfamiliar and intimidating. Effective compiler technology even for the vector-based CRAY-1 was only at an immature state at the time. The CRAY-2 project was in very real danger of having operating hardware available but without nearly adequate system software structures and with no clear timely path to discovering them. For a small new company in need of a strong successor story to help sell its first products, this was not a promising formula for success. There would be more starts and restarts of the CRAY-2 project before it could successfully fill a new application space using a moderate number of vector processors but with a competitively larger memory subsystem that was able to exploit dense dynamic memory chip technology. In fact, the first production.

Cray designers were sensitive to the notion that there are CPUs that run “fast” and then there are computers that solve problems *fast*, and it was becoming clear that fast CPUs would be single chip

microprocessors with on-chip multi-level cache. The personal computer and workstation markets embraced this solution, which drove down production costs by orders of magnitude, but there were serious difficulties for supercomputer designers trying to exploit this opportunity. High production volumes precluded any alterations to the internal design of the CPU for the very high performance market. Due to a very limited pin count, the balance of functional unit performance with the delivery of data from outside the device was seriously tilted in the wrong direction. If that were not enough, there was one more hurdle: The single chip processors were getting high performance in no small measure from onboard cache subsystem. This created a nightmare for managing coherence of data across a large multiprocessor system. Yet the microprocessors were becoming impossible to ignore as internal clock rates were becoming incredibly fast and at ever lower costs as generation after generation followed Moore’s Law. From the supercomputer designers’ perspective these upstarts were extremely frustrating!

The CRAY T3D was the first serious attempt to have at least some success in influencing the I/O properties of a commercial 64-bit microprocessor so that large numbers of processors could cooperate efficiently. Additional special purpose hardware around each CPU to fill in the gaps. CRAY T3E came incrementally closer to the mark. Eventually and inevitably, microprocessors for desktop computers hit some of the same fundamental obstacles that supercomputer designers had faced decades earlier. Desktop (and even notebook) CPUs became multi-core. Seymour Cray’s early hardware vision was at last shared, and its challenges faced, by a much broader spectrum of computer systems designers.

Equally critical to the evolution of massively parallel systems were significant advances in operating system, compiler and applications software technology. The success of the CRAY T3E was due in large measure to a unique collaboration of hardware, system software, and user applications designers from academia, government laboratories, and private industry. The programming obstacles encountered by Seymour Cray’s first CRAY-2 project had finally been overcome.

The Cray T3E

The Cray T3E, which first shipped in 1996 to the Pittsburgh Supercomputing Center, was Cray Research,

Inc's second-generation MPP supercomputer, the follow-on product to the first-generation Cray T3D. The T3D and T3E were the first Cray Research supercomputers to use commodity processors instead of in-house-designed custom CPUs. The T3E was also a departure from the T3D because it was self-hosted, had a very different interconnect architecture, and an entirely new I/O subsystem.

In a technology world driven by Moore's Law, the T3E enjoyed a relatively long service life: It remained in production for over 5 years with some systems still in use in 2010. It was popular with users primarily because of its good communication characteristics and its high ratio of bandwidth between processors, relative to the performance of the processors when compared to the ratios achieved on simple clusters. This made it much easier for users to attain high efficiency and good scaling performance on parallel applications. In addition, the large distributed memory proved very valuable to users. The T3E was also valued by data center managers for the efficiency of its operating system and the high utilization that could be sustained on high-performance computing (HPC) production workloads.

The T3E was "self-hosted," running a distributed version of Cray's Unix operating system, UNICOS/mk. UNICOS was the Unix port to Cray hardware that had been in use since the early 1980s on the CRAY-1, CRAY-2, and all later models of Cray parallel-vector systems. The/mk designation was taken from Chorus, a company that produced a Unix microkernel, which was used as the basis for the Unicos microkernel and server structure. UNICOS/mk was unique because it incorporated some of the latest operating system ideas from both microkernels and servers and also maintained the UNICOS user interface across a distributed memory. Essentially, the system was standard UNICOS reorganized into servers so as to support different varieties of Cray hardware, different scales of system size, and all the features needed to meet existing requirements for usability, performance, and manageability.

The distributed nature of both the operating system and the hardware allowed UNICOS/mk to provide improvements in resiliency. Distribution of OS services simplified the software that ran on any particular processing element (PE) and made it easier to isolate problems. The resultant simplification also made the software more robust. Concerns about the reliability

impact of the significant increase in the number of hardware components necessitated by the T3E architecture had generated a requirement that the T3E should be able to ride through PE failures. But, because UNICOS/mk was conceived as a distributed system, a compute PE failure was easily managed.

The T3E software architecture had two main components: "system" PEs and "application" PEs, whose sole purpose was to run user applications code. There were three specialized types of system PEs: OS PEs, Command PEs, and I/O PEs. Command PEs were used for user login and job launch. The user interface on a command PE was the standard UNIX interface. The operating system ran only system PEs distributed throughout the machine at a ratio of 1 system PE for every 16 application PEs. System PEs could also flexibly be substituted for failed user PEs as necessary to maintain a full complement of application PE's. The ability to map in replacement PEs and eventually repair, reboot, and reintegrate failed PEs, without the need to reboot the whole system, was a tribute to the effectiveness of the distributed hardware and software architecture.

The CRAY T3E was available in two versions that varied by cooling technology and system scale. The liquid-cooled (LC) version scaled to 2048 user processing elements (PEs) while air-cooled (AC) systems scaled to 128 user PEs. The first system was introduced using the 300 MHz version of the DEC Alpha EV5 microprocessor. This first release was later dubbed the T3E-600 (referring to the peak MFLOPS performance of each Alpha processor). Subsequent product versions tracked Moore's Law improvements in the performance of the microprocessor and the EV5 was supplanted by the advanced-process EV56 (21164A) resulting in increased clock speeds of 450 MHz (T3E 900), 600 MHz (T3E 1200), and 675 MHz (T3E 1350). Memory per PE could be configured in sizes ranging from 64 Mbytes to 2 Gbytes, for a maximum aggregate system memory of 4TBytes.

In traditional Cray style, the T3E was designed to be a balanced system and, courtesy of the CRAY Model F I/O subsystem, could be configured with prodigious I/O throughput that was commensurate with its computational capability. This distributed I/O system used Cray's GigaRing network channel to string together chains of I/O PEs hosting channel adapters attached to external disks, tapes, and communications networks in

fault-tolerant ring topologies. Each GigaRing channel was capable of sustained data transfer rates of over 900 Mbytes/s and the system could employ 1 GigaRing for every 4 PEs in the system.

In 1998, a 1280 PE T3E-1200 became the first computer to sustain more than 1 TFLOPS (Trillion Floating Point Operations Per Second) on a real application code, LSMS (Locally Self-Consistent Multiple Scattering), a first-principles metallic magnetism simulation code written by Oak Ridge National Laboratory and optimized by Pittsburgh Supercomputer Center for the T3E. An earlier MPP system, known as ASCI Red, was already installed at Sandia National Laboratory, and in June 1997 was the first system to demonstrate a *peak* performance of 1.3 TFLOPS, but the T3E was able to deliver *sustained* performance in excess of 1 TFLOPS from a system with a peak performance of 1.54 TFLOPS.

Architecture

Processor Choice

Initial work on the T3E architecture and design started in 1992, more than a year before the first shipment of its predecessor, the T3D. Although the T3D used the DEC EV4 microprocessor and Cray was well aware of DEC's next-generation, more powerful, EV5 design they nonetheless investigated alternative processors for the T3E and initially favored a design being proposed by the start-up company MicroUnity. That processor, code-named Terpsichore, would have been implemented in MicroUnity's own Bi-CMOS technology and was designed to use several advanced single instruction multiple data (SIMD) architectural features to enable very high performance on regular vectors of data. Terpsichore was connected to memory and peripheral chips using multiple high-speed ring networks derived from the emerging Scalable Coherent Interface (SCI) channel standard. If successful, it would have run at a then unheard-of 1 GHz clock frequency and would have provided the very large address space and latency-hiding features necessary for large-scale distributed systems. Unfortunately manufacturing process problems, excessively high power dissipation in test chips, and pressure from majority investors to target wider, more-easily attained markets, such as television set-top media processors, caused delays and ultimately abandonment of the Terpsichore chip. Consequently, Cray quickly

started over with the DEC EV5, but some concepts from the MicroUnity experience, notably the aggressiveness of the SCI channel signaling and ring architecture, significantly influenced Cray's designers and were incorporated into the GigaRing I/O channel and the design of the T3E communications link.

The DEC Alpha EV5 superscalar processor was a large step over its predecessor. Many of its performance characteristics that were important to the T3E were a result of improvements to its memory interface, including support for up to two outstanding 64 byte cache line fills and the addition of a 96-Kbyte on-chip second-level cache. Since the T3D and T3E both emphasized bandwidth improvement over latency reduction, no board-level caches were provided in either system.

Global Memory

At the time there was considerable concern about memory management and memory use in MPP systems, and Cray focused considerable attention on issues such as memory mapping, translation look-aside buffer (TLB) misses, communication performance between PEs and I/O. The features that are described here provided a set of tools for both system and applications software that made the new environment much more easily used than expected, and in some ways better than on more conventional systems.

The T3E followed in the design footsteps of the T3D and implemented a distributed memory architecture, but with a shared global address space (GAS) that allowed fine-grain communications between processors without hardware-imposed cache coherency for remote memory. Conventional distributed memory computers have isolated local memories in each PE that can only be directly referenced by the local processor(s), with data communications between PEs accomplished using an I/O-like mechanism. These designs incur relatively large transfer overhead and start-up penalties that dramatically reduce both efficiency and performance on small or nonuniform access patterns. For example, the IBM SP-2 MPI ping-pong latency was greater than 100 μ s, compared to about 1 μ s for the T3E. The T3D and T3E were designed to support direct access of other PEs' memories using loads and stores (or intermediate "puts" and "gets"), enabling higher payload-to-overhead ratios on the sparse communications patterns that are important to many scientific algorithms.

The EV5 (aka, 21164), the second-generation “Alpha” 64-bit architecture processor from Digital Equipment Corporation, was the world’s most powerful microprocessor in its day but, like all microprocessors intended for desktops and conventional servers, its memory interface was designed to operate in an environment where the memory was physically close (on the same printed circuit board), small (a few Gbytes at most), and accessed using address patterns that made profitable use of large caches as a latency-avoidance mechanism. Unfortunately, none of these characteristics are present in large-scale distributed global memory architectures like the T3E, so a major architectural challenge was to provide external extensions to the address space, the memory management, and the latency-hiding capability. A maximum scale T3E might have over 4 Tbytes of addressable memory, beyond the addressable range of the EV5; conventional memory management translation look-aside buffers (TLBs) could only map a very small fraction of the T3E global address space, making significant performance delays due to TLB misses on every memory reference a near-certainty; and, latency hiding was required because the memory of a remote PE might be thousands of clock periods away, thus stalling a processor that was waiting on a data load.

The Global Segments (Global Memory Segments, GSEGs) capability was provided to help with remote memory access. The operating system was able to convert a user process I/O buffer address to a GSEG and pass it through the service PEs to the GigaRing device processors directly. The GigaRing devices were then able to use the address and do a zero-copy RDMA to or from the user’s buffer directly to a device. This was a mechanism that was as simple and high performance as the previous I/O subsystems used by Cray vector mainframes.

Although the T3E team had to freeze the design very early in the life of the T3D, much was learned from the predecessor system and the accumulated experience of compiler, library, and application developers as they struggled to generate efficient and scalable code for a distributed memory architecture. As a first-generation design, the T3D had provided programmers a variety of mechanisms to extend the addressing and memory interface limitations of the Alpha microprocessor and enable a processor to read or write data from a remote PE’s memory. Address extension for direct loads and

stores to remote memory used an external address segment register set called the annex. Latency hiding was accomplished by using either a prefetch queue (PFQ) (a set of first-in, first-out registers that could be the targets of “special” loads), or an external block transfer engine (BLT) that could move memory autonomously, but imposed significant overhead penalties. T3D memory management also required that all PEs participating in a computation have the same local mapping of memory, causing a page miss in one processor to require identical fix-ups in all PEs. While helpful, these mechanisms could be confusing and poor choices were punished by poor performance. Overall, achieving high efficiency was difficult unless the programmer deeply understood and carefully planned around the performance quirks.

E-Registers

The T3E architecture simultaneously simplified the way global shared memory was supported and greatly increased performance through the introduction of a large set of registers external to the microprocessor, called E-registers. This set of 512 user-level registers plus 128 system registers was mapped to a section of the EV5’s memory space normally reserved for memory-mapped I/O devices. Data could be moved efficiently between E-registers and processor-internal registers using standard loads and stores. The EV5 automatically merged sequential loads or stores to I/O space into four 64-bit word transfers that maximized the external chip data bandwidth.

A meta-instruction set controlling E-register operations was defined that could be issued by the processor by writing to additional special memory-mapped addresses. The particular address used represented the appropriate op-code, and instruction arguments could be passed in the data.

Possible E-register operations included “gets,” which would accomplish a data load from local or remote memory into an E-register, and “puts,” which would store data from an E-register into memory. To fetch data from a remote PE’s memory, the programmer would issue a “get” by storing the desired virtual address in the encoded memory address. The destination E-register would be implicitly specified in the op-code. Circuitry external to the EV5 then translated the global virtual address to determine the physical PE containing the

desired data and forwarded the request over the network. The returning data would land in the reserved E-register, to be subsequently loaded by the processor from its memory-mapped location. As many “gets” could be outstanding as there were available E-registers to act as destinations for the returning data, thus providing an efficiently pipelined latency-hiding mechanism. E-registers also supported advanced memory-based synchronization primitives including atomic memory operations (such as fetch and increment, compare and swap, and masked swap) and user-space messaging queues.

Using E-registers enabled the T3E to sustain network-saturating data transfer speeds even on global memory reference patterns with large non-sequential address “strides.”

Memory Management

The T3E implemented a unique global memory management and virtual address translation scheme that supported implicit data distributions provided by languages like Fortran-D and Cray’s CRAFT, as well as allowing independent and different mappings of each PE’s local memory, even as it is shared and viewed as globally contiguous. This was accomplished by using a hardware “centrifuge,” which could separate PE-designating bits and PE-oriented address bits from the virtual address, and remote translation of the virtual address to the physical address within the remote PE’s memory. The remote translation mechanism also implemented an “atomic memory mover” that allowed relocation of memory pages even while the page was being accessed, preventing common memory management tasks from disrupting computation.

Local Memory

The T3E provided no board-level cache and the EV5 was only permitted to cache local memory. Global memory references changing data in local memory were kept coherent by a back-map that automatically invalidated any cached copy on the processor. Instead of board-level cache, the T3E provided stream buffers that detected and pre-fetched sequential streams of data (as are common in bandwidth-intensive scientific applications), resulting in sustainable streamed data rates over twice

those achieved in server designs using the same processor but with conventional board-level caches (470 Mbytes/s compared to 190 Mbytes/s).

Synchronization

E-registers enabled advanced memory-based synchronization primitives including atomic memory operations (such as fetch and increment, compare and swap, and masked swap) and user-space messaging queues. Synchronization was further enhanced using a virtual barrier network that allowed arbitrary membership, and had the ability to send messages over embedded virtual spanning trees in the data interconnect network.

Network

Perhaps the most remarkable and visible attribute of the T3E was its 3D torus interconnect network. In this scheme PEs are physically connected to their nearest neighbors in three dimensions and the faces of the resulting logical cube are “wrapped around.” The router in each PE consisted of a fully adaptive router switch steering traffic among seven pairs of high-speed (600 Mbytes/s) channels: carrying data simultaneously in both directions of three dimensions, plus a connection to the PE. Traffic was routed according to predetermined routing tables in direction order: +x, followed by +y, followed by +z, followed by -x, -y, and -z. Five virtual channels were utilized: Four to prevent deadlock and one to enable adaptive routing. The routing algorithm was designed to send each packet along the shortest possible route, but adaptive routing allowed packets traveling in the network to route around broken or congested paths by selecting an alternative route. The T3E’s “minimal adaptive routing” strategy allowed packets to change the order in which they traversed the various x, y, and z hops, but the actual path length was not changed. One advantage of a 3D torus interconnect topology is the ability to route a packet “the other way” along any dimension and, in some failure cases, “long way around” routing was needed to route around faults, but this was accomplished by changing the routing tables.

The T3E network and communications infrastructure was optimized for pipelined delivery of fine-grain messages. Packets traveling through the network could have payloads as small as one 64-bit word, making the

T3E very efficient at random communications supporting sparse matrix algorithms.

The router internal clock ran at 75 MHz, however data was transmitted on the communications link at five times the internal frequency (375 MHz). The links were 14 bits wide, for a raw bandwidth of 656 Mbytes/s. Peak data payload was around 500 Mbytes/s after protocol overheads. The network of the T3E provided a bisection bandwidth of over 150 GBytes/s at 512 PEs and nearly flat global bandwidth of over 600 Mbytes/PE over scale to that size system.

Technology

The T3E was implemented using a combination of DEC Alpha EV5 processors, commodity DRAM memory chips, and Cray-designed CMOS application-specific integrated circuits (ASICs) blended in a custom architecture using the exotic packaging, power, and cooling technologies that were a hallmark of Cray supercomputers to achieve high-performance in a dense form factor.

The custom ASICs were sourced from LSI Logic and used a 0.8 micron process and three metal layers to provide a maximum of approximately one million gates per chip.

A single large printed circuit board (PCB) with more than 20 layers formed the motherboard for a T3E module. Each PE consisted of a processor chip, a C-chip that connected the processor to both the local memory and the interconnect network router, and a router or R-chip that completed the implementation of a single PE in the T3E's 3D torus network. Four PEs were laid out on each motherboard, and motherboards were attached to a "cold plate" for cooling. In the LC configuration, the cold plate was an aluminum heat exchanger through which a chilled inert fluorocarbon liquid (3M's "Fluorinert") was circulated. The cold plate had a series of machined "plateaus" on the surface that protruded through holes in the PCB beneath each chip, thus making direct contact with the chip. Heat was conducted through the plateau into the cold plate and removed through an external chilled water heat exchanger.

Fluorinert, though quite expensive, was used for the closed-loop in-chassis cooling cycle because it has the property of being electrically nonconductive and noncorrosive, so no damage to the densely packed electronics would occur in the event of a leak.

The LC cold plate was approximately a half-inch thick and was configured as a sandwich between two motherboards supporting a total of 8 PEs per module. AC cold plates supported a motherboard on one side and were machined with conventional air-cooling fins on the other, so they only supported 4 PEs operating at a somewhat elevated temperature, compared to the LC design.

Standard-package DRAM memory chips were mounted separately from the motherboard on four daughter cards per PE. Each daughter card also held an M-chip, which drove a bank of memory and interfaced between the DRAM and the C-chip. Pairs of daughter cards were sandwiched on two thin aluminum plates, which were then plugged as mezzanine assemblies over each PE. The memory aluminum cool plates contacted cold plate plateaus, providing a thermal conduction path for the heat of the DRAM to the cooling fluid or air, depending on the LC or AC configuration. No cooling fans were used in the LC design.

The 8-PE LC module, including memory mezzanine memory cards, was approximately 14 by 22 in. and a mere 2 in. thick. Connectors for the router channel wiring cables ran along both long edges of each motherboard, and used a unique zero-insertion-force connector design that required insertion of a tapered metal wedge, after seating the module in the chassis, to slide individual pin shuttles into contact with the sockets on the boards. Each LC module had a blue and red hose (hot/cold) with quick-disconnect inlet and outlet connectors to plug into Fluorinert manifolds mounted on each side of the rack.

The AC chassis could support up to 16 four-PE modules per chassis, and two chassis could be connected together to create a max-scale 128 user PE system. The LC system had considerably higher density, with 34 module slots to accommodate up to 256 user PEs per chassis. Power supplies, pumps, and Fluorinert/chilled water heat exchangers occupied perhaps two thirds of the chassis, with a single stack of modules in the front.

Flat cables, one per router channel, were strung between the modules in the chassis (the design of the torus network was "folded" so no cable ever had to cross over to the opposite module side) on the sides of the chassis. In larger configurations (greater than 256 PEs), multiple chassis would be arrayed in an alternating line, with every-other chassis facing the opposite

direction and overlapping by the depth of the module stack, “cheek to cheek.” This allowed torus network connections between chassis with the shortest possible cable connections as well as enabling side access to the pumps, power supplies, and heat exchangers in the rest of the chassis. From overhead, a large T3E looked like a very large zipper.

With no fans, the sound level of a full-scale LC T3E was considerably less than the AC version, or any contemporary conventional server racks.

Operating System Software

The development of a distributed operating system for the T3E was a significant effort for a small company like Cray. The transition from UNICOS on vector systems to UNICOS/mk on massively parallel systems was a major effort for the Cray software group. In order to meet the schedule, average of 100 people worked on the system for more than 4 years, while a skeleton crew of 15 senior people was assigned to manage and support UNICOS on Cray’s entire customer base. This was an extremely high-risk approach. In effect, the Software Group was betting on the extremely high reliability of the installed UNICOS systems, which proved to be a sound decision.

The competing requirements of supporting a new hardware architecture while also carrying forward an existing customer base presented significant challenges. Some of the new ideas for the Cray Parallel Programming Environment were very different from the interfaces and functionality that had been in use on vector mainframes. All of this contributed to the uncertainty experienced by the software system designers as they debated how to prepare for a new machine that was expected to run a whole new set of applications.

Historical Perspective

By the early 1990s, there was an ongoing sea change in supercomputing system software. The first wave, in the mid-1980s, had been the transition from vendor-proprietary operating systems to UNIX. Despite early skepticism, the Unix operating system and environment had successfully replaced the traditional operating systems of the mainstream supercomputer vendors. Furthermore, as supercomputers moved from research labs to production engineering groups, a new expectation of higher reliability was sweeping through the industry.

At Cray, the view had always been that the very highest performance systems, pushing the limits of technology, would never be as reliable as more common computers. Cray was designing at the leading edge of technology, and reliability was inevitably compromised in favor of higher performance, in the same way that specialist high-performance cars are often less reliable than family automobiles. Traditionally, Cray customers had an “early-adopter” culture whereby they were willing to accept a degree of risk in return for the earliest possible access to new, more powerful, systems. However, their users were now raising the bar. The new expectation was that systems had to be for what had previously seemed like long periods of time – now measured in months rather than weeks. This trend had been in progress for several years, but in the 1990s the market requirement was rising sharply. Hardware was becoming more reliable at the component level, but massively parallel systems contained many more components, and the pressure was on software to find methods that would make the overall system more reliable.

The advent of UNIX had brought a change to the way programmers thought about systems. The use of a high-level implementation language (C) and standardized interfaces was a very different approach from the assembler-programming techniques that most companies and laboratories had used in the 1970s. However, the actual evolution of UNIX was surprising to its originators: Rather than collaborate on an industry standard, each vendor produced its own flavor of UNIX. All the companies that adopted UNIX were under pressure to differentiate their products, and porting features from a proprietary OS that their customers had come to depend on was one way to differentiate. But this approach led to divergence of UNIX implementations, and at this point, in the early 1990s, there was no Linux with its common kernel. There were some industry standards but they did not cover as many interfaces as were in common use, and they did not cover the machine-dependent variations.

However, in many cases these vendor-specific additions to UNIX constituted useful improvements. For example, the original UNIX did not have the performance-oriented features needed for supercomputers, such as a fast file system or a tunable process scheduler. UNIX also lacked a number of features, such as job accounting, that were necessary for managing

large shared computational resources. Operating system developers were quick to resolve these problems by adding features to the kernel. Even though the kernel was not really the place where much of this code belonged, expediency and the pressure to deliver performance and resiliency were the rationale for making this entire code kernel based.

The consequence of all this feature addition was to take a lightweight kernel, roughly 20,000 lines of code in AT&T System V circa 1984, and create multimillion line kernels by the early 1990s.

The Evolution of Microkernels

At Cray, by the early 1990s, the UNICOS kernel had grown to more than 500,000 lines of code. This was far too much for even the best developers to keep in their heads, and ongoing software reliability was a concern. So the development team began to look at microkernels with the goal of separating the kernel components and creating a set of “firewalled” functions with defined interfaces. Microkernels were a new idea at that time. The Defense Advanced Projects Research Agency (DARPA) was actively supporting a microkernel called MACH, developed at Carnegie Mellon University, but there was another microkernel, Chorus, that had originated at the French national research institute, INRIA, and had been adopted by AT&T. There was much discussion at Cray about the relative merits of the two microkernels and much speculation about the potential performance loss that was expected from using either of them. The performance loss was certain because this architecture required multiple additional context switches between user, microkernel, and operating system services. The question was whether the performance loss would be an acceptable price to pay for the benefits.

When the T3D project started at Cray, the Software Group was reorganized into multiple OS development teams, based on the T3D, the T3E and future Vector Systems, each with its own views of the evolving software world. The T3D developers chose to use a modified version of the MACH microkernel for the back-end MPP, and were successful in producing a viable MPP. The Vector team elected to build a prototype version of UNICOS (Cray's proprietary UNIX operating system) on top of the Chorus microkernel. Chorus did not require virtual memory (unsupported by Cray vector system)

as MACH did, so it was possible to port Chorus and UNICOS to a Cray vector system. The experiences of the T3D team with the difficulties of MACH and the decision to make T3E self-hosted made Chorus the obvious choice. The final problem with MACH that caused Cray to abandon it as a potential microkernel for self-hosted systems was a set of fundamental security issues that were also being experienced by the developers of the Open Software Foundation's OSF/AD, which was also based on MACH.

As a result of its vector and T3D experience, Cray then began to look at a combination of Chorus and UNICOS as not just a potential OS for future MPP systems, but also as a next-generation implementation of UNICOS on vector systems. The big difference between the T3D, which comprised an MPP running MACH front-ended by a vector machine running UNICOS, and the T3E was that the T3E MPP would run as a complete single system without front-end support. The T3E would be “self-hosted”; simply running a microkernel on all the MPP PEs would not suffice. In addition, a primary objective of the T3E software design was to present a single system image, defined as a single Process Identifier space (pid space) and single file-name space, to the user, and to achieve this goal the operating system would have to be distributed across multiple MPP PEs. Thus the microkernel was conceived to be the low-level PE OS responsible for providing communication between all the PEs. But, the big departure was to take the rich set of UNICOS services and distribute them in “stacks” across MPP PEs depending on the software-defined PE type and the need for system services. These ideas were speculative at the time. No previous high-performance computing (HPC) company had delivered a distributed system, and there were a number of valid concerns starting with the potential performance of a single HPC application distributed across many PEs and the performance impact of PE-to-PE communication on a mixed scientific workload.

The Cray software group as a whole was divided almost into thirds in their views of the wisdom of this direction. A little more than a third of them wanted to go forward with the microkernel-based UNICOS plan; a little less than a third were convinced that this technological approach would fail; and about a third thought the whole MPP concept was doomed anyway.

The people at DARPA who had been funding MPPs and the development of MACH were also extremely unhappy that Cray had decided not to continue with MACH.

Distributed Software Architecture

There were serious technical issues in dividing UNICOS into servers (serverization). The organization of the Unix system was built around the concept of files, and separating the process management services from the file system, while also creating a simple interface, proved difficult. The idea of firewalling the microkernel from the servers was dropped because of performance issues in the context switching. Without the firewall the concept of being able to reboot individual services instead of the whole OS (on a node) was not a reality. This made some of the resiliency hopes less possible. Still, the idea of rebooting individual PEs, instead of the whole system, was possible and was an important step toward a resilient HPC system.

Besides resiliency, there were other compelling reasons to go forward with a distributed UNICOS operating system on the T3E. First, the back-end T3D-style of MPP had been difficult for programmers to run and debug applications. A back-end system, by definition, is always more opaque than a system with which the user interacts directly when testing a code, and the limitations of the T3D in this respect were a concern for Cray customers. Second, UNICOS had evolved on vector systems to become a very stable, high-performing, full-featured HPC Unix system. The customers liked it and the idea of a UNICOS version running on the T3E was well received. In addition, the performance of a microkernel-based UNICOS running on a single Cray vector CPU had proven to be much closer to the performance of native UNICOS than most people had thought possible. Finally, there were not a lot of alternatives. This technological direction was undoubtedly risky, but the whole T3E program was risky. So the company decided to go forward, and carefully manage the risk by establishing well-defined milestones and deliverables. As is often the case, there was a protracted debate over a less critical issue, the OS name, but UNICOS/mk stuck. It was naming similar to the Chorus-enabled version of Unix from AT&T and it preserved the UNICOS brand.

Serverization

The following diagram shows the structure of the OS stack and all the possible servers ([Fig. 1](#)).

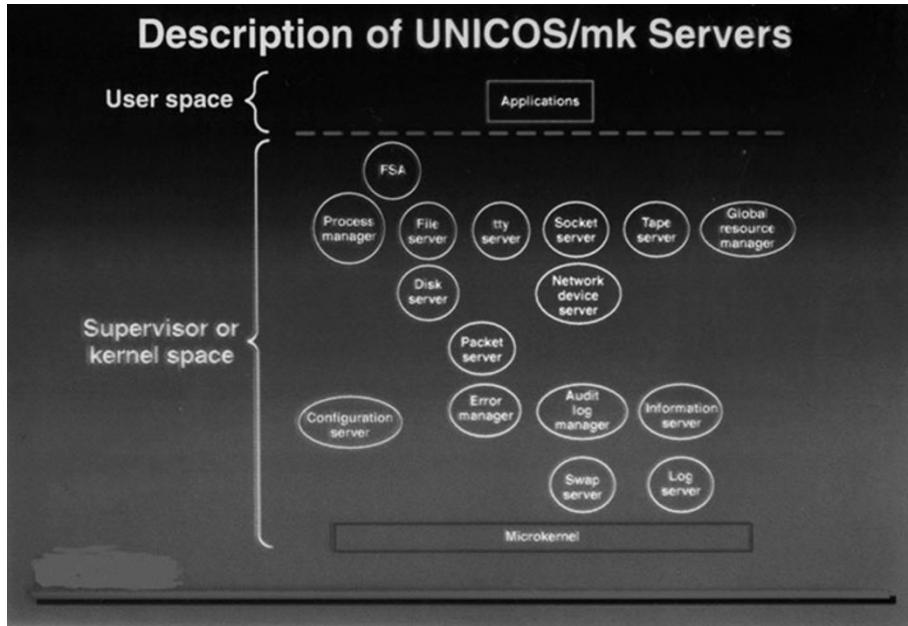

This simple example of server stacks shows compute PEs with minimal services and OS PEs with complete stacks of services ([Fig. 2](#)).

A useful way of demonstrating the contents of both service and applications PEs was to use the Cray 3D viewer. Here are three examples of different views of two support PEs and a command PE in the torus, and the processes running on those PE's ([Figs. 3–5](#)).

The system PEs did not allow user processes to run. Users logging into the system were automatically directed to a command PE where the user interface appeared to be standard UNICOS, but the underlying system was actually distributing the user's processes across multiple command PEs as needed. Compute PEs were only able to execute applications that had been submitted to the resource manager/schedulers.

The distribution of system services meant that some set of PEs became "system PEs." This was hotly debated because the market expected that a T3E with "N" PE's would allow a single application to run on "N" PEs simultaneously: Cray customers had become accustomed to the idea that a user application could access all the user-programmable hardware resources of the machine in a single execution. Thus system PEs could not be included in the advertised processor count and needed to be "extras." The fact that the system PEs could not be used by applications was irritating to some users, who saw them as pure overhead, and the cost of these extra PEs also had to be considered.

However, reality was that operating systems services are essential to the running of any application, but the cost of such services on conventional mainframes had traditionally been accrued as system overhead. Also, on mainframes, this overhead was a variable number that depended on application characteristics, whereas the T3E serverization approach essentially allocated a fixed proportion of total system computational resource to system services. The resolution was to peg the number of system PEs, as a percentage of total PE's, to the overhead of a non-distributed OS on a shared-memory vector system. As a result Cray decided, based on the measured performance of the installed base of CRAY C90 vector systems, to use no more than one in 16 T3E PEs

CRAY T3E. Fig. 1 The Unicos/mk Software Stack – The microkernel and all the OS servers

(6.25%) for dedicated system purposes, and to include these PE's as "free" PEs that were not included in the MPP processor count. Thus a 1280 PE T3E would actually comprise 1280 computational PE's and up to 80 PE's dedicated to OS services, for a maximum of 1360 PE's.

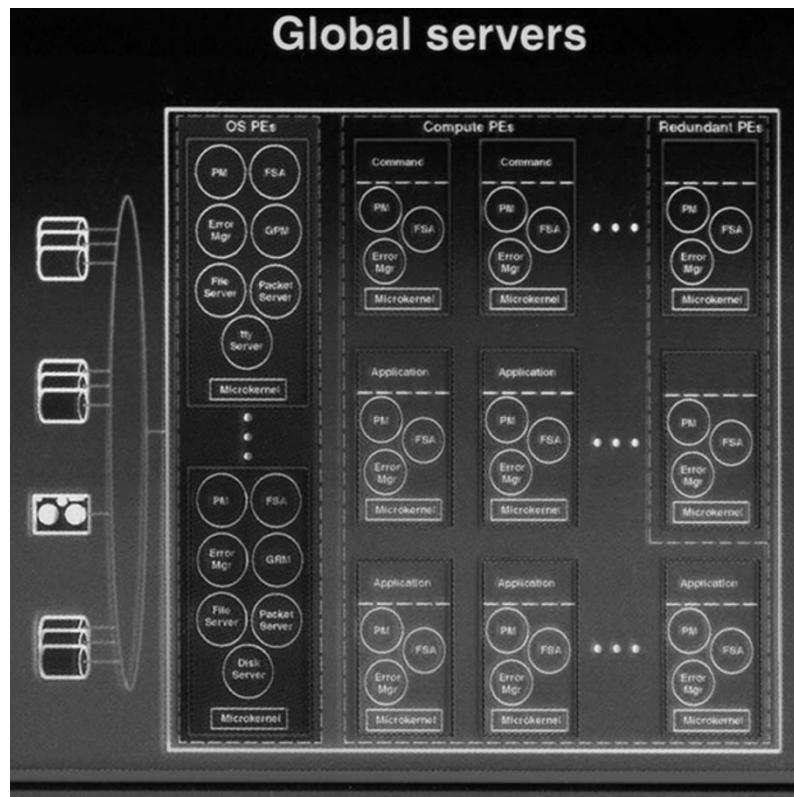

All system services ran on the service PEs, including PEs used by users logging into the system on "login" PEs. A few extra PEs were also kept available as replacements for failed compute PEs, which might be lost between planned maintenance outages. The operator could repurpose the replacements and, later, a PE reboot feature was added that allowed operators to restart failed compute PEs. The T3E cabinet to support this system organization held a maximum of 272 PEs: 256 user PEs; 16 system and/or redundant PEs.

As part of scaling, and also of distribution, the stack of OS services on an OS PE was differentiated. The most obvious difference was "Command" PEs that were used for user logins. But other OS services were separated or replicated onto OS PEs. Depending on the system size and configuration, there could be different numbers of these specialized OS PEs. OS PEs could be allocated to services based on the utilization of the service within the system. I/O device support was often configured on I/O channel-connected PEs with no other services. This

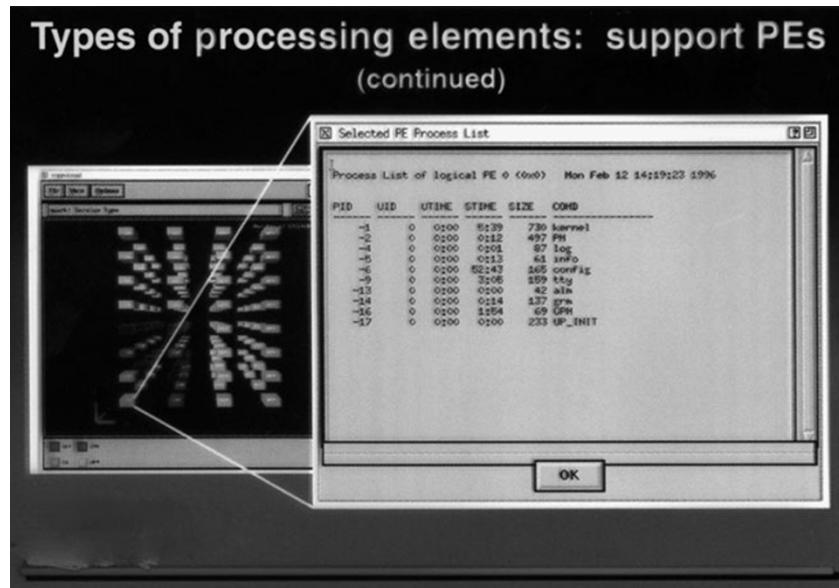

reduced the number of different activity types on the OS PEs, and thereby reduced the number of interactions between different services, which had been the source of many failures on vector systems. Focusing the tasks allocated to any given PE and simplifying the services made the system inherently more resilient and easier to debug.

The use of OS PEs also allowed for the development of Global and Local service divisions. This was used extensively in process management. The local process manager (PM) could respond on its own to a `getpid()`, but would forward a `kill()` to the Global Process Manager (GPM). This global/local split was popular because it improved local performance and reduced the amount of communication.

Another example of local versus global servers was the development of the File System Assistant (FSA). File system requests are dominated by read and write requests. The extra requests to OS servers from compute PEs and the copying of data across multiple PEs was something to avoid. The FSA communicated the user's `open()` request to the file servers. In the file server's reply to the FSA open request there was a disk server address and a set of disk blocks for the file. Depending on the request type there could be multiple disk servers and multiple block allocations. Read and write requests

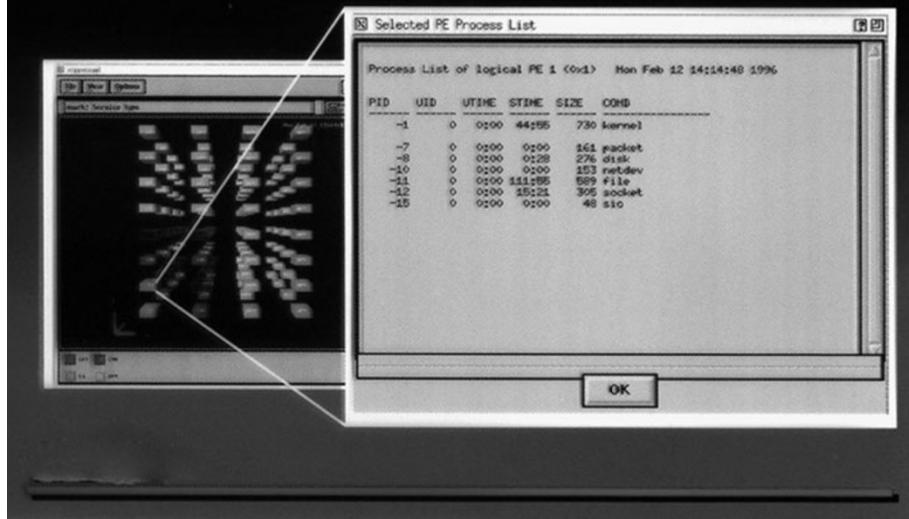

CRAY T3E. Fig. 2 The Unicos/mk OS deployed on a system showing the bulk of the OS servers on OS PEs and a light weight set of servers on the Compute PEs

from the user could now bypass the file server and be sent from the FSA directly to the disk servers. The file server was responsible for managing and guaranteeing coherency.

There were a number of key optimizations of the T3E serverized system. The distribution of global process management and file I/O was primarily via system-call forwarding from either compute or service PEs to the process-management and file-server PEs respectively. The code for these calls was optimized to do as few data transfers as possible. The goal was to keep the PE interconnect as free of service requests as possible. The term “piggybacking” was used to describe these optimizations. Substantial changes were made to the IPC mechanism to improve performance including the creation of interrupt threads to reduce the latency of thread switches for forwarded requests. Another optimization that was important in process management was the separation of `fork` from `exec`. In small Unix systems, often a `fork/exec` would be the same program replicated, like a shell. In HPC, the `exec` on a compute PE was guaranteed to be an application code not the shell that forked it. This optimization eliminated the unnecessary copying of process images across the interconnect network. High-performance application workloads were a performance benefit for the operating system too. These applications were invariably compute-bound and made few system calls, which helped with reducing overhead and non-application communications.

The amount of available memory on compute PEs was a critical resource. The OS was allowed to use all the memory on service PEs, but had to be using the absolute minimum on compute PEs. The target was set initially at 10% of a 128MB PE and this turned out to be a good target. Later, other MPP operating systems were found to be using 90% or more of compute-PE memory and this became a competitive marketing advantage for Cray.

Schedulers

Scheduling had been an important part of HPC operating systems on vector machines, but the MPP required a new scheduler to manage the compute PEs. This scheduler became important in providing overall system utilization. There was a performance advantage in locating processes on PEs that were “close” to the other PEs running processes for the same application. The scheduling

needed to be fast, accurate, and ensure that no compute PEs were loaded with more or less than a single runnable process. A simple algorithm was developed to make a serial array of the three dimensions of the compute PEs in the T3E torus. This made allocation and management much simpler and defied earlier predictions of poor placement. UNICOS/mk supported space-sharing from the outset; that is, the ability to split the system into multiple disjoint partitions and run a different job in each one. An interesting additional feature was coarse-granularity time-sharing with gang-scheduling within a set of PEs. This was the ability to have a partition load processes from multiple different applications, and then run simultaneously all the processes from a specific application across the whole partition. This would idle the other applications that happened to share PEs with an active application and, where there was a discontinuity in the number of PEs a process used, even more PEs might be idled. However, combined with scheduling constraints at the job level, the process/memory scheduler was tuned well enough that it was able to overlay applications across PEs and achieve a remarkably good overall utilization of the compute PEs.

Checkpoint/Restart

The T3E was one of the last systems to have a completely usable checkpoint/restart capability. At the outset of the program, many developers considered this feature to be impossible to implement successfully. The number of processes, the size of the checkpoint image, and the difficulty of coordinating the saving and restoring of process state all presented daunting challenges. However, the checkpoint feature was an important requirement of several large customers and Cray decided to invest in the best implementation possible. This project took a long time to complete and was hard to debug completely, but utilization charts subsequently produced by the National Energy Research Scientific Computer Center (NERSC), which reported system utilization greater than 99%, vindicated the effort put into this feature.

The interesting technical lesson learned from this project is that a process checkpoint can be viewed as a primitive that, once in place, allows the development of other features such as process migration. The migration feature had never been considered in the original design process, but the checkpoint capability had essentially created the potential for the system to package an

active process and restart it at a different location in the MPP array, which is the definition of process migration. The availability of process migration is of significant benefit to a datacenter operation that wants to run an interactive program development environment during the daytime hours and a batch processing environment overnight. Many of the big production batch jobs may need to run for several days, and thanks to process migration they can be automatically suspended, saved, and rescheduled in a flexible manner. It also provides an effective mechanism for unscheduled high-priority jobs to preempt an existing workload on some or all of the compute PEs. This workload scheduling capability was fundamental to the outstanding results achieved by NERSC.

System Scaling

Despite concerns that the operating system would not be ready in time to support the early hardware deliveries, the OS software was actually delivered more or less as planned. Because there was market demand for T3E from a number of T3D users and a constrained initial production capacity, Cray decided to allocate smaller numbers of PEs to each of several early adopters to be followed by upgrade deliveries, rather than allocate the whole initial production to a single large customer. In practice, as the installed systems transitioned from small to larger scale, the software team was able to deal more easily with the inevitable scaling issues than if they had to deal with a single full-size machine from day 1.

As a general rule of thumb, it seemed that every factor-of-2 increment in system size unearthed new scaling problems. The distribution of process management and process running between service and compute PEs scaled pretty easily. There was not a lot of stress on the process management PEs except when they were subjected to specific stress tests. The compute PEs were sufficiently balanced that most applications could run without generating much OS overhead and communication to the process services, even though almost all system calls were forwarded. So, distribution worked without a lot of hierarchical scaling, which was a relief. I/O and networking had been predicted to scale quickly from one file system PE to many, but this happened more slowly than expected. There were probably a lot of reasons for this, but in practice it was not a major

issue as application I/O usage definitely lagged behind the system's ability to scale.

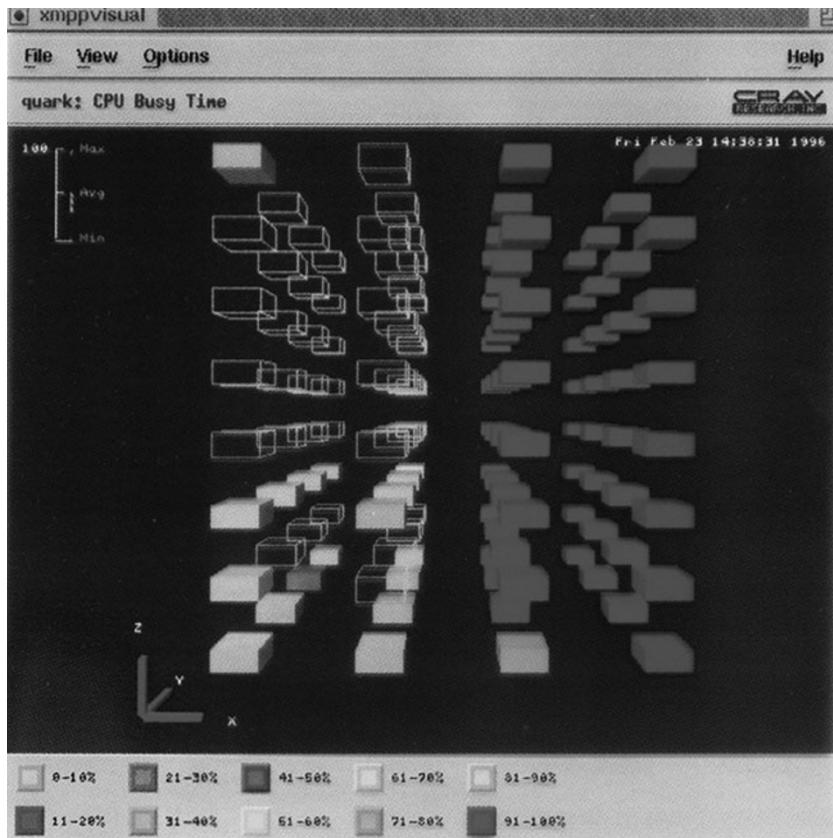

Scaling I/O is a good example of the work done to scale the T3E system and user software. The system could improve scaling by splitting the software stack onto different PEs. This was "vertical scaling." As discussed previously, this was separating drivers onto channel-attached PEs, and file and network services onto other OS PEs. Each group of drivers or file server PEs could be scaled independently, horizontally. I/O scaling was also improved by shortcircuiting the global communication between servers whenever possible. Finally, in another effort to group requests, users were given new interfaces that allowed lists of I/O requests across multiple destination PEs.

Overall, the development team was somewhat surprised at how easily the system worked. Features that they were concerned about mostly seemed to scale without problems. The hardware was actually helping the OS in that the interconnect network was so fast and able to communicate so many small messages quickly that running the inter-service communication mechanism was less of a problem than had been expected. The user interface looked like a conventional shared-memory vector UNICOS system and was easy to demonstrate to customers. Explaining the system organization had been difficult because the concepts were new, but the development of a graphical 3D display of the PEs and PE status finally gave a view of the system to users that could be readily understood. Internally, the microkernel architecture had transformed much of the original UNICOS kernel into special processes or threads, thus allowing the developers to use standard debuggers on many of the kernel processes. It had made productive programmers out of the majority of the Operating Systems Group.

Here are a few examples of the 3D viewer measuring processor utilization on all the PEs in a system. Note that not all the PEs are running applications in these examples. This allowed us to demonstrate activity in the system and how it changed as applications started and stopped (Figs. 6–8).

OS Jitter

One of the clear lessons from the T3D related to the necessity of coping with what later became known as OS jitter; that is, the effect that typical general-purpose

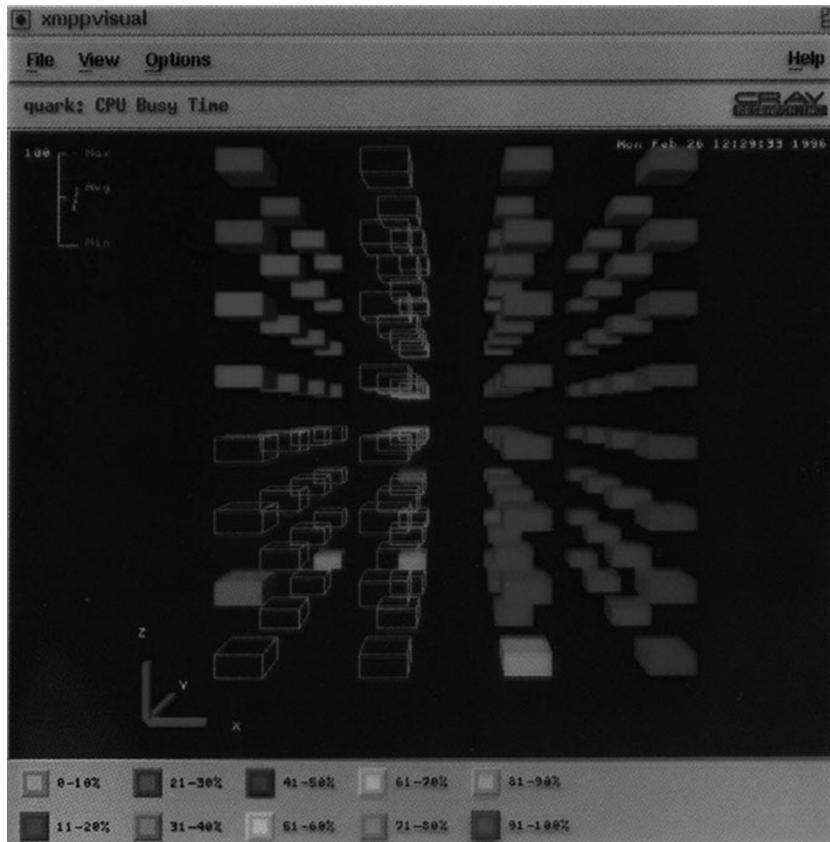

CRAY T3E. Fig. 6 A snapshot of a system showing processor activity on different PEs. This system is running several applications. The snapshot shows application placement and available compute PEs

OS services could have in a thousand-processor collective execution. Because the T3D and T3E were targeted at tightly coupled problems, the frequency of inter-processor synchronization in applications was high, often in the range of every 50 to a few hundred microseconds. At each of these synchronizations, if even one processor was delayed due to some other OS service, all the remaining processors would wait for the lagging processor to catch up. Even in the T3D's constrained back-end configuration and accompanying microkernel OS architecture the effect of timer interrupts (used for a variety of purposes, such as dead-man timeouts) that were unsynchronized across the whole system often cost a factor of 2 or more in performance.

The major changes to address OS jitter on the T3D were to drastically reduce the actual frequency of timer interrupts on the compute PEs, in effect

coarsening the response time, and to synchronize these coarse timer interrupts across all the PEs in the system. This was made possible by the global clock in the T3D/T3E, which is no longer typical of high-end parallel systems. These changes addressed the issue sufficiently for the T3D, but UNICOS/mk had a decidedly richer set of system services that were used by daemons, subsystems, etc., and further steps were necessary.

The T3E compute-PE OS stack was limited to the microkernel and a process manager. This reduction in local services ensured that the PE itself would be "quiet." This is more important than synchronization. Synchronizing ensures "lockstep," but reducing the services gives cycles to the user application and reduces the need for synchronization. The global clock provided synchronization, similar to the T3D. This kept time-related "housekeeping" in parallel, but communications

CRAY T3E. Fig. 7 A snapshot of a system showing multiple applications running and available compute PEs

between services, such as “heartbeat” checks had to be carefully examined and reduced as the system scale increased. There had always been an ethic at Cray related to ensuring the services did not reduce the time and space available for applications. This new environment was another lesson in monitoring system overheads and developing an awareness of their communications impact.

Programming Environment

Programming Models

Cray learned from the T3D that there were a variety of programming approaches for MPP systems, and no single approach was likely to satisfy everyone, although message-passing was emerging as the most common. Both the T3D and T3E provided fertile substrates for programming model development and exploration, as the hardware global address space (GAS) and fast

interconnect and synchronization meant the building blocks for a wide variety of approaches could be made to run fast.

Most of the T3D/T3E development team (both hardware and software) came from the legacy of Cray parallel-vector machines, which had a global address space and shared memory (though not hardware cache-coherence, as there were no caches, and the software managed the “cache” implemented by the vector registers). Many at Cray believed that the global address space provided a significant benefit in both ease of programming and performance, and wanted to find ways to expose that appropriately through the prevailing languages of the day, Fortran and C. This put Cray at odds with many other MPP pioneers, who had adopted the message-passing approach as being simple and less dependent on specific hardware, compiler, and run-time capabilities that might not be available on all systems.

CRAY T3E. Fig. 8 A snapshot of a system showing applications in different states of starting and completing

Message-Passing

Cray had implemented the Parallel Virtual Machine (PVM) interface on the T3D in 1992–1993, partly because of the need for a mechanism not only to communicate among the distributed processes on the T3D but also to communicate between the parallel-vector host system (a CRAY Y-MP or CRAY C90) and the distributed processes. Since then the message-passing community had coalesced and the Message-Passing Interface (MPI) standard was under development. While PVM was still supported for backward compatibility with T3D customers, most of the T3E focus for message-passing development was on MPI.

The E-register mechanism in the T3E hardware was a much better infrastructure for message-passing implementation than the block transfer engine (BLT) and prefetch queue (PFQ) of the T3D, and the resulting performance was very good. The MPI libraries could drive the hardware interconnect at 260 MB/s for bigger

transfers (100 KB or more), and the ping-pong latency was good (14 us), but not yet to the 1 us level achieved in later GAS machines.

SHMEM

SHMEM was a direct result of the fertile hardware communication and synchronization infrastructure provided by the T3D. One of Cray's MPP performance specialists realized that the T3D prefetch queue (PFQ) could be used to overlap communication with computation, and wrote a small prototype library that exposed this capability. He used it in a variety of codes and realized its advantages for fine-grained communication. When it came time to implement libraries for the T3E, the team realized that this interface, now known as SHMEM, was valuable and should be carried forward. The T3E's E-registers were a major expansion of the capabilities of the PFQ, enabling much more data to be in flight between remote processes and the

requesting process, and so SHMEM was consequently a much more potent performance enhancer. The T3E SHMEM implementation exploited the larger number of outstanding requests, each for 8 64-bit words of data (compared to a single 64-bit word for each PFQ request) to deliver the full bandwidth of the T3E interconnect (350 MB/s) for even small transfers of 1–4 KB and delivering unprecedented 1- μ s latency for single-64-bit-word requests. The much better performance of SHMEM reflected in part the close match with the underlying hardware and partly Cray's minimal experience with optimizing MPI protocols onto GAS hardware.

Language-Based Global-Address-Space Models

Researchers and developers had proposed and implemented a variety of language approaches to parallelism. OpenMP was becoming a standard by this time, targeted at cache-coherent systems of modest scalability. Vienna Fortran and Fortran D had both proposed and implemented early interfaces from Fortran to distributed memory systems, and Cray had implemented its own version, CRAFT, on the T3D. These languages had explored different approaches, but had in common the provision of global variables and a means of specifying their distribution across the PEs of the system and the use of those variables. Cray's experience with CRAFT on the T3D was mixed: A few developers had excellent success in both speed of development and performance, but the CRAFT implementation was incomplete in some respects (e.g., there were no collective operations) and not deeply optimized. In addition, its portability was limited to Cray systems, and many of the most avid user proponents of GAS, especially those whose workloads were characterized by the GUPS benchmark, had migrated to C as their base language of choice, not Fortran. As Cray was deciding what to implement for the T3E, the High-Performance Fortran (HPF) group was gaining critical mass, and it was clear that implementing a GAS Fortran language different from HPF made no sense. Unfortunately, interactions between the HPF team and the Cray software team were not the best, so HPF did not incorporate all the CRAFT lessons, notably the difficulty of optimizing even less-general distributions than were supported by HPF and the magnitude of effort required to provide a fast comprehensive run-time and libraries. For its part,

Cray was so constrained by its own financial difficulties that it did not implement HPF in its own compilers, instead relying on third-party compilers from The Portland Group and others. While HPF's progress took several years to unfold, ultimately it was unable to provide the performance that most MPP users expected, and consequently withered away.

However, Cray's mainstream compiler development was not the only source of language-based ideas for using the T3E. A T3E performance specialist, with help from the Fortran front-end group, integrated his ideas for a simple “PE-oriented” approach, first embodied in SHMEM, into Fortran in an interface first known as “F--”(F minus minus, a parody of C++) and later, at the request of for a less negative spin, formally named Co-Array Fortran (a contraction of covariant array, a mathematical term). The key innovation was to extend indexing operations with another set of square brackets that indicated the PE on which data resided; indexing without this extra information defaulted to the local PE. This work was eventually released in the late 1990s as part of the Cray Fortran90 compiler, though not fully documented and supported, and was later incorporated into the Fortran standard in 2005.

Similar ideas had been percolating in groups that focused on C more than Fortran. A team from the Institute for Defense Analyses Center for Communications and Computing had developed the ac compiler on the T3D, exploiting its PFQ similar to the way SHMEM did, though integrated with the C language. A team from Lawrence Livermore National Laboratory had implemented the Parallel C Preprocessor (PCP) first on the BBN TC2000 system and later the T3D, and a team at UC Berkeley had implemented the Split-C compiler. These languages attempted to extend C's close-to-the-hardware nature with minimal mechanisms supporting distributed memory. The ac compiler was ported to the T3E, but the bigger story was that these three efforts merged into the Unified Parallel C (UPC) effort, which later delivered compilers that work on a variety of parallel systems.

The fertility of the T3E infrastructure was proven by one last effort, little known at the time, a project at Lawrence Berkeley Laboratory/NERSC that resulted in the Parallel Problems Server being ported to the T3E. The tool later was commercialized by Interactive

Supercomputing as Star-P, extending the M language of MATLABTM to run on distributed memory clusters.

Tools

Compilers

The T3D/T3E Fortran and C compilers were hybrid, with the front-ends being those used on Cray's parallel-vector (PVP) systems and the back-end being a heavily modified version of the Compass compiler back-end. While the use of the Compass back-end quickly delivered the ability to generate decent code for the T3D/E PEs, based on the Alpha microprocessors, the shift to distributed memory was a more profound step for which neither the PVP nor Compass components were designed. This difficulty was largely side stepped because of the decision not to support any distributed memory programming language on the T3E, so the compiler developers were able to focus on single-core robustness and performance. The PVP compilers were legendary for their ability to analyze code deeply for parallelization via vectorization, though they had no technology for optimizing the use of cache (which the PVP systems did not have). Conversely, the Compass back-end was not designed to work with a front-end that could provide such robust information about the parallelism inherent in the input program. The rework of both segments of the compiler was possible, but resource constraints and the compiler group's need to split its focus between the T3E and PVP systems hampered the delivered performance of code on the T3E. Due in part to deficiencies in the use of cache, the T3E compilers never reached the performance levels of the compilers for the Alpha processor itself.

Libraries

The strong similarity between the UNICOS and UNICOS/mk operating systems at the system-call level drastically simplified the task of providing (single-processor) libraries for the T3E. Of course extensive parallel libraries needed to be delivered, including synchronization (e.g., barriers, eurekas) as well as the MPI, PVM, and SHMEM libraries. Parallel I/O was supported by independent, positionally nonoverlapping calls to the parallel I/O infrastructure and file system. The Fast File I/O (FFIO) library layer was also ported

from the PVP systems, providing a caching layer on top of the typical system libraries. Parallel scientific libraries were another strong focus, as the Cray scientific library, LibSci, developed for the PVP systems was redesigned to a great extent so as to run effectively on the distributed-memory T3E.

Debugger

The debugger for the T3E was Cray TotalView, which Cray had licensed from BBN for the T3D and ported to its UNICOS MAX operating system from the original platform on the BBN Butterfly and TC2000, and then ported to UNICOS/mk. It supported debugging capabilities that coped effectively with programs up to 128 cores. Beyond bridging the OS differences, the Cray development work focused on exposing the T3E hardware mechanisms and scaling TotalView's debugging capability to larger processor counts.

Profiler

Cray's MPP Apprentice profiler was built on ideas pioneered by ATExpert, a prior tool developed to optimize programs written with Cray's AutotaskingTM software, a precursor to OpenMP. The Apprentice dynamically instrumented code at the basic block level and could report timing results at the loop, condition, or other statement blocks with the time spent executing, synchronizing, and communicating reported separately. Also, the results could be split for an individual processor or summed for all the processors. Further, this information was provided in the context of the user's original source code, which was not uniformly true for parallel performance tools of that era. The instrumentation was done so as to be suitable for execution of very large programs, measured either by lines of code or length of execution, running on a thousand processors or more. The development team pioneered a number of innovations that enabled this advanced level of information.

Conclusions

The User Experience

While the T3D and T3E projects embodied many powerful technical innovations one can argue that the proper measure of their significance to users lies not simply in those innovations but, more importantly, in

the stunning improvement in the applicability of highly scalable computers to a host of important scientific and engineering problems, as evidenced by the number of successor systems extending the path pioneered by T3D and T3E.

Work on T3D began against the background of microprocessors having advanced beyond simple integer and text processors to support high-precision floating-point calculations at useful speeds. Although powerful individually, they could not compete with the purpose-built multiprocessor systems from Cray and others that were designed from the ground up for use on the most challenging scientific and engineering applications. Software, in the form of callable libraries, notably Parallel Virtual Machine, was available to support cooperative work on multiple processors using the message-passing paradigm. However, for the most challenging scientific applications, the hardware support essential for HPC-level performance did not exist. Well-integrated, high-bandwidth, low-latency inter-processor communications capability was simply not available on even the best of the microprocessors. Creating an appropriate interconnect was particularly difficult because the microprocessors had been built, and highly optimized, for working singly on a quite different set of applications. Furthermore, the design and development effort for those microprocessors dwarfed the resource typically available for custom HPC systems. The large commodity microprocessor market justified that effort, but modification of those processors specifically for HPC was not economically feasible.

There had been other efforts to build highly parallel computers from microprocessors notably the Intel Corporation iPSC/860 and Paragon systems that were solely message-passing and the Thinking Machines Corporation (TMC) CM-2 and CM-5, which were blends of SIMD and MIMD functionality with significant architectural innovation in global addressing, synchronization, and programming (CM Fortran). Each of these systems had proved essential points about the ability to decompose application codes for distributed memory and explored a variety of system mechanisms to enable the execution of scalable applications. Cray's MPP design team greatly benefited from detailed discussions with early customers of the Intel and TMC machines regarding their experience of using those systems, and

the mechanisms that would be necessary for effective scaling of the most challenging HPC applications.

In addition to the substantial investment made by Cray in developing the T3D and T3E systems, there was a correspondingly sizable user investment in the application reprogramming effort needed to take proper advantage of the new scaling features, especially distributed memory. The new mechanisms had been designed specifically to enable an increase in the number of compute PEs that could be allocated to a single application before reaching the “point of negative return,” where the increased communications and/or synchronization overhead causes application performance to decrease as the number of applied processors increases. In earlier, fully shared-memory systems those overheads were controlled by both an extremely costly shared-memory interface and a very low bound on the number of processors. Applications codes were successfully exploiting the largest of those shared memory systems, but to realize the full potential of the T3D and T3E required converting codes to the message-passing style of work-partitioning. The next step, after the codes had been converted, was to drive up their scalability by artfully improving the efficiency of the message-passing process and allowing it to overlap with computation. Both of these techniques had long been used to reduce the I/O overhead in HPC applications, but the message-passing problem was more demanding. In some cases, the computational algorithms themselves needed to be modified.

Moving from a commodity cluster to an HPC-capable MPP system required not only the creation of a powerful, scalable message-passing network but also the provision of an adequate I/O system. I/O capability is sometimes an afterthought, but it can often be the performance-limiting feature for HPC applications requiring the input and output of huge amounts of data in combination with the computational load. For the T3D, I/O was channeled through its host vector machine, already endowed with HPC-class I/O; but, being self-hosted, the T3E required its own I/O capability.

For the T3E to qualify as a supercomputer-class MPP it needed not just an extremely flexible and powerful hardware I/O capability, but also the hardware and software to make that capability a fully shared resource able to be focused on one or many jobs independently

of their location within the 3D torus interconnect structure. Segregating I/O handling gave a degree of predictability to the performance of application PEs; and the rare applications that heavily stressed the T3E's I/O capacity, for a given number of I/O PEs, could be further isolated by explicitly placing them in the torus close to the I/O PEs servicing their needs.

With the development of the T3D, Cray quickly realized that application development would be critical to the success of both the T3D and T3E. Consequently, the company fostered and explicitly supported the necessary user activity by instituting a Parallel Application Technology Partnership (PATP) program, which involved researchers and application developers associated with five major HPC centers around the world. Cray provided access to T3D hardware for participating organizations to work alongside Cray applications staff in effectively parallelizing a host of applications of both scientific and commercial interest. This joint effort required both programming expertise and the cooperation of the owners or authors of the codes that were to be modified. The PATP program helped ensure the success of the T3D and T3E programs by significantly contributing to the rapid development of a critical mass of applications.

A prominent early adopter of the CRAY T3D, and an effective member of the PATP program, was the Pittsburgh Supercomputing Center, whose scientists report that early achievements included:

- The first high-resolution model of the Gulf Stream, reproducing benchmark realistic features
- Prediction of the location and structure of severe storms 6 h in advance, providing economic benefit to airline companies
- Microsecond-length simulation of the villin headpiece sub-domain and implementation of improved, more accurate algorithms
- Real-time fMRI: coupling the T3E to an fMRI instrument, allowing observation and analysis of functional brain response in real time
- Elucidation of the mechanism for HIV Reverse Transcriptase
- Simulation of unsteady combustion using a commercial code (FLUENT)

For a typical application, initial conversion to message-passing produced a code that would improve in

performance almost linearly for low numbers of processors but quickly reach the point of negative return, where messaging overhead would begin to dominate over the decreasing computational load per processor. However, with effort and experience, the range of performance improvements that could be achieved by ever-increasing processor counts could be expanded. Typically, impressive results were obtained over a period of several months. In many cases, it was possible to bring to bear the total processing power and memory of a full T3D (often 128–512 PEs) on a single problem. Both the aggregate processing power and the aggregate memory were much larger than previously available on traditional vector supercomputers. Depending on the application, new scientific ground was broken because of the computational power, total memory size, or both.

The T3E Contribution

The history of computing, and especially supercomputing, is a continual co-evolution among hardware designers, software developers, and end-user scientists. The scientists constantly demand much higher performance to achieve the breakthroughs they see just beyond their grasp. The hardware designers work within their physical realities and devise architectures that better deliver the key performance metrics. System software developers simplify access to the hardware structures from the prevailing languages. This process is not linear though, since some new hardware approaches ultimately prove to be usable with current software technology and some, such as Seymour Cray's original CRAY-2, do not. The development of the CRAY T3E is therefore best viewed in the context of research and development done in the prior years by Cray Research and others.

Cray developed the T3D and T3E against a background of fully commoditized but weakly performing clusters. Superimposing Cray's engineering capabilities, and its understanding of the needs of high-performance technical computing, onto the prevailing cluster architectures enabled the company to pioneer the successful HPC transition to massive parallelism. The critical hardware engineering innovation was the low-latency, high-bandwidth interconnect, and its 3D torus topology. Adopting an expressive programming paradigm (message-passing), which was the result of industry-wide collaboration, helped overcome the programming

obstacles experienced by the original CRAY-2. Additionally, the ability to support substantially larger, albeit distributed, memories benefited a huge range of applications; and the I/O architecture, which separated I/O from message-passing traffic, was a shared resource to the entire system, unlike earlier clusters. Coalescing all of these attributes into a single, coherent, easily usable, and manageable total system was UNICOS/mk, the first general-purpose distributed operating system. In the best Cray tradition, the T3E was truly balanced in respect of processor power, memory, and I/O, all combining to deliver maximum performance to the end-user through an efficient software system.

Also, for the first time, true supercomputers were on the same Moore's Law development curve as microprocessors. Users could look forward to increased processor power becoming available at lower cost every 2 years or so, rather than the 4-year cycle that had been typical of earlier supercomputers.

With the advent of the T3E the industry was clearly and demonstrably heading toward enabling scientific users to access unlimited computational power, constrained only by their ability to develop highly scalable applications programs and the size of their budget. Contemporary (2010) systems are now achieving PetaFlop performance levels, barely more than a decade after ASCI Red and the T3E first broke the TeraFlop application barrier in 1998. ExaScale systems, a million-fold increase over the T3E, are within reach. Operational systems with more than 200,000 PEs (cores) are available today, and million-core systems are being contemplated.

Clearly, the continuing successful growth of HPC computing power, and resultant expansion of the range of beneficial applicability, now forms a "virtuous circle" driving that growth faster than Moore's Law. However, it is strongly believed in some circles that major processor and memory changes will be required to take HPC from the PetaFlop to the ExaFlop range. Those changes may dissolve the currently productive marriage of commodity components and HPC, conceivably requiring another T3E-like development effort.

After more than a decade of research and experimentation, the T3E had given the users real leverage based on the relentless progress and economics of the microprocessor industry. The T3E hardware and software had finally bridged the gaps between

commodity and high performance, and had become the industry's first widely used MPP system. The T3E user environment and system tools provided an effective platform to develop and run production applications at very high scale. Applications programmers and system managers responded enthusiastically to their new tools, and the installed base of almost 100 T3E systems established a new baseline of expectations among users and the industry that became the foundation for the next phase of the supercomputing roadmap.

The singular T3E contribution was "proof of concept." DARPA, DOE laboratories, NSF researchers, Cray Research, Intel, TMC, and others had collectively formulated the vision. The CRAY T3E provided hard evidence that those ideas could indeed be transformed into usable, flexible, resilient physical reality at a new, more attractive, price point.

Definition

Vector processing at the instruction set level is translation of a high-level language program into a series of scalar and *vector* instructions. Vector instructions use scalar and vector registers, where each vector register holds a maximum number of elements as specified by implementation-specific MAXVL, typically in the range 32–256. Vector processing at the hardware level executes VL elements of an instruction in *parallel* across an implementation-specific number of lanes or

pipes. Each pipe contains a complete copy of functional units and possibly memory data paths and a colocated subset of elements of the vector register file. Vector Instruction Set Architectures (ISAs) allow easy translation by a compiler of loop-level code parallelism into compact instructions that are very efficient in terms of fetch, decode, and issue. Vector ISAs lend themselves to straightforward replication of hardware components for achieving high levels of parallel execution across multiple functional units and multiple pipes. Vector processors are an easy and natural way to provide long periods of uninterrupted pipelined operation for high processor efficiency.

Discussion

The discussion of Cray vector systems is presented in three parts. First, a historical perspective of the rise, domination, and decline of Cray vector systems is presented. The focus is on reasons for this evolution. Second, a technical discussion of architectural and performance advantages of vector systems is presented. These fundamental advantages drive the introduction of vector-enhanced architectures seen today in the x86 SSE and AVX instructions set extensions and SIMD designs of graphics processing units (GPUs). Finally, a chronology of Cray vector systems is presented from the Cray 1 in 1976 to the Cray X2 in 2007.

Introduction and Historical Perspective: The Rise, Domination, and Decline of Cray Vector Systems

Cray vector computers played a unique role in the history of high-performance computing (HPC) and advancement of computer architectures. The genius of Seymour Cray as evidenced by his long track record of designing high-performance computers with Control Data Corporation (CDC) and introduction of the Cray-1 in 1976 earned him the accolade of “Father of the Supercomputer Industry.” The Cray-1 was introduced with a Reduced Instruction Set Computer (RISC) processor and system clock of 80 MHz, whereas state-of-the-art microprocessors of the time ran with 1–2 MHz. This gave the Cray-1 a huge advantage even for scalar codes, and all customer codes experienced immediate and significant speedup compared to microprocessors. As Cray’s vectorizing compiler improved and customers realized how to write vector loops, an additional

improvement of ×5–10 was possible. Fast scalar processing and low memory latency resulted in excellent vector performance for “short” vector loops compared to competing “long” vector machines. The hallmark of Cray systems has been *balance* between CPU computation, memory bandwidth, IO bandwidth, and software stacks to deliver performance.

Government laboratories had in the Cray-1 a computer capable of doing long simulation runs of realistic physical problems. While 8 MB memory capacity of the Cray-1 is tiny by current standards, scientists of the day were able to resolve problems in 1D and 2D geometries. There also was a base of government data-analysis users whose codes benefited from fast and extensive 64-bit integer and logical operations and random access to memory. Soon scientists and engineers in many private companies were buying Cray vector computers to gain competitive advantage by reducing time to market for new products. Early purchasers of Cray supercomputers were from industries such as petroleum, car-crash simulation, computational chemistry, aerospace, structural mechanics, electronics, and weather/climate. Cray vector machines were so much faster than alternatives that, despite \$10–20 M price tags, demand for the technology allowed Cray Research to grow rapidly. Following the Cray 1 were many generations of Cray vector systems with increasing processor count, memory capacity, clock rate, peak performance, and memory bandwidth. During the mid-late 1980s Cray Research owned approximately 70% of the HPC market.

While Cray systems dominated the HPC market for many years, technology changes in the industry and interest from computing companies much larger than Cray Research began eroding competitiveness of Cray vector machines. As IC technology advanced during the late 1980s, some performance advantages of Cray vector systems became price-performance *disadvantages*. Cray Research did not have resources to design full-custom logic CMOS chips, as was done by large microprocessor companies. Dense CMOS logic allowed microprocessors to have large, low-latency, multilevel caches, which are an inexpensive way to provide bandwidth. Low latency to cache is important to prevent stalls of the processor due to allowing only a small number of outstanding memory references. Microprocessor companies chose to design memory hierarchies

with a bandwidth profile strongly peaked at lowest level cache with modest main memory bandwidth based on commodity DRAM chips. Cray systems traditionally were designed with no caches and high-bandwidth crossbar switches to SRAM memory parts that were banked across individual double words rather than cache lines. This provided a uniform memory access (UMA) shared memory system and was ideal for applications with no spatial or temporal locality. For applications with good locality of reference it became more cost-effective to run on microprocessor systems.

Fast, low-density ECL chips and SRAM memory parts resulted in Cray vector machines with many chips on many printed circuit boards and many wires connecting them – expensive components. New microprocessors of the era, such as the IBM Power 2 and DEC Alpha series, were getting close enough in absolute performance to low-end vector machines that *price/performance* became a significant part of the customer's buying decision. This trend continues to the present.

The HPC market is much smaller than the general microprocessor market. It was difficult for Cray systems to realize economic advantages of large-volume production. This problem was exacerbated as low-end customers began shifting from writing vector code to scalar code, since their applications were being targeted for the larger volume superscalar market. This was especially true of Independent Software Vendor (ISV) codes. By the mid-1990s application codes without significant vector content ran faster on microprocessors than on vector systems, as dictated by Amdahl's Law.

In the mid-1990s there were two other intertwined innovations in the computer industry that signaled a shift away from vector systems. First, massively parallel processor (MPP) machines began entering the marketplace. These systems used hundreds or thousands of commodity microprocessors with locally attached DRAM memory and connected with low-bandwidth networks. Second, what made these systems usable and ultimately led to a new *de facto* standard architecture for HPC systems was a standard *distributed memory* inter-processor programming model. The initial standard model was the Processor Virtual Machine (PVM) interface. In time PVM gave way to today's standard – the Message Passing Interface (MPI) model. The 1987 Gordon Bell Award was awarded to Benner, Gustafson, and Montry at Sandia National Laboratory

(SNL). The scientists did weak scaling studies and used a distributed memory message passing model to give $\times 400\text{--}600$ parallel speedups on a 1024 node NCUBE on three applications from SNL.

While early MPP systems had performance issues and lacked production-quality robustness, these systems were an affordable means to scale the number of processors and amount of memory to levels much higher than supported on shared memory vector systems. However, it can be challenging for even MPP systems to run well when processor counts are in the range $10^4\text{--}10^5$. Cray Research was a late comer to the MPP marketplace, but used its experience in delivering HPC systems to contribute to this market segment. During the 1990s the Cray T3D and T3E MPP systems using the DEC Alpha EV4 and EV5 series of processors soon dominated the MPP marketplace, largely due to unique features supported in the Cray proprietary network interface chip and router.

There is nothing that requires the processor in a distributed memory MPP to be a scalar processor. Cray engineers designed several scalable, distributed memory systems with powerful *vector processors* as compute elements. The Cray SV1 system introduced in 1998 was an early version of *multi-threaded vector* operation. Users could specify with a compiler flag that four vector processors on different modules could operate either as four independent vector processors, or as a single, four-way *multi-threaded* vector processor. The Cray SV1 was followed the Cray X1 system introduced in 2003 and the Cray X2 system introduced in 2007. The Cray X1 improved multi-threading by placing the four vector processors on a Multi-Chip Module with tight synchronization. These systems combine massive parallelism *across* many compute elements and *within* each compute element.

While traditional shared memory Cray vector systems are no longer produced, vector hardware concepts are key to two advances in recent HPC architectures. First, x86 processors are moving toward improving performance through SSE and AVX instructions, which are akin to fixed vector lengths of 2, 4, or more elements per register. Second, graphics processing units (GPUs) gang together a moderate number (8–64) of threads of execution in a single-instruction-multiple-data (SIMD) manner. Equally important to vector hardware concepts are vector *compiler* technologies for efficient use of SSE and

AVX instructions and GPUs. Cray compiler techniques for handling outer loop, four-way thread parallelism, and inner-loop vector parallelism with predicated execution of the Cray X1 and X2 are directly applicable to compiling for multi-threaded vector parallelism of GPUs.

The historical perspective of Cray vector systems ends on the note that vector processing will continue to be an important component of future HPC systems. For this reason, it is helpful to understand in more detail the breadth and inherent advantages of vector architectures.

Architectural and Performance Advantages of Cray Vector Systems

Parallel Hardware Needs Parallelizing Compilers and Parallel Application Codes

For HPC users to benefit from increased parallel capability of hardware, HPC application codes must be written so as to allow compilers to identify at multiple loop levels task and vector parallelism. The triad of parallel hardware, parallelizing compilers, and parallel application codes are equally dependent on one another for efficient utilization of modern HPC systems. The Fortran programming language introduced by John W. Backus of IBM in 1953 was well-suited for expressing numerical discretization and similar algorithms that an auto-parallelizing and vectorizing compiler could analyze.

Application programs can contain parallelism at several levels. At the lowest level, a compiler generates many instructions for each line of code written with a high-level language. Generally groups of these instructions involve different registers and can be issued in parallel on the same clock cycle. This is instruction level parallelism (ILP), and is supported on all processors today. *Vector* processors target intermediate-level *data* parallelism when operations between elements of vectors or arrays are independent and can be expressed as a *single* instruction. An example of a simple vector loop is a TRIAD operation

```
Do i=1,N ← vector parallel over do-i
  z(i) = x(i) + a*y(i)
Enddo
```

A vectorizing compiler with maximum vector length 64 breaks this loop in chunks of up to 64 iterations. Vector instructions for TRIAD load 64 values of x(i) with a

one instruction, 64 values of y(i) with one instruction, do 64 multiplies of a vector times a scalar with a single instruction, etc. For the final iteration vector length is reduced as necessary, on architectures that support it. Vector parallelism also could be considered data level parallelism (DLP).

At the third level is loop-level *task* or *thread* parallelism. Here iterations of the loop contain independent streams of either purely scalar instructions or mixed scalar and vector instructions. For example, a task-parallel TRIAD loop is

```
Do j = 1,M ← task parallel over do-j
  Do i = 1,N ← vector parallel over do-i
    z(i,j) = x(i,j) + a*y(i,j)
  Enddo ! i
Enddo ! j
```

This thread parallel loop could be detected with an auto-parallelizing compiler, or could be identified by user-inserted OpenMP directives before the do-j loop. A vectorizing compiler will translate the inner loop into scalar–vector instructions, whereas a non-vectorizing compiler translates the loop into purely scalar instructions.

The highest level parallelism in HPC codes today is inter-processor parallelism, usually programmed with the MPI model.

Pipelining and Vector Processing

The design of efficient HPC processors is inexorably linked with the concept of *pipelining*. Vector architectures are a natural and effective way to implement pipelining.

Hardware pipelining is the decomposition of logic blocks and data paths into a series of stages that allow back-to-back transmission of intermediate results or final data packets associated with a computation through the processor and memory system. The goal of pipelining is that at every clock cycle functional units and data paths can accept new input data, perform an operation, and advance output data to the next stage of the pipeline. For example, in processors today a floating point multiply operation might be broken into four stages, which leads to a four clock latency for a single multiply to complete. Moreover, in a pipelined design the first and subsequent stages are able to accept new

input operands *every clock*. For example, in a hypothetical pipelined implementation with 4 clock multiply latency the time to complete a stream of 64 MULTIPLY operands is 67 clocks – 4 clocks for the first result to finish the last stage of the multiply unit, plus 63 clocks for each successive result to finish the last stage of the multiply unit. It is apparent that a vector register containing 64 elements provides a natural implementation for providing a “pipelined stream of 64 operands.”

Vector Pipes and “Chime” Time

To boost performance, vector processors can be designed with multiple *pipes*. An n -pipe implementation contains $1/n$ of the maximum number of vector elements of all vector registers colocated with a complete copy of all functional units and possibly data paths to the memory system. In a vector processor with two pipes, a pipelined stream of 64 operands would complete in 32 clocks. The *chime time* of a vector implementation is

```
Vector chime time = MAXVL/#pipes,
```

where MAXVL is the maximum number of elements in a vector register. The biggest challenge for a processor to maintain pipelined operation is in the memory system – it is difficult and expensive to design a memory system that provides load operands in a fully pipelined manner. Pipelining of a memory system extends from address translation, to cache coherence directory consultation (if caches are present), to crossbars and banks of the memory system, and back to processor registers. A well-pipelined memory system can be illustrated with a Cray C90, first introduced in 1991. The Cray C90/16 was a 16-processor shared memory system that ran at nominal 250 MHz with 512 SRAM memory banks, each capable of providing a 64 bit double word (dword) every 4 clock cycles. This provided a peak bandwidth at the banks of $(512 \text{ banks})^*(8\text{B/bank}/4 \text{ clocks})^*(0.25 \text{ GHz}) = 256 \text{ GB/s}$. Each Cray C90 processor had two vector read ports and one vector write port with the goal of supporting high performance for memory-intensive loops like TRIAD. The maximum memory bandwidth a single processor could ask for was four dwords load data and two dwords store data per clock for total of 6 dwords per clock. 16 processors of a Cray C90/16 had a maximum memory request rate of $(16 \text{ proc})^*(6\text{dwds/clock/proc})^*$

$(8\text{B/dword})^*(0.25 \text{ GHz}) = 192 \text{ GB/s}$. The bandwidth at the banks was over-provisioned compared to peak processor request rate by factor $256/192 = \times 1.3$. This was to compensate for inevitable contention between processors in crossbars and memory banks. In practice a fully loaded Cray C90/16 could compute TRIAD with aggregate bandwidth of about 102 GB/s, which is 53% of the maximum processor request rate.

Advantages of Vector Processors

Traditional vector processors have significant advantages over traditional superscalar microprocessors for HPC applications. These include: (a) reduced instruction issue bandwidth requirements, (b) high processor concurrency for latency tolerance, (c) good fit with IC technology for functional units and registers, and (d) vector *chaining*.

(a) Reduced instruction issue bandwidth requirements

A significant advantage of vector ISAs is reduction in instruction issue bandwidth requirements. This lowers power and silicon area requirements for instruction fetch and decode. Vector ISAs afford an easy way for the compiler to convey data parallelism to hardware. For example, with MAXVL = 64 vector load/store instructions have one of two generic formats

<code>v1 [a1, a2] ← constant stride load</code>
<code>[a1, a2] v1 ← constant stride store</code>
<code>v1 [a1, v2] ← gather (indexed load)</code>
<code>[a1, v2] v1 ← scatter (indexed store)</code>

For the constant stride case, the base address of the load is in address register a1 and the stride of the load/store is in register a2. For the gather/scatter case (indirect addressing), vector register v2 contains 64 integer values that are word-offsets relative to the base address of each successive element of the vector reference. The destination register of the load or operand register of the store is v1. A *single* vector load instruction loads 64 words from memory with all 64 addresses generated *automatically* in vector hardware – element-by-element address increment instructions are not required. A scalar processor requires 64 load instructions and 64 address increment instructions for a total of 128 instructions. On a vector processor *scalar* instruction issue bandwidth can be relaxed, since scalar execution in support of vector loops can be “hidden” under vector

chime time. The Cray-1 had length 64 vector registers and one vector pipe, so its chime time was 64 clocks. This gave ample opportunity for scalar instructions to issue without interrupting back-to-back issue of vector instructions. The reduced instruction issue requirement of vector processing is taken advantage of when the Intel x86 ISA added SSE and AVX instructions, which have fixed vector length of 2, 4, or 8, and in GPUs which execute SIMD manner with an equivalent maximum vector length in the range 8–64.

(b) High concurrency for latency tolerance

A second advantage of vector processing is the large concurrency available to hide memory latency. The register file in a Cray X2 processor introduced in 2007 has 32 vector registers with 128 elements each for a total of $128 \times 32 = 4096$ doubleword (quadword for x86) elements. The implementation of the Cray X2 allows each processor to have up to 4096 outstanding dword load elements. The Cray X2 has hardware support for direct load/store access to any address in the system. Each processor has sufficient concurrency to tolerate local memory latency of 310 ns and even remote memory latencies of several microseconds.

(c) Good fit of vector hardware to IC technology

A third advantage of vector processors is they are a good match to IC technology in terms of functional units and register files. The vector register file is large (good for pipelined operation) and simple to control. Each vector processor of the Cray X2 has eight vector pipes. From a logic design perspective, adding vector pipes is a straightforward replication of functional unit groups (FUGs) for each pipe with each FUG having two read ports and one write port into its per-pipe registers. For example, FUG1 on the Cray X2 contains FP Add, INT ADD, a LOGICAL unit, COMPARE, etc. FUG2 contains FP MULTIPLY, INT MULTIPLY, and a SHIFT. The vector load/store unit also has ports into and out of the per-pipe register file. One vector instruction from each FUG can issue per chime, as long as there are no issue conflicts. In contrast, a superscalar microprocessor has a more complex and smaller register file. In a 4-way-issue machine, in *each clock four instructions* for correctness need full access into any individual element of the register file. Issue

logic is more complex, since register and FUG availability and data path conflicts have to be examined to determine how many instructions can issue in the next clock. Complexity of scalar register files grows quadratically with number of registers. Vector register file size can grow with no increase in complexity by increasing maximum vector length.

(d) Vector “chaining”: vector processing of dependent instruction streams

Vector register files and chime time lead to an architectural advantage of vector processing related to pipelining called *chaining*. Chaining occurs when an output vector register of an instruction executed in one functional unit is pipelined as an input vector register into a *dependent* instruction in a different functional unit. Register bypass paths between functional units are standard in microprocessors, but chaining extends this concept with large vector length. From a compiler perspective, chaining allows vectorization *across* independent sets of *dependent* instructions. This architectural advantage of vector processing merits exploration with a concrete example.

The top of Fig. 1 shows a loop of 64 iterations containing a line of code with pairwise-dependent MUL-TIPLY/ADD instructions. Figure 1a shows instruction sequences for Y(I) on a superscalar processor (left half of table) and vector processor with MAXVL = 64 (right half of table). Not shown are load instructions (presumed to hit in cache) that fill input registers R0 on the scalar side and S0 on the vector side. Calculation of Y(I) is parallel (vectorizable) over I, but assume register pressure from other statements in the loop body prevents a superscalar compiler from unrolling or software pipelining calculation of Y for different I. The assumption of no pipelining on the scalar processor may seem unnecessarily restrictive, but the point is to illustrate the advantage of the *length* of registers rather than the *number* of registers. This effect has been seen in real application codes. Consider execution of this line of code on an out of order (OOO), 4-way superscalar processor and an in-order, single-pipe vector processor with MAXVL 64. Assume both processors can load or store one doubleword per clock from cache with 3 clock load latency, and both processors have MULTIPLY and ADD latencies of 4 clocks.

```

DO I = 1,64
...
Y(I) = X1(I)+A*( X2(I)+A*X3(I) )
...
ENDDO

```

Cray Vector Computers. Fig. 1 Illustration of vector chaining for loop with dependent pairs of MUL/ADD instructions whose loads hit cache with 3 clock latency. Floating point functional unit latency is 4 clocks. (a) Instructions with issue times for OOO superscalar processor (*left*) and in order, MAXVL = 64 vector processor (*right*). (b) Explanation of issue times for each instruction and processor

Figure 1a is a table showing when each instruction issues on the superscalar and vector processors. The timing table reveals differences in issue constraints and

performance between the two processor types. Figure 1b is a table explaining what determines issue time of each instruction on the two processors. On the superscalar

processor loads of one scalar value can issue every clock and issue OOO. The left half of [Figure 1a](#) shows that by clock 4 performance is limited by the 4 clock *functional unit latencies* of MUL and ADD instructions, leading to a total of 19 clocks for *each* iteration I. Total time for this one line of code for 64 iterations is approximately **1216** clocks.

On the other hand, on the vector processor there is a single vector iteration of length 64 for calculating $Y(1:64)$. Vector loads or stores can execute only once every 64 clocks, since each vector memory reference busies the data path to cache for 64 clocks. As can be seen from the right half of [Figure 1a](#), functional unit latency on the vector processor just adds a few extra clocks to execution time. Issue timings (column 5 of [Fig. 1](#)) for instructions 1, 3, 5, and 8 show that performance is limited by memory system bandwidth – functional unit latencies are basically hidden by pipelining from vector registers. To vector execution time (see green “64” in instruction 8 of [Fig. 1a](#)) is added time for the vector store to complete, as the first vector load following calculation of $Y(1:64)$ cannot begin until the store relinquishes the data path to the cache. Total time for this one line of code for 64 iterations is approximately **203** clocks.

The difference in performance between the vector and superscalar processors for calculation of $Y(1:64)$ is approximately **6×** ($1216/203$). This dramatic speedup is due to *vector architecture*, even though the processors have *equal* peak performance and cache bandwidth. It is much more efficient to stream 64 elements from cache and pipeline them through MULTIPLY and ADD functional units, than to individually fetch words from cache and pay MULTIPLY and ADD latency separately for each iteration. For the *complete* loop in [Fig. 1](#), the difference in performance between the two processors will be less than $6\times$, depending on how much work is in parts of the loop not shown. If arrays $X1(I)$, $X2(I)$, $X3(I)$, and $Y(I)$ are not in cache, performance on both systems will be limited by memory bandwidth and possibly memory latency (superscalar case, due to low concurrency). Of course, to the extent scalar pipelining is possible, the relative speedup of the vector case will be reduced.

Chronology of Cray Vector Systems

While the basic Cray-1 ISA persisted within Cray for nearly 30 years, there have been many implementation

improvements over the years. The following are highlights of Cray vector (and non-vector) systems beginning with the Cray-1. Some specifications are nominal, since different models of a given system can ship with slightly different parameters.

Cray-1S/M

The Cray ISA was one of the first Reduced Instruction Set Computers (RISC) in a commercially available computer. There were 8 integer-only address registers (24-bit) A0–A7, eight general-purpose scalar registers (64-bit) S0-S7, and 8 vector registers (64-bit) V0-V7 with MAXVL = 64. 64 B and T registers were used to do block loads of scalar data from memory and as spill space for A and S registers, respectively. The clock speed was 80 MHz for a peak performance of 160 MFLOPS. The Cray-1 was a single processor system with no caches and up to 32 MB of bipolar memory and supported a load path and store path to memory. Memory latency was 11 clock cycles. Memory was dword-addressable (rather than byte-addressable) and *real* as opposed to *virtual*. [Figure 2](#) shows Seymour Cray and the Cray-1 supercomputer. The iconic “C” shaped footprint allowed routing short-length wires between processor and memory modules. The padded seat perimeter housed power supplies and plumbing for the liquid cooling system. The IO system was housed in a separate cabinet. Dedicated IO processors could read and write main memory and disk without diverting the CPU from computation. An optional solid state disk (SSD) cabinet delivered much higher performance for codes that repeatedly accessed datasets too large to fit in central memory. First customer ship was in 1976.

Cray XMP2/4

The Cray XMP came in 1-4 processor models. The Cray-1 ISA was expanded to add 8 “shared” and 8 “semaphore” registers. These registers allowed fast synchronization between processors and IO resources. A later version of the machine was the Cray XMP-EA (Extended Architecture). Expansion of A and B registers to 32 bits permitted the architecture to address up to 4 GWords (64-bit double words) main memory. Clock speeds up to 117 MHz gave peak performance of 235 MFLOPS per processor. The number of paths to memory increased to two loads and one store path per processor. Memory latency was approximately 13 clock cycles.

Cray Vector Computers. Fig. 2 Seymour Cray and the Cray-1 supercomputer

Flexible chaining was introduced to allow more frequent overlap of functional units. Pioneering work was done on the Cray software stack to implement Macro-Tasking™ libraries that harnessed multiple CPUs on a single user program. A second version of parallelizing software, optimized for finer granularity parallel work, was Micro-Tasking™. User-inserted directives were inserted before a parallel loop, which the compiler translated into efficient work-sharing code using low-latency shared registers. It was common to get parallel speedups greater than 3.5 on a four-processor Cray XMP. The Cray XMP was introduced in 1982.

Cray-2/4

The Cray-2 was renowned for two innovations. First main memory was expanded up to 4 GB, which allowed for much higher resolution scientific computing. Large memory was made possible by use of high density but low bandwidth DRAM chips. This allowed scientists and engineers to begin 3D simulations. Second, the system was very compact – its cabinet footprint was a

1.35 m circle and its height was 1.15 m. The computer used total immersion Flourinert cooling, with plumbing to a distantly located cooling tower. The processor ran at 244 MHz for a peak performance of 488 MFLOPS per processor. The Cray-2 also introduced a 128 KB, compiler-managed, local memory. The Cray-2 system ran the UNICOS operating system, which started the shift toward UNIX-based OS within Cray. The Cray-2 was introduced in 1985. Like the Cray-1, the Cray-2 system was designed by Seymour Cray. Follow-ons Cray 3 and Cray 4 were built by Seymour Cray as part of Cray Computer Company in Colorado Springs during the early 1990s. The Cray 3 and Cray 4 pushed miniaturization of packing and were difficult to manufacture in volume.

Cray YMP/8

The Cray YMP was the follow-on to the Cray XMP and had from 1 to 8 processors. Clock speed of 167 MHz gave peak performance of 333 MLOPS per processor. Memory latency was approximately 17 clock cycles. There were several versions of the YMP designed for different market needs. The baseline system came with a 1 GB SSD and 256 MB memory, but for memory-intensive applications a DRAM memory part option allowed up to 32 GB memory. For low-end markets the YMP-EL was an air-cooled CMOS implementation of the YMP.

Cray C90/16

The Cray C90 had up to 16 processors. Clock speed was a nominal 250 MHz. An implementation change relative to the YMP was to have *two* vector pipes with vector registers 128 elements each, which boosted performance to 1 GFLOP per processor. To maintain processor and memory bandwidth balance, each vector pipe had two load and one store paths to memory. Memory latency was about 23 clocks, and memory capacity was 0.5–8 GB. The C90 was introduced in 1991.

Cray T3D MPP

Though not a vector system, the T3D was Cray's first MPP system. The T3D was hosted by a Cray YMP Model E system, which ran the Cray UNICOS operating system and provided I/O and most system services to the MPP. DEC Alpha EV4 150 MHz processors were the compute engine of a node and ran a microkernel

operating system. Each node contained two EV4 processors connected to a proprietary network interface chip (NIC). The NIC arbitrated access of the two processors to a Block Transfer engine (BLT), which performed direct memory access (DMA) transfers to/from the local node to remote nodes via a link to a proprietary router chip. The router chip supported bidirectional 3D torus connections to other router chips in the system. The first Cray T3D system was shipped in 1993 to the Pittsburgh Supercomputer Center (PSC).

Cray CS6400

Cray Research acquired the assets of Floating Points Systems in 1991, which led to formation of subsidiary Cray Research Superservers in 1993. These systems were based on Sun Microsystems' SuperSPARC microprocessor and utilized high-bandwidth buses in a fault-tolerant, partitionable SMP configuration. The Cray CS6400 team was developing the Starfire system when it was sold to Sun Microsystems after SGI purchased Cray Research in 1996. The Starfire became Sun's very successful Enterprise 10,000 system.

Cray J90/32

The Cray J90 had 8, 16, or 32 processor models. This machine was the follow-on to the Cray YMP-EL, so it was an air-cooled CMOS implementation. The J90 had two noteworthy innovations. First the CPU was split into two chips, one for scalar processing and one for vector processing. Initially both chips ran at 100 MHz, but the Cray J90se (scalar enhanced) model ran with 200 MHz on the scalar chip. The second innovation (for Cray) was presence of a 1KB *scalar* cache. Presence of a cache-based processor introduced new issues for Cray designers, such as maintaining coherence between scalar and vector memory transactions. The cache was software managed, so the compiler was responsible for hardware invalidations when required. The J90 began shipping in 1994.

Cray T90/32

The Cray T90 had 4, 8, 16, and 32 processor models. The T90 had two innovations. First was addition of a mode that would use either IEEE or traditional Cray floating point format. IEEE mode was particularly important to ISVs who wanted single source code to run on many platforms. Second was a redesigned memory

system in which vector memory references no longer had synchronized access to data paths, but requests and responses were individual packets for each element of the vector reference. Vector loads no longer completed in order, and the processor could issue multiple vector loads (however, still only 8 vector registers) without stalling unless a destination register in an instruction was not completely full. A T90/32 could execute the STREAMS benchmark at 360 GB/s. The clock rate was 450 MHz, which required Fluorinert cooling. Like the Cray C90, the T90 had two vector pipes, so its peak compute rate was 1.8 GFLOPS per processor. The T90 was introduced in 1994.

Cray T3E MPP

The Cray T3E system was a self-hosted follow-on to the Cray T3D system. The 3D torus network was maintained from the T3D, although the T3D used *dimension-order* routing while the T3E used *direction-order* routing. The latter routing enabled better network fault tolerance. Link bandwidth and functionality of the T3E router chip were enhanced over the T3D. Two T3E router enhancements were adaptive routing of packets as network contention was detected (also improved fault tolerance) and a virtual barrier network. The T3E used a single DEC Alpha EV5 or EV56 processor connected to the NIC. One of the most significant new features of the T3E NIC was "E registers." There were 512 user-accessible E registers that were manipulated by the local processor to do direct, un-cached DMA transfers to/from memory of remote nodes. The ability to easily use E registers led to the successful SHMEM communication model, which implemented the first direct, high-performance GET/PUT semantic communication model for MPPs. The first Cray T3E system was delivered to PSC in 1996. The T3E's performance and scalability led it to become the gold standard of the MPP market in the late 1990s.

Cray SV1/32

Silicon Graphics purchased Cray Research in 1996. The Cray SV1 was completed in the Cray Research division of Silicon Graphics. The SV1 was binary compatible with the Cray YMP and J90, so computed solely using traditional Cray floating point arithmetic and had vector registers with 64 elements each. There were three innovations introduced in the SV1. First each SV1 cabinet

had a 256 KB software-coherent merged scalar–vector cache. For vectors the cache primarily served to filter bandwidth rather than reduce latency. Second the concept of “Multi-Streaming” was introduced. Here, under control of software, groups of four processors of an SV1 cabinet could be ganged together at the task level of parallelism in a program to serve as a single, 4-way multi-threaded vector processor. This was the first attempt within Cray to develop a more powerful “single processor,” but the concept was little used due to lack of key hardware support. The third innovation was multiple SV1/32 cabinets could be combined with a Cray proprietary Giga-Ring™ interconnect to form a “Scalable Vector” system up 32 SV1/32 “nodes.” The original SV1 systems ran at 300 MHz, and the SV1ex follow-on ran at 500 MHz. Peak performance of a single processor was 1 GFLOP and 32 GFLOPS for the 32 processor node of SV1ex. A full 32-node system had a peak of 1.0 TFLOPS. The Cray SV1 began shipping in 1998.

Cray XMT

In 2000 Tera Computer Company bought the Cray Research division of Silicon Graphics. The new company was renamed Cray Inc. The experience of Tera engineers in designing and building highly multi-threaded systems led to the Cray XMT system. This system was uniquely able to satisfy market needs for applications with abundant levels of non-predictable, graph-based parallelism.

Cray X1

The Cray X1 was the first truly scalable vector-based system designed by Cray. It shipped in late 2002. As described below the Cray X1 system had a limited version of coarse-grained multi-threaded vector operation, which shares with Cray XMT systems some of the same compiler techniques for loop-based task and vector parallelism. The Cray X1 had many innovations over past Cray vector machines.

1. There was a major upgrade of the Cray-1 ISA: The Cray X1 ISA supported only IEEE arithmetic; 64 64-bit A registers; 64 64-bit S registers; 32 64-bit V registers with 64 elements each. 8 vector mask (VM) registers, each with 64 elements and one-bit wide, were added to allow rapid evaluation

of conditional code using predicated execution. Furthermore, almost all vector instructions were subject to predicate execution as specified by VM registers, element by element. A relaxed memory model was defined with a rich set of synchronization and Atomic Memory Operation (AMO) instructions were defined.

2. There were two processor modes. In Single Stream Processor (SSP) mode, each vector/scalar CPU was a separate processor. In Multi-Streaming Processor (MSP) mode, a group of four SSPs packaged on an MCM was treated by the compiler as a 4-way multi-threaded vector processor. Applications were compiled either in SSP mode or MSP mode via a compilation flag. The compiler could either automatically detect outer loop task-level parallelism with vector code generation on inner loops, or the compiler could key off user-inserted Cray Streaming Directives (CSDs) to schedule SSP threads across loops possessing subroutine call trees. Each SSP thread could discover vector parallelism as the thread traversed the call tree. A fast MSYNC synchronization instruction was both a control and memory barrier between SSPs in an MSP.
3. Each SSP processor was a two-pipe CPU with vector registers of 64 elements. The scalar part of the SSP ran at 400 MHz while the vector unit ran at 800 MHz. This led to a peak 64-bit rate of 3.2 GFLOPS, and 32-bit mode had peak of 6.4 GFLOPS.
4. Each SSP was operated in a fully *decoupled* manner. The first level of decoupling was that scalar execution ran “ahead” of vector execution by hundreds of clock cycles in each SSP. The scalar processor issued, completed, and marked for graduation scalar instructions early while vector instructions were dispatched to deep queues to await scalar operands, if needed. The second level of decoupling was early, non-blocking processing of vector load addresses into the memory system to prevent into load buffers data that would be moved into a vector register when the load executed at the vector execution pipeline. Vector store addresses were also decoupled from vector store data to allow for pre-allocating store requests in cache.
5. The MSP had peak 64-bit flop rate of 12.8 GFLOPS. The four SSPs on the MCM shared a 2 MB L2 cache,

while each SSP had a 64 KB scalar cache. High bandwidth directory caches in the Memory (M) controller chips processed cache coherence messages without degrading performance.

6. Each of four MCMs on a node was connected to 16 M chips with peak nodal memory bandwidth of 200 GB/s. Each M chip had two bidirectional cache-line address sliced ports into a proprietary Cray X1 network. The network had multiple 2D slices between cabinets, and had cross-bar routing among nodes in a cabinet.
7. The Cray X1 was scalable up to 1024 nodes: fully cache coherent system but only caching node-local data; entire system is globally addressable – processor and network support native ISA remote scalar and vector memory references with “remote translation” (map all system memory so there were no network TLB misses). The latter feature was borrowed from the Cray T3E NIC.

Cray X2

The Cray X2 was the follow-on to the Cray X1 with a number of noteworthy differences. First the concept of MSP was dropped. On the X1 some applications ran very well in MSP mode, but the marketplace generally favored SSP mode as being more efficient – Amdahl’s Law exacts a large penalty if parts of an application do not have task-level parallel loops to use the 4 SSP threads. Second, each X2 CPU was an 8-pipe vector unit with vector registers of 128 elements each, double the length in the Cray X1. Scalar and vector clock rates were 800 MHz and 1.6 GHz, respectively. This resulted in peak performance of 25 GFLOPS per processor. Each CPU had a 0.5 MB vector/scalar cache. Vector Atomic Memory Operations (AMOs) were added to allow high performance on certain loops with potential memory conflicts. Another difference was the X2 used a fat-tree topology for the network. The Cray X2, like the X1, was globally addressable across the system. The proprietary router processed single dword or cache line requests at very high bisection bandwidth.

The Cray X2 was the latest and last proprietary vector computer designed at Cray Inc. However, many of ideas of vector processing apply to future versions of the x86 ISA and implementations and programming models of GPUs. In particular, vectorizing compiler

technology will continue to play a large role in delivering performance on future HPC systems.

Bibliographic Notes and Further Reading

Vector processing and related architectures preceded founding of Cray Research in 1972. The ILLIAC IV from Burroughs was an early SIMD computer. A control unit broadcasted an instruction to an Array Subsystem containing 64 processing units with local memory and mode bit control [1]. Two vector machines that appeared in the early 1970s were the Texas Instruments ASC [2] and the Control Data Corporation (CDC) STAR-100 [3]. However, it was the Cray-1, introduced in 1976, that combined a vector RISC ISA with technology improvements that made vector processing so dominant in the first 20 years of the modern HPC era. The Cray XMP and YMP design teams were led by Steve Chen [4].

Many academic investigators have studied vector architectures. James E. Smith, while at Cray Research in the early 1990s and at the University of Wisconsin-Madison, published extensively on vector processing [5, 6]. The Berkeley Intelligent RAM (IRAM) project included design of a processor-in-memory chip that sought to address the growing imbalance between fast processors and low memory bandwidth [7]. The chip took advantage of traditional strengths of vector processing, such as low power for issue and control, low design complexity, mature vector compiler technology, etc., and combined those with on-chip DRAM memory bandwidth. One target application area for such chips is on-demand media processing. The first edition of the classic text on computer architectures by Hennessy and Patterson [8] is recommended for a quantitative approach to computer architectures and comparisons between scalar and vector processing. Detailed performance models are presented extending from processor to memory system. The authors emphasize importance of scalar performance and low memory

latency leading to overall low start-up time for vector loops. Vector machines and SIMD machines share many features and can be programmed similarly. The book by Guy Blelloch gives in-depth examples of how algorithms with irregular memory access can be coded in vector/SIMD manner [9]. Studies of vectorizing compiler techniques, important for usability of vector systems, can be found in [10–13]. A detailed description of many advancements of the Cray X2 system is given in [14].

Cray XMT

LARRY KAPLAN
Cray Inc., Seattle, WA, USA

Definition

The Cray XMT is a shared memory parallel computer consisting primarily of aggressively multi-threaded processors derived directly from the Tera Multi-Threaded Architecture (MTA) (see ►Tera MTA) [1]. It is packaged using the same infrastructure and support as the Cray XT3 (see ►Cray XT3 and Cray XT Series of Supercomputers). The main difference in hardware from the XT3 is the replacement of the socket 940 Opterons on the compute nodes with Cray Threadstorm processors. These processors implement the Multi-Threaded Architecture with support for 128 hardware threads in each processor. Systems of up to 512 Threadstorm processors are supported.

Discussion

Introduction

Shared memory parallel programming can provide simplicity to the programmer by allowing the placement of data to be ignored. All memory is essentially equally distant in such a system. However, implementing a shared memory system in a scalable fashion has several challenges. The biggest challenge is making a distributed memory implementation of the memory appear as uniformly shared to the programmer by hiding the latency to the memory as seen by the processors. In addition, several other important features are required to make best use of the shared memory environment including support for fine-grained synchronization. The Cray XMT implements these features using the custom Threadstorm processor and SeaStar2 interconnect.

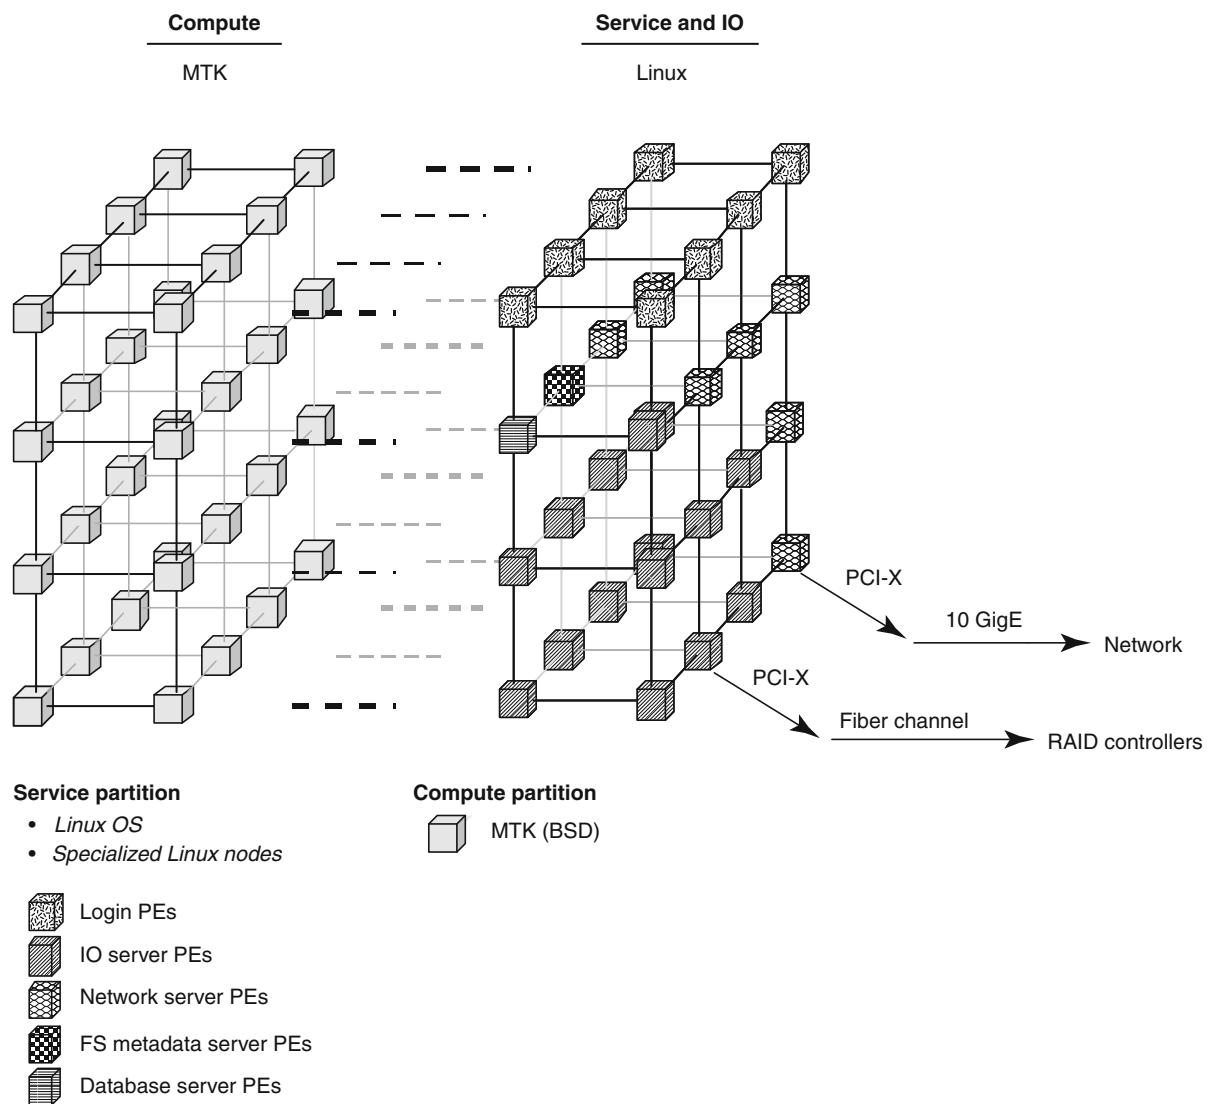

Note that in addition to the main Threadstorm multi-threaded processors on the XMT compute nodes, an XMT also contains service nodes that use standard AMD Opterons. The system hardware architecture is shown in Fig. 1.

These service nodes provide external connectivity via PCI-X cards, and a login environment with compilation and other programmer tools. These nodes can also be programmed using standard Linux tools. Except where explicitly noted, most of the discussion presented

here is specific to the multi-threaded compute portion of the system.

Threadstorm

The Threadstorm processor is a direct descendant of the MTA-2 processor. As with its predecessor, Threadstorm contains 128 hardware threads or *streams* multiplexed onto a single execution pipeline on a cycle-by-cycle basis. By context-switching every cycle, the execution latency of any individual instruction can be effectively

Cray XMT. Fig. 1 XMT architecture

reduced or hidden from the point of view of the processor. This is especially important for memory operations in instructions because the latencies for these operations can be relatively long in terms of processor clock cycles.

In addition, each stream within the processor, in concert with the compiler, implements a release consistent memory model [2] and can have up to eight memory references (e.g., loads and/or stores) outstanding simultaneously. This allows for a total of 1,024 memory references to be outstanding from a given Threadstorm processor.

Threadstorm also includes an integrated DDR1 memory controller, primarily due to the fact that it sits in an Opteron socket 940, which expects such functionality to be present. In addition, Threadstorm contains a HyperTransport (HT) interface over which it communicates with SeaStar, which implements the high-speed interconnect.

The processor and memory controller, which in Threadstorm is on the same die as the processor, supports fine-grained synchronization through the use of *state bits* stored in memory. Conceptually each 64-bit memory location supports four additional bits that together are used to implement various forms of synchronization. Unlike in the original MTA, some assumptions on the use of those bits are leveraged to allow the implementation to only have two extra bits per memory location. The directly supported forms of synchronization include mutual exclusion locks, single word producer-consumer, among others.

Because the processor is latency-tolerant, most memory used in the Cray XMT is distributed across all of the memory units that reside at every processor. A pseudo-random distribution is used to avoid any stride access conflicts or other memory reference patterns that might create hot memory units, assuming the references are not accessing the exact same memory word (or small set of words).

Some other differences between the MTA-2 processor implementation and Threadstorm include:

- Number of processors supported increased from 256 to 8,192
- Memory distribution changed from every word to every eight words

- Data TLB increased in size to cover 512 terabytes (was only 128 terabytes)
- Amount of memory supported per node increased from 4 gigabytes to 16 gigabytes

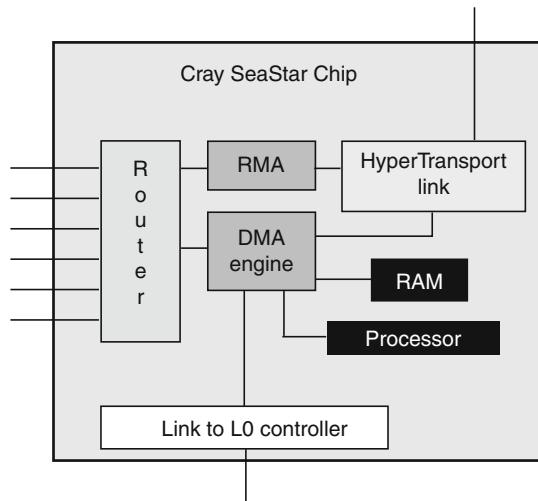

SeaStar

The Cray SeaStar 3-D Torus interconnect (see ►[Cray XT4 and Seastar 3-DTorus Interconnect](#)) was originally designed for use in the Cray Redstorm system that ultimately became the Cray XT3. It is primarily designed for message passing types of communication through the use of a direct memory access (DMA) engine and an embedded processor. In order to support the XMT, a *Remote Memory Access* (RMA) block was added that could process the memory reference style of communication used by Threadstorm. The resulting ASIC is known as SeaStar2 and is shown in Fig. 2.

RMA transactions are used exclusively between Threadstorm nodes. Message passing transactions are used to communicate with the Opteron-based service nodes. Portals [3] is used to drive the message-passing transactions though only a small subset of the Portals API is implemented on the compute nodes.

Programming Model

The Cray XMT inherits the majority of its programming model from the Tera MTA and presents a flat, shared memory to the programmer that is accessed

Cray XMT. Fig. 2 SeaStar2

using enhanced C and C++ languages via a compiler that provides automatic parallelization [4]. Fortran is not supported on the Cray XMT.

The Cray XMT programming model is supported by an advanced runtime library that is linked in with the application. Due to certain aspects of the hardware design, this runtime is able to assume various responsibilities normally associated with an operating system [5]. Such responsibilities include thread-level scheduling and exception handling. The MTA hardware allows for thread creation and destruction in user mode and delivers all exceptions directly to the privilege level in which they are raised. Events such as floating point and memory synchronization exceptions are delivered directly to user mode if they are raised there.

Various tools from the MTA have also been updated and repackaged for the Cray XMT. Debugging is provided by the mdb debugger that is based on gdb [6]. The compiler analysis tool Canal is available. Tracing is provided by Tview. Bprof provides block-level profiling. Cray Apprentice2 provides a graphical interface for viewing the output of these tools [7].

Operating System

The compute processors of the Cray XMT run an operating system called MTK, which is derived from the 4.4 Berkeley Software Distribution (BSD) of Unix with a custom microkernel. The microkernel handles most of the hardware-specific processor functionality, including memory allocation and process-level scheduling, while the BSD layer provides a familiar environment for applications. The operating system treats all of the XMT compute processors as a single instance with a Uniform Memory Access (UMA) model of memory. The main exception to this treatment is that instructions are replicated to every Threadstorm processor in order to make it easier to deliver the required instruction fetch bandwidth.

The service processors of the XMT are identical to those in the Cray XT3 and run a version of Linux derived from SuSE Linux Enterprise Server (SLES). Each service node runs its own instance of Linux.

Built on top of the low-level Portals communication protocol used between the compute and service nodes, the Lightweight User Communication (LUC) library is available for user programs to transfer data between the

service and compute nodes. TCP/IP is also supported between the two node types.

Infrastructure and Administration

As previously described, from a packaging standpoint, the Cray XMT is simply a Cray XT3 system where the Opterons on the compute nodes have been replaced by Threadstorm processors (and SeaStar2 interconnect ASICs are present). As such, all of the other infrastructure and support for XT3 systems, other than the XT3 compute node programming environment, applies to XMT. By using the XT3 infrastructure, the Cray XMT can leverage the reliability, manufacturability, and economies of scale that XT3 provides.

Cray XMT systems are administered in a very similar fashion to XT3. They have the same System Maintenance Workstation (SMW) and Hardware Supervisory System (HSS) as is used in XT3, with some extensions to specifically support the Threadstorm processor. As with XT3, users log into Opteron-based service nodes for access to the system and programming environment. Jobs are then launched from the service, or login, node and run on the compute nodes.

Target Applications

The Cray XMT excels at applications that operate on large volumes of unstructured data such that the data does not fit into the memory of a single node of a typical computer and that data is also not easy to partition for locality to multiple nodes of such a computer. Some application areas that have this type of data include social media analysis, power grid contingency analysis, high-throughput video analysis, and some forms of text document processing.

Follow-on Designs

The concepts contained in XMT and Threadstorm have been considered for some other designs.

Scorpio

As part of the research for the DARPA HPCS program, Cray investigated the design of a highly multi-threaded, multi-core processor called Scorpio that planned to include several of the features present in the Threadstorm processor. These features included the multiplexing of many hardware streams onto an execution

pipeline and the implementation of extra memory state bits on every 64-bit word of memory for fine-grained synchronization (though the bit definitions were somewhat different than with XMT). Scorpio has never been manufactured.

XMT2

A new design of the Threadstorm processor and XMT system is being investigated by Cray to address some of the current shortcomings of the XMT. The main areas of improvement being considered include:

- DDR2 memory controller (instead of DDR1)
- Larger per-node memory sizes
- Use of XT5 infrastructure (rather than XT3)

Definition

The Cray XT3 supercomputer is a large-scale Massively Parallel Processing (MPP) supercomputer from Cray Inc. The design for the Cray XT3 is based on the Red Storm supercomputing system which was designed in cooperation with Sandia National Laboratory (Sandia). The system was announced in November of 2004. Subsequent products have included the Cray XT4, Cray XT5, and Cray XT6 supercomputers, each based on successive versions of AMD Opteron processor, but essentially retaining the basic Cray XT3 architecture. The Cray XT series of supercomputers has proven to be a very successful product line, selling over 1,500 cabinets in a 5-year period.

Discussion

In 2001, the U.S. Department of Energy's National Nuclear Security Administration (NNSA) set aside funding for Sandia to obtain a new high-end computational capability to address mission needs. Sandia sent

out a Request for Information; however, no existing architecture was able to satisfy the lab's scalability and cost requirements. Subsequently, a Request for Quotation was issued by Sandia. Two suppliers responded with proposals; however, neither was able to fully meet the requirements laid out in the proposed Statement of Work with existing or planned products.

The proposal from Cray indicated a willingness to custom engineer a supercomputer to meet Sandia's needs within the budgetary envelope which was approximately \$90M. The project would require a custom ASIC, custom packaging and cooling, a custom classified/unclassified interconnect switch (known as the "red-black" switch), a custom hardware supervisory system (HSS), and a custom software stack. Despite this, the Red Storm project was completed and delivered in only 30 months. Concurrently, with this initial delivery, Cray launched the Cray XT3 supercomputer in November of 2004 in Pittsburgh, PA, at the SC2004 conference.

Architecture

The Cray XT3 system is a massively parallel system consisting of two types of nodes, grouped into two partitions, respectively:

- Compute nodes run application programs. All compute nodes run a Cray XT3 light weight kernel.
- Service nodes handle support functions such as login management, I/O, and network management. All service nodes run a full Linux-based Cray XT3 operating system.

The nodes are tightly coupled with an interconnection network that supports fast MPI traffic, as well as a fast I/O to a global, shared-file system. The interconnection network is based on a 3-D torus topology that combines HyperTransport and proprietary protocols. The Cray SeaStar chip on each node functions as the router chip. It has seven bidirectional ports, six for the 3-D interconnection network and one for the HyperTransport link to the node's processor. [Figure 1](#) shows the basic architecture of a Cray XT3 system.

Each Cray XT3 system also includes a Cray RAS and Management System (CRMS). The CRMS includes a System Management Workstation (SMW), which functions as the administrator's single-point interface for

booting, monitoring, and managing Cray XT3 system components. The SMW communicates with all nodes and RAID disk controllers via a private Ethernet network.

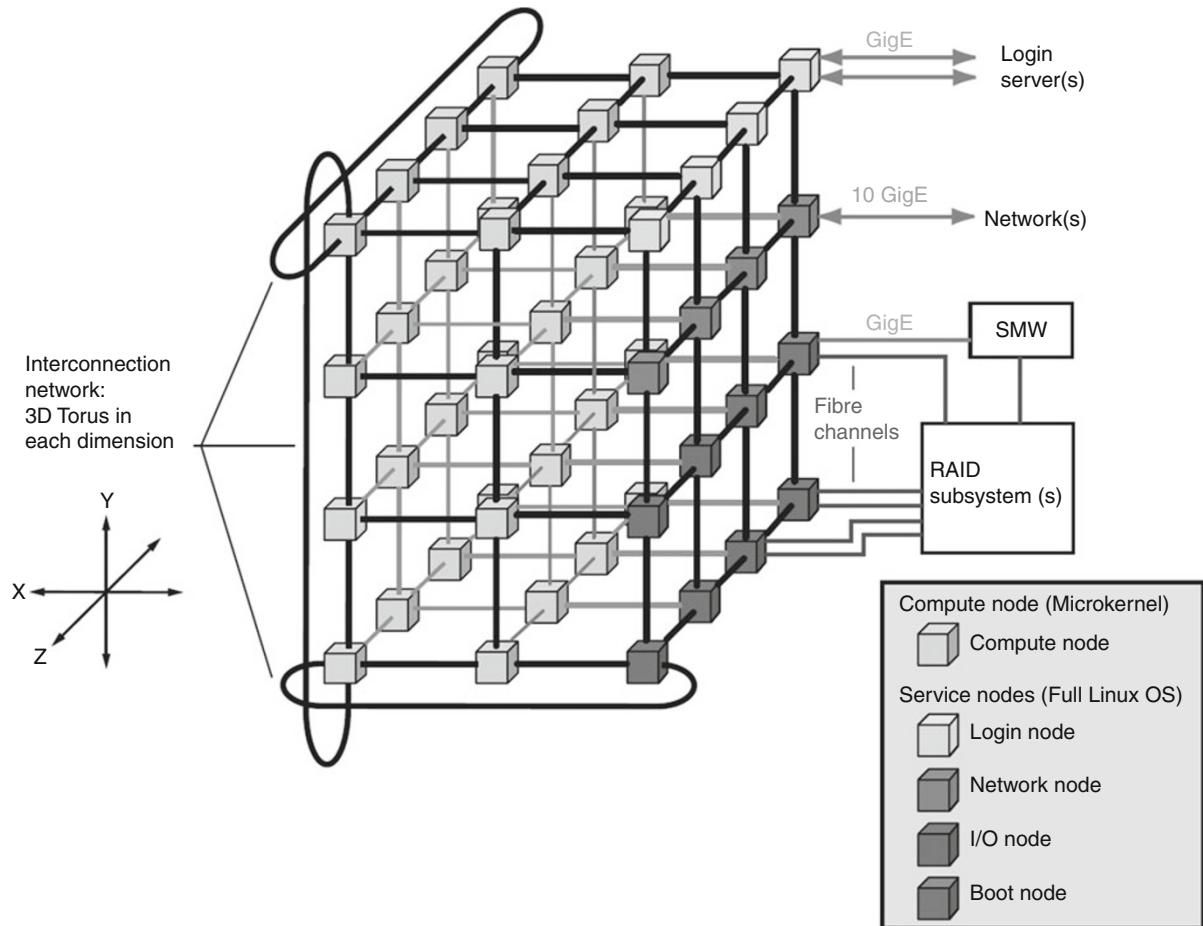

Processor

The AMD OpteronTM processor was selected for the Red Storm project. There were several reasons for this:

1. The processor featured an open, high-speed interface called HyperTransportTM. This would allow the processor to be tightly integrated with a custom high-performance interconnect chip. Because HyperTransport was an open interface, there was extensive third-party IP available. This would serve to reduce risk and development time for the interconnect ASIC.
2. The processor is *fully compatible* with the X86 processor architecture. This ensured compatibility with a vast quantity of existing software, including compilers, libraries, and applications. This would serve to reduce risk associated with operating system and application software.
3. The processor featured extensions to the X86 architecture specified by AMD allowing applications to use 64-bit addressing. This mode is called X86-64. Applications can be ported to 64-bit mode, yet full compatibility and performance is retained with 32-bit applications. Intel ultimately followed this convention, ensuring its market relevance for the long term.
4. The AMD Opteron pulled the function of the Northbridge chip onto the processor die itself. In particular, the memory controller is on the Opteron itself. This resulted in a very low-latency interface to memory (~51 ns) and a dedicated high-bandwidth interface for each processor (6.4 GB/s).
5. Since the Northbridge is in the Opteron itself, there is considerable savings in components (one integrated circuit per node) and power (approximately 11 W/node) since no separate Northbridge chips would be necessary. This served to reduce component count and increases reliability.

Node Memory

Each node has four slots for memory DIMMs. These slots provide 1–16 GB of local memory for the node.

Cray XT3 and Cray XT Series of Supercomputers. Fig. 1 Cray XT3 system architecture

Each DIMM has 72 bits: 64 data bits and 8 error-correcting code (ECC) bits.

Memory is protected using single-symbol correction/ double-symbol detection (SSC/DSD) enhanced ECC. This enhanced ECC can detect and correct single-symbol errors, or can detect two-symbol errors, but cannot correct them.

Compute Node

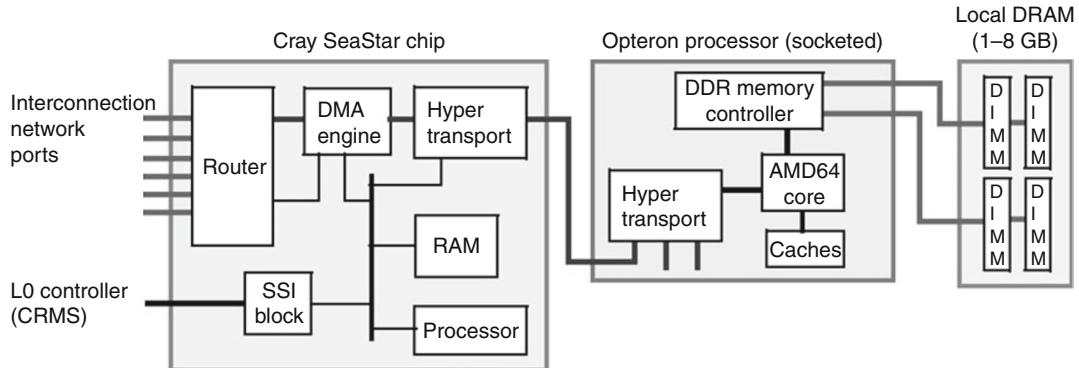

Figure 2 shows a block diagram of a Cray XT3 compute node. Each compute node consists of one processor socket populated with minimum of a 2.0 GHz single-core AMD Opteron processor, four DIMM slots which provide 1–8 GB local memory, a Cray SeaStar chip that connects the processor to the high-speed interconnection network, and an L0 controller (also referred to

as blade control processor) interface which is used for system management.

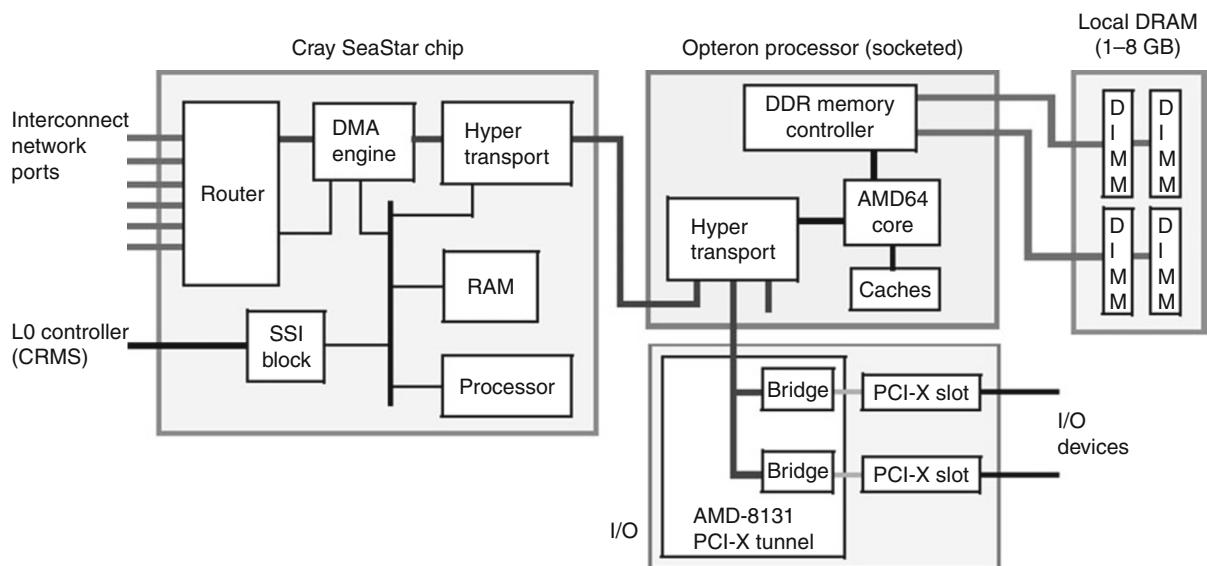

Service Nodes

Figure 3 shows the architecture of a service node. Service nodes use the same processors, memory, and SeaStar chips as compute nodes. In addition to these components, the service node has an AMD-8131 HyperTransport PCI-X tunnel chip that drives two PCI-X slots. Each slot is on its own independent 64-bit/133 MHz PCI-X bus. PCI-X cards plug into the PCI-X slots and interface to external I/O devices. Later versions of the Cray XT series implemented PCI-Express slots on these nodes.

Each Cray XT3 system includes several types of service nodes. Each type performs dedicated function

Cray XT3 and Cray XT Series of Supercomputers. Fig. 2 Compute node architecture

Cray XT3 and Cray XT Series of Supercomputers. Fig. 3 Service node architecture

and requires a minimum of one PCI-X card. The types include:

- *Login Node*: Users login into the system via login nodes. Each login node includes one or two single-port Gigabit Ethernet PCI-X card that connects to a user workstation. Copper and fiber cards are available.
- *Network Service Node*: Each Network service node contains one 10 Gigabit Ethernet PCI-X card that can be connected to customer network storage devices.
- *I/O Node*: Each I/O node contains one or two dual-port Fibre Channel (FC) Host Bus Adapter (HBA)

card. The Fibre Channel ports connect to the system's RAID storage.

- *Boot Node*: Each system requires one boot node. A boot node contains one FC HBA and one GigE PCI-X card. The FC HBA connects to the RAID and the GigE card connects to the System Management Workstation of the CRMS.

Interconnection Network

The Cray XT3 system uses its interconnection network to link nodes in a 3D torus topology and to facilitate the system's high-communication bandwidth. Physically, this network includes the Cray SeaStar routers (the heart of the network), router ports, and cables.

Key performance data for the interconnection network are:

- A bidirectional injection bandwidth of more than 2 GB/s per direction. This is the bandwidth from the processor core into the SeaStar router.
- A sustainable bandwidth of 6.5 GB/s for each of the six directions of the torus. The SeaStar router supports an aggregate bandwidth of almost 40 GB/s.
- An MPI latency of less than 7 μ s between a processor pair.

This Cray SeaStar network allows efficient MPI messaging and also high-sustainable bandwidth to the Object Storage Servers (OSS) driving the disks systems for the global Lustre filesystem.

A Cray SeaStar chip a HyperTransport connection to the node's AMD processor – its six ports connect the 3D torus. The X, Y, and Z dimensions use two ports each. The network uses a Cray proprietary protocol.

Network connections are made three ways: within the blade, on a backplane that the blades plug into, and with groups of network cables. The network cables can be configured in multiple ways to create various topologies based on system size.

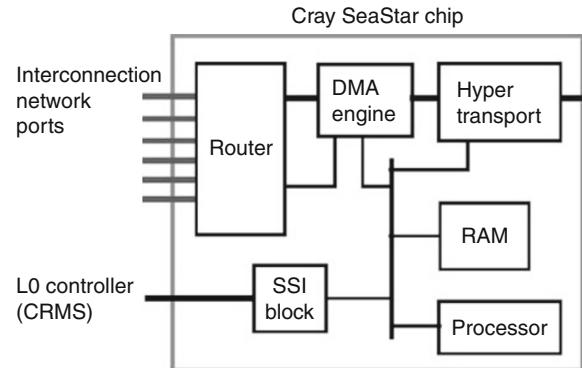

Configuration tables are used for data flow mapping across the interconnection network. These tables are loaded at system boot time. They can also be reloaded to reconfigure the interconnection network following a hardware failure.

Cray SeaStar Chip

There is one Cray SeaStar chip for each Opteron processor in the system. The chip connects the Opteron processor to the 3D interconnection network. It offloads all send/receive work so that compute work is not interrupted. Here is a block diagram of the SeaStar chip ([Fig. 4](#)):

The SeaStar chip is a system-on-chip design that combines third-party hardware components and interface definitions with Cray custom logic and functionality. It contains the following major blocks:

- A HyperTransport interface provides a bidirectional link between the Opteron processor and the SeaStar chip. The HyperTransport Link has a maximum data

Cray XT3 and Cray XT Series of Supercomputers.

Fig. 4 Cray SeaStar chip

transfer rate of 3.2 GB/s in each direction between the Opteron processor and the SeaStar chip.

- A custom router that enables the Opteron to communicate with other nodes via the interconnection network. The router has six ports that connect to the interconnection network. The peak bidirectional bandwidth of each port is 7.6 GB/s, with a measured sustained bandwidth of 6.5 GB/s.
- A communication interface that consists of a Direct Memory Access (DMA) engine, on-chip processor, and on-chip RAM connected to a local bus. These components function as a message processor that route send/receive data packets to their appropriate destination.
- A synchronous serial interface (SSI) that connects the module controller (known as the L0) to the internal SeaStar local bus. This connection allows the L0 controller access to the Opteron memory and status registers. The L0 controller is part of the CRMS, which is used for booting, maintenance, and monitoring the Cray XT3 system.

In order to achieve the lowest possible system latency, it is necessary to provide a path directly from the application to the communication hardware without the time-consuming traps and interrupts associated with traversing a protected operating system kernel. The SeaStar chip uses the Portals interface to provide this path.

More information about the Cray SeaStar interconnection network is available in the entry on [▶Cray XT4 and Seastar 3-D Torus Interconnect](#).

Packaging

Cray XT3 Compute Cabinet

Each compute cabinet contains three module chassis as follows:

- Each chassis is populated with any combination of eight blades (compute or service).
 - A compute blade contains four compute nodes, including providing four Opteron processors, up to 16 GB of DIMM memory per processor, and four SeaStar chips. A single compute cabinet can hold up to 96 compute nodes.
 - A service blade consists of two service nodes, including two Opteron processors and 2–16 GB of memory per blade, depending on the functions of the service nodes. The blade has four SeaStar chips to allow for a common board design and to simplify primary interconnect configurations. Some service blades also contain PCI-X slots for external connections. A single compute cabinet can hold up to 48 service nodes.
- The cabinet contains all power and cooling equipment for these blades; no external equipment is required.
- Each cabinet is air-cooled. A single blower assembly, located toward the front, below the cages, air cools all components within the cabinet. The blower pulls underfloor air into the cabinet and forces air vertically through the three chassis. Warm air exhausts through the top of the cabinet. A blower speed controller varies the speed of the blower to maintain the correct air pressure and temperature.

Ethernet switches and the cabinet controller (known as the L1 controller) are located at the rear of the cabinet. These components are part of the CRMS.

The following figure shows the component locations of a compute cabinet. A single mechanical assembly contains three identical chassis that house blades. Blades plug into the front of the chassis. Each chassis has a backplane assembly at the back ([Fig. 5](#)).

Software

Cray XT3 system software is based on software from the Sandia Red Storm project, plus the addition of commercially available tools and features. This creates a system

that, to the application programmer, is an optimized parallel processing machine and, to the system administrator, features a single boot image and a single root file system.

The software allows programmers to optimize applications that have fine-grain synchronization requirements, large-scale processor counts, and significant communication requirements.

Cray XT3 system software falls into four major areas:

- Operating system
- File system
- Programming Environment
- RAS Management System software

Cray XT3 Operating Systems

The Cray XT3 operating system functions fall into three categories, identified by the role of the components on which they run:

1. Service nodes run the full Linux Cray XT3 operating system.
2. Compute nodes run a Light Weight Kernel called *Catamount*.
3. CRMS components (the L0 and L1 controllers) run an embedded real-time Linux kernel.

SuSE Linux Operating System

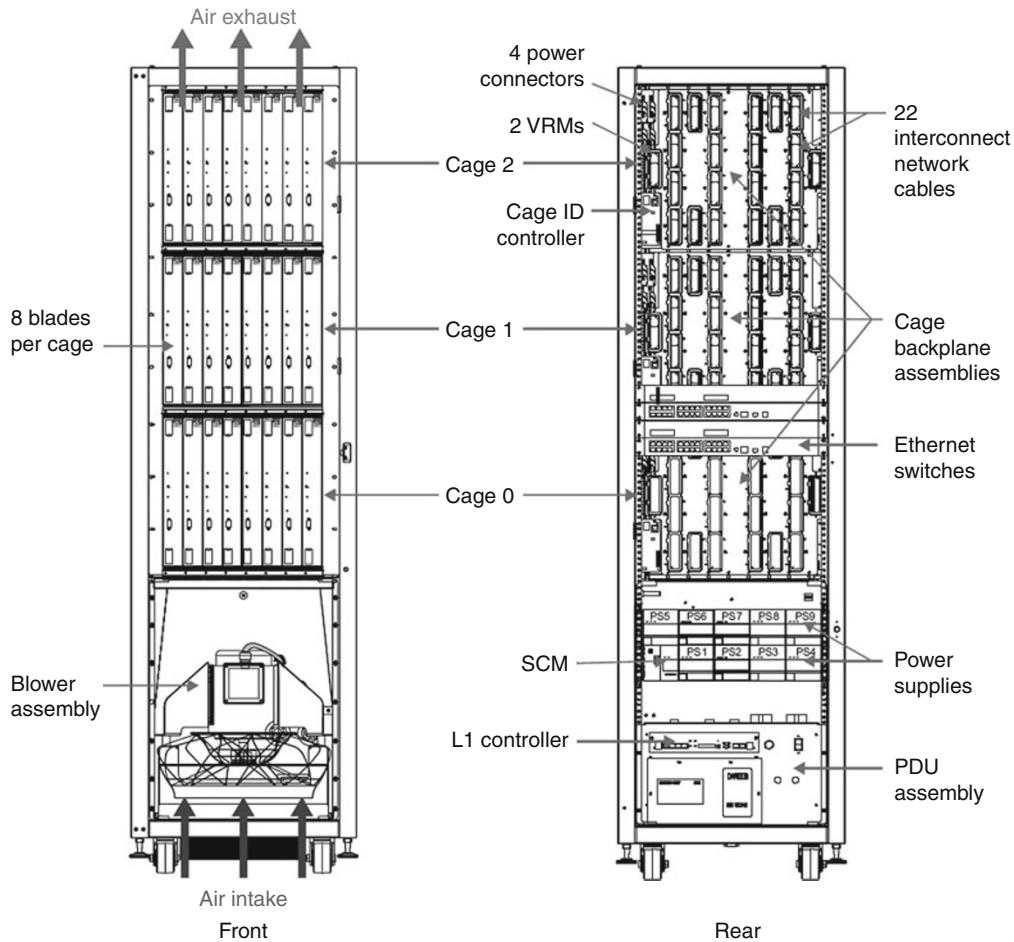

Cray XT3 system service nodes run a full, Linux-operating system based upon SuSE Enterprise Server 8.2. This was later upgraded to SuSE Enterprise Server release 9.0 in 3Q2005 ([Fig. 6](#)).

The operating system supports six types of service nodes:

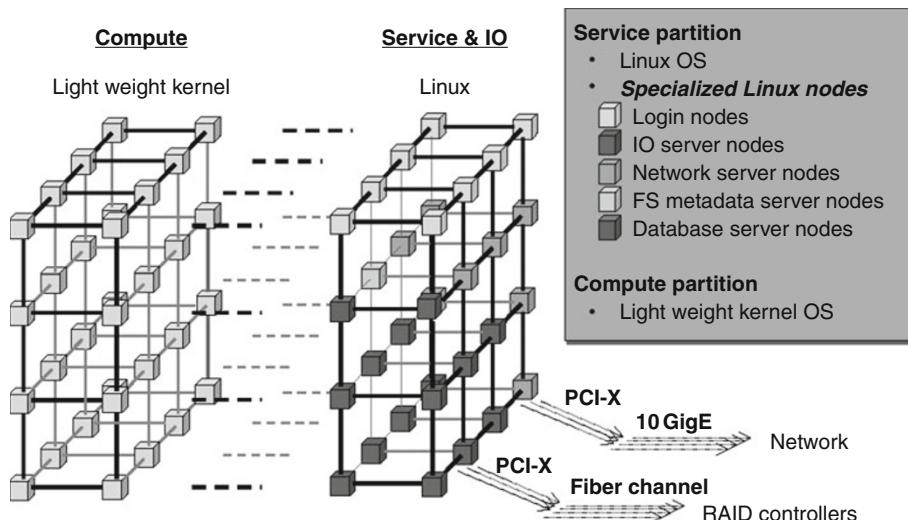

- Login Nodes
- I/O Server Nodes
- Network Server Nodes
- File System metadata Server Nodes
- Database Server (Admin) Nodes
- Boot Nodes

SuSE Linux Overview

With SuSE Linux, the Cray XT3 system provides users with all standard Linux interfaces and working environments. SuSE Linux was selected for the Cray XT3 operating system for a number of reasons:

Cray XT3 and Cray XT Series of Supercomputers. Fig. 5 Compute cabinet

Cray XT3 and Cray XT Series of Supercomputers. Fig. 6 Node functions

- *Open Source.* The availability of source code for the operating system allows it to be customized. This is not possible with proprietary operating systems.
- *Widely Supported.* Several vendors provide Linux support, in addition to the legion of programmers who are constantly enhancing the operating system.
- *Familiar to Users.* Many HPC users develop codes on Linux desktops. Most users are more comfortable with this familiar operating system than they would be with a proprietary solution.
- *64-bit aware.* At the time, it was chosen for the Cray XT3 system, SuSE was one of few companies actively targeting the 64-bit market place. SuSE software was already ported to the AMD Opteron architecture, so its close-working relationship with AMD made it the obvious choice.
- *Cooperation.* SuSE worked with Cray to further the development of SuSE Linux into the High-Performance Market Place.

Single System View (SSV)

The Cray XT3 system presents a Single System View (SSV) to users and system administrators. The following list of SSV features is provided:

- *Single point of Administration:* An administrator can perform system administration tasks from the system boot node, without needing to log into additional nodes. Any administrative file in the machine can be modified from the root node.
- *Global file space:* User home directories and data directories are visible across the entire machine and may be accessed from anywhere using the same path.
- *Single user process space:* All user processes on the system are visible from any node. Each has a unique PID and can be signaled from any node.

Lightweight Kernel (LWK)

Because the Cray XT3 system was designed to scale to very large processor counts, it runs a computational environment that has very little system overhead, using a lightweight kernel (LWK) named *Catamount*. This LWK, developed jointly with Sandia National Laboratories, is a small, low-complexity OS that manages access to the physical node resources and infrastructure

for application execution, yet keeps system overhead at a minimum. It provides virtual memory addressing, physical memory allocation, memory protection, access to a high-performance message-passing layer, and a scalable job loader. While parallel jobs retain an agent (*yod*) on the login node that launched them, actual computation runs under the LWK on the compute nodes. And, as compute regions do not need to run standard Linux daemons, all standard requests are executed from the service partition. This significantly reduces to the LWK, and more compute cycles are reserved to the user. The ultimate benefit is that parallel jobs run in shorter times.

Some system calls are handled by the LWK, others are forwarded either to the *yod* agent running on the login node, or directly to I/O nodes for services that require a high degree of concurrency. The Catamount LWK is made up of two parts: the quintessential kernel (QK) and the Process Control Thread (PCT).

QK – The Quintessential Kernel

The QK provides an operating system kernel for the compute nodes that is resilient and scalable with minimal system overhead.

Resilient: Its simple design provides only essential functions required to run applications, much less than a full OS. It has been designed, tested, and evolved over two generations of MPPs.

Scalable: The QK design eliminates synchronization or communication between QK's on different nodes. This independence allows the system to scale to thousands of processors. Performance is achieved by using a simple and minimal system protocol that minimizes overhead for invoking kernel functions. Except for PCT, there are no processes or daemons that can interrupt programs and degrade performance of tightly coupled applications.

Process Control Thread (PCT)

On top of QK, a special user-level process, the Process Control Thread (PCT), performs services on behalf of application processes. Its primary responsibility is to start user applications, track them, schedule them, and relay completion and signal information between the application and *yod*.

LWK and Message Passing

The native messaging protocol for the Cray XT3 system is Portals version 3.3. It is a low-latency, low-overhead protocol, ideal for scalable, high-performance network communications. It is connectionless (i.e., it does not stay connected across consecutive communications), so the amount of system RAM memory used to provide buffers for message passing is independent of both the number of compute nodes in the system and the number of compute nodes assigned to a particular job.

The LWK is designed to support a high-performance MPI implementation. It lays applications out in memory in a linear fashion so that virtual memory can be mapped to real memory in a relatively simple offset scheme. As a result, Portals entries can span large chunks of real memory, and it is possible to map *all* memory using the available Portals table entries in the Cray SeaStar chip.

Kernels on the compute nodes and on the service nodes implement the Portals communication primitives. The Cray Seastar chip includes firmware that offloads the Portals message-passing overhead from the Opteron processor. At the user level, application processes communicate with one another by linking libraries that support the Portals interface.

Programming Environment

The Cray XT3 Programming Environment provides comprehensive support for 64-bit application development under an MPI model. It includes the following:

- Compilers
- Application libraries
- Application and system state monitors
- Application launch utilities
- Debugger
- Performance API
- Modules utility

Single Copies of Tools

On the Cray XT3 System, a single instance of each programming environment tool (compilers, debuggers, and so on) can be accessed from any login nodes on the system as if it were loaded on a disk connected to that node. Likewise, the Lustre file system provides a consistent view from anywhere within the system so that any

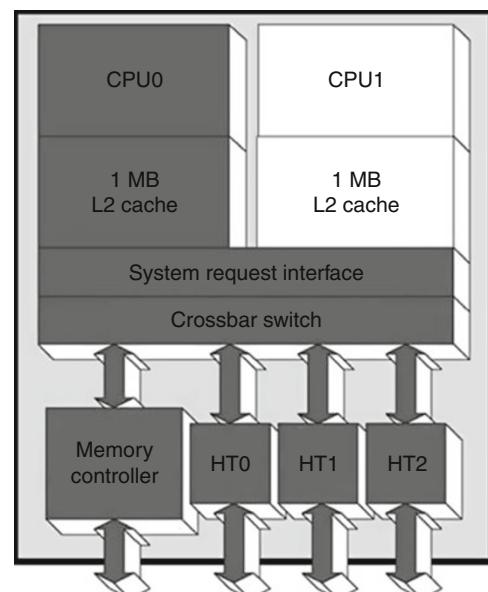

files that are required for program execution will have an identical path name no matter where the job is run.

Product Enhancements

XT3 Dual Core

The peak performance of Cray XT3 systems was significantly increased with the introduction of AMD Opteron dual-core processors. The AMD Opteron dual-core design increases application performance without having to redesign the socket or board.

[Figure 7](#) depicts the processor die with two CPU cores, each core having 1 MB L2 cache. The caches in some sense are shared in case one CPU sees a cache miss for its associated cache. The data however are available in the other CPU's cache, so it is directly loaded from there through the System Request Interface (SRI). The AMD Opteron was designed to add a second core, with a port already existing on the crossbar/SRI. The dual-core drops into existing AMD Opteron AM2 sockets, thus also enabling upgrades of single-core systems. The two CPU cores share the same memory and HT resources found in single core. The integrated memory controller and HT links route out the same as today's

Cray XT3 and Cray XT Series of Supercomputers.

Fig. 7 Interface for second processor in the AMD opteron dual core design

implementation. Almost all of Cray's initial single-core Cray XT3 customers took advantage of this upgrade.

Cray Linux Environment

The original operating system for the Cray XT3 was based on SuSE Linux for the Service Nodes and Catamount for the Compute Nodes. With quad-core processors coming, Cray needed a more full-featured OS on the compute node but needed to retain the scalability properties of Catamount. Cray transitioned to an operating system for Cray XT systems called the Cray Linux Environment (CLE) that is Linux based throughout.

Cray Linux Environment (CLE) uses a lightweight kernel operating system for compute nodes. The lightweight kernel includes a runtime environment based on the SUSE SLES distribution. It provides outstanding performance and scaling characteristics, matching the performance seen on the Catamount software stack.

CLE on Compute Nodes offers the full functionality of a Linux kernel, including:

- POSIX system calls (as supported by SUSE Linux kernel)
- Programming models, including OpenMP, MPI (version 2.0, based on MPICH), Cray SHMEM, and CAF. (*Note: Other programming models work as well. These include Global Arrays (the communication layer used by NWChem) and Charm++ (used by NAMD). Cray does not distribute this software but interacts closely with its developers (PNNL and the University of Illinois respectively) to make sure they work on the Cray XT systems.*)
- Application networking (Sockets)
- POSIX threads

PCI-Express SIO Blades

To improve the performance of Service and I/O Nodes (SIO) on Cray XT systems Cray transitioned from PCI-X to PCIe interfaces. The following figure shows the architecture of a Cray XT dual-core service node. Service nodes use an AMD Opteron dual-core processor, but the same DDR memory and interconnect SeaStar2 processors as compute nodes. In addition to these components, the service node has Broadcom HT-2100 HyperTransport PCIe tunnel chip that drives two PCIe slots.

The Broadcom HT-2100 modular bay on which the tunnel chip is mounted provides two PCIe slots for cards to interface to external I/O devices:

- a 16x PCIe slot provides 4 GB/s full duplex communication
- an 8x PCIe slot provides 2 GB/s full duplex communication

Each PCIe slot has independent buffers and shares (fairly) the bandwidth back to the attached Opteron. The HT-2100 HyperTransport PCIe tunnel chip is connected to the dual-core Opteron via a 4-GB/s HT2 link (Fig. 8).

Follow on Products

Cray XT4

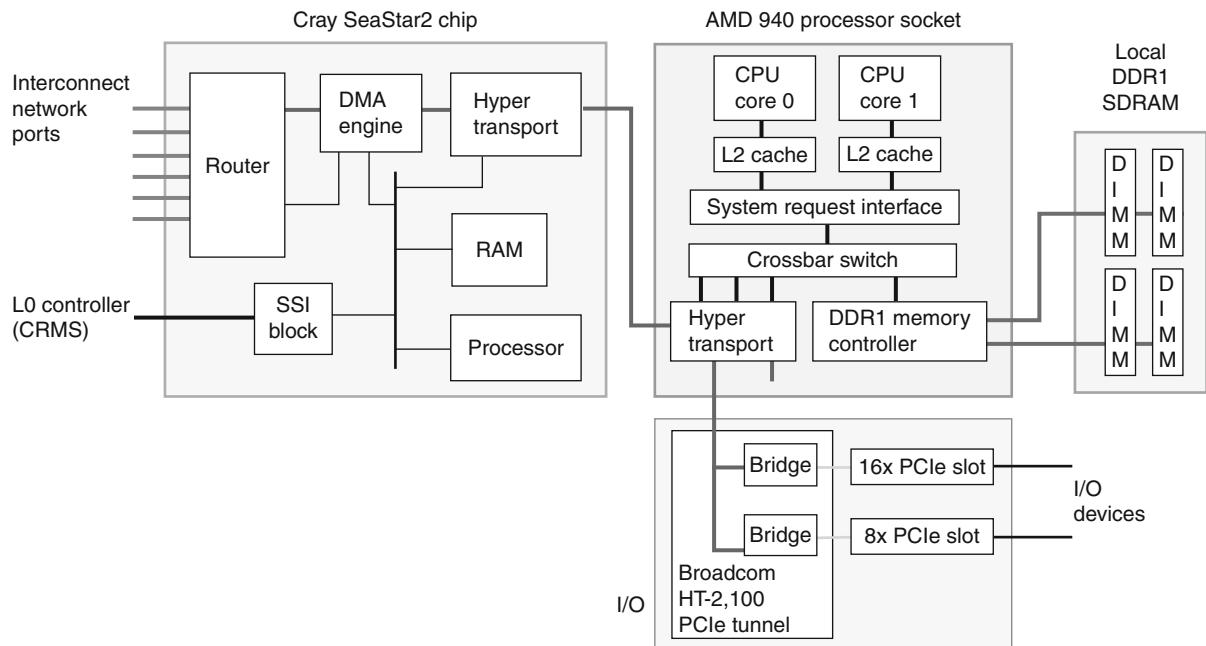

The Cray XT4 represented the second system in the Cray XT line of supercomputers. A new compute blade was designed to accommodate the new processors from AMD and the rest of the Cray XT3 system (service blades, boot infrastructure, software stack, cabinets, backplanes, power supplies, etc.) was retained. The network router chip, SeaStar, was enhanced and renamed SeaStar2. The Cray XT4 provided a significant performance increase over the Cray XT3 system in the same floor space. Initial Cray XT4 systems shipped with dual core AMD Opteron processors and DDR2 memory.

Later enhancements of the Cray XT4 compute nodes include the use of Quad-Core AMD Opteron processors. These processors were also capable of four floating-point results per cycle per processor core which provided a large increase in peak performance. Service and I/O nodes (SIO) were upgraded to dual-core AMD Opteron processors. Cray XT3 customers could upgrade to the Cray XT4 system by simply replacing compute blades.

The largest Cray XT4 system installed is “Franklin,” a 102-cabinet system installed at the National Energy Research Scientific Computing center (NERSC).

Cray XT5

The Cray XT5 provided another significant improvement in performance over the previous generation Cray XT4. The processor technology for the Cray XT5 included the quad-core “Barcelona” and “Shanghai” processors from AMD, and also the Six-Core “Istanbul”

Cray XT3 and Cray XT Series of Supercomputers. Fig. 8 Cray XT service node architecture (PCIe interface)

processor. A significant change from the Cray XT3 and Cray XT4, the Cray XT5 system packed four dual-socket nodes on a single compute blade. The form-factor for the compute blade was retained resulting in an overall doubling of compute density. Each system cabinet contains up to 192 AMD Opteron processors.

The system cabinet was enhanced to accommodate the increase in power and density. The backplane was designed to handle higher current and an enhanced power supply and blower system was designed to power and cool the system.

The compute node on the Cray XT5 system is either 8 or 12-core, depending on the Opteron used. The interconnect router chip was also improved for the Cray XT5. The new SeaStar2+ chip yields higher bandwidth and lower latencies than previous generation SeaStar and SeaStar2 routers.

The service blades and service infrastructure of the Cray XT5 was retained from the Cray XT4 system.

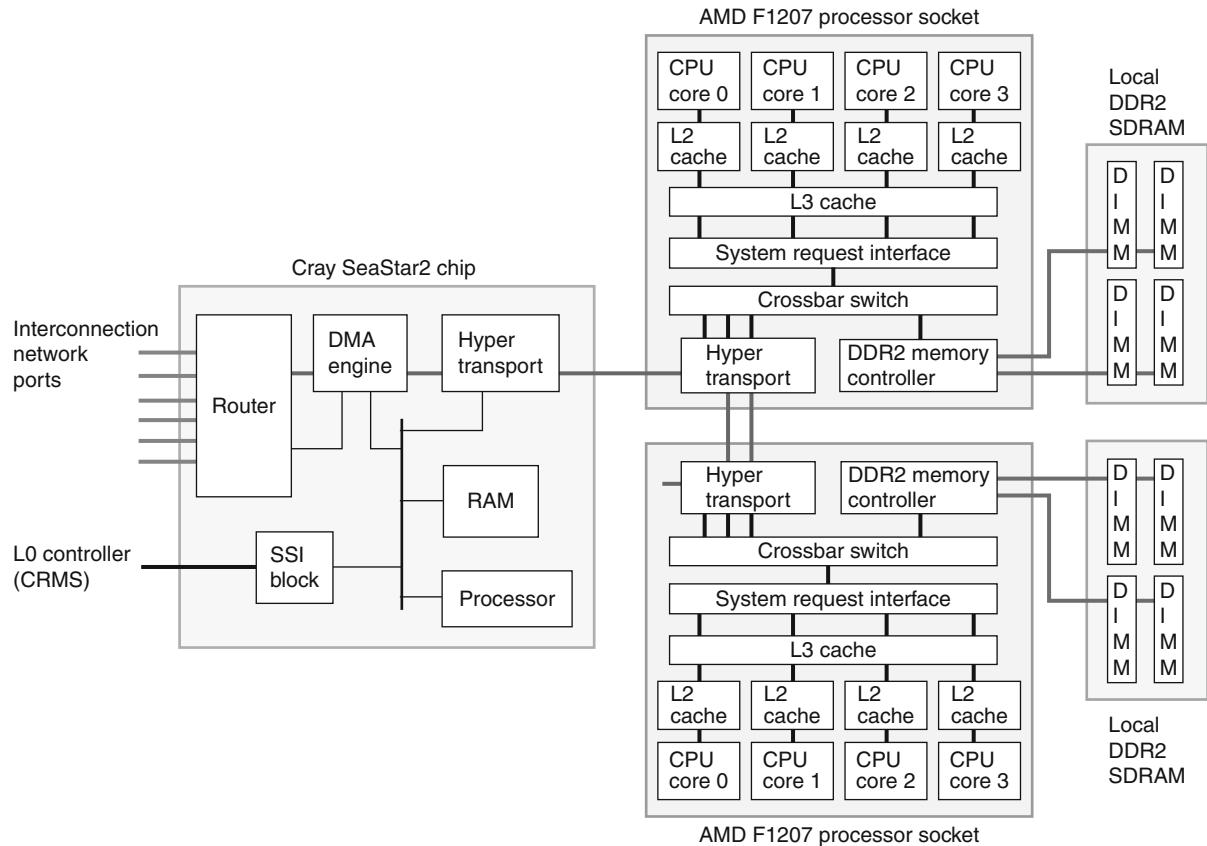

The following figure shows a block diagram of a Cray XT5 compute node. Each compute node consists of two processor sockets populated with AMD Opteron quad-core (or six-core) processors, eight DIMM slots, a Cray SeaStar2 ASIC that connects one processor to the high-speed interconnection network, and an L0 controller

interface used for system management and coherent HyperTransport connections between the two Opteron sockets. With the quad-core sockets, this provides an eight-way NUMA shared memory node (Fig. 9).

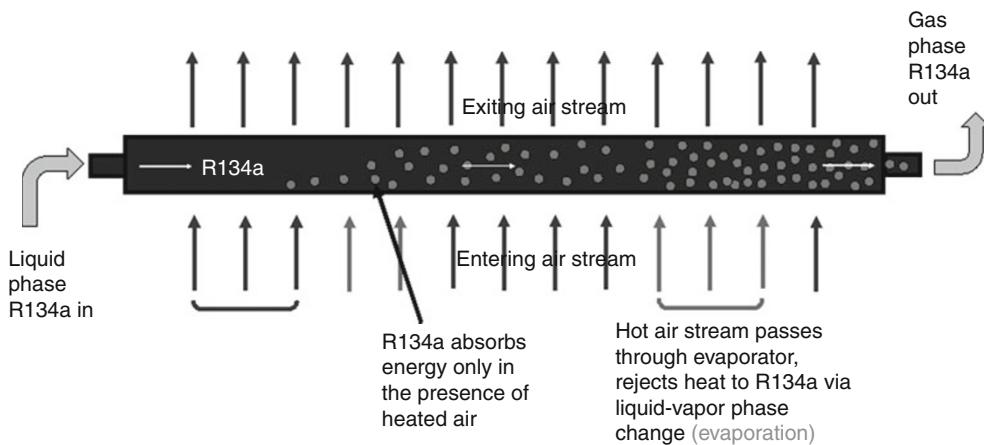

Cray ECOphlex Cooling

The Cray XT5 also introduced a new phase-change heat-removal system known as “Cray ECOphlex” cooling. Unlike traditional water cooling solutions available in the market, the heat generated by the compute blades is rejected to a fluid refrigerant – the R134a – via a liquid-vapor phase change (evaporation) as illustrated in the figure below. The bottom-to-top airflow on the Cray XT5 results in a limited surface area that can be used for heat removal at the top of the system cabinets. Since phase-change cooling is about an order-of-magnitude more effective per unit area compared with traditional water coils, it represented an ideal match for the Cray XT5 system (Fig. 10).

The Cray ECOphlex system includes one or more Heat Exchange Units (HEU, also known as XDP). This HEU is connected to the building water circuit, and its purpose is to recondense the R134a which runs in a closed loop between the evaporators in each system cabinet and the condenser coil in the HEU. A single

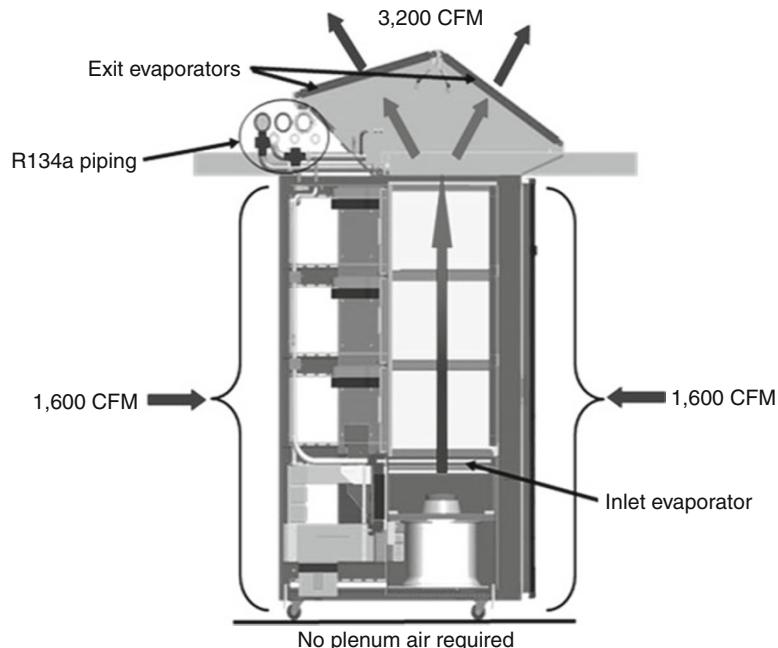

Cray XT3 and Cray XT Series of Supercomputers. Fig. 9 Cray XT5 compute node architecture (2 processors)

Cray XT3 and Cray XT Series of Supercomputers. Fig. 10 Liquid-vapor phase change

blower located in the bottom of each system cabinet is used to move air over the system blades. The blower pulls computer room air into the cabinet and forces air through the three chassis and ultimately through the

R134a evaporators. A blower speed controller varies the speed of the blower to maintain the correct air pressure and temperature and control logic within the XDP ensures that R134a is never below the dew point.

Cray XT3 and Cray XT Series of Supercomputers. Fig. 11 Schematic of Cray XT5 cabinet with ECOphlex cooling

Additionally, this liquid cooling allows customers to potentially dramatically reduce yearly cooling costs by leveraging the “Free Cooling” concept. The concept of “Free Cooling” is taking advantage of cool outdoor air to help save energy in data center chilled-water cooling systems.

In a data center facility, a typical mechanically generated chilled water system consists of the following equipment that uses electrical energy:

- Water chiller
- Computer room air-conditioning units
- Chilled water pumps
- Condenser water pumps
- Cooling tower fans

The water chiller is by far the biggest energy user (approximately 60%) in a chilled water system. If the water chiller’s compressor(s) can be shut down during cool weather, the outside ambient temperature can be used to help save energy in the chilled water system. The Cray XDP cooling system can operate with a higher chilled water set point temperature than a typical computer room air-conditioning unit. Thus, it is possible to bypass the chiller more with ECOphlex cooling compared to traditional air-cooling.

A traditional approach to free cooling is an indoor, water-cooled chiller connected to an outdoor closed-loop cooling tower. Typically, automatic valves and crossover piping are employed to bypass the chiller during when outside conditions are suitable.

An additional benefit of free cooling is extending the useful life of the water chiller by reducing its operating hours (Fig. 11).

The largest Cray XT5 system delivered is the 200 cabinet system at Oak Ridge National Laboratory, known as “Jaguar.” Jaguar holds the distinction of being the fastest system in the world as of November of 2009 (Fig. 12).

Cray XT6

Cray introduced the Cray XT6 in March of 2010. The Cray XT6 provided several major enhancements over the previous generation Cray XT5.

1. The Cray XT6 Compute Node uses two socket G34 (45 nm technology) AMD “Magny Cours” processors with eight or twelve cores per socket. Compute nodes on the Cray XT6 use two processors and hence have 16 or 24 cores per node.

Cray XT3 and Cray XT Series of Supercomputers. Fig. 12 200 cabinet ORNL Jaguar system with Cray ECOphlex cooling

2. The Cray XT6 Compute Node memory uses DDR3 technology rather than the DDR2 memory of previous generation Cray XT systems.
3. A new system cabinet was developed (the Series-6 cabinet). Enhancements included a more efficient ECOphlex evaporator design, a new system blower, and an enhanced power distribution system.
4. The Cray Linux Environment 3 (CLE3). This version of the system software includes a “Cluster Compatibility Mode” which allows users to install and run Independent Software Vendor (ISV) packages with no changes. CLE3 retained the “Extreme Scalable Mode” as the default OS image for native applications. A user can select either partition at job submittal time.

Shipments of the Cray XT6 started in the first half of 2010. At the time of this writing, the largest Cray XT6 system is installed at HECToR, the United Kingdom’s National Supercomputer Service. This system has over 44,000 processor cores.

Definition

The Cray XT4 system is a distributed memory multi-processor combining an aggressive superscalar processor (AMD64) with a bandwidth-rich 3-D torus interconnection network that scales up to 32K processing nodes. This chapter provides an overview of the Cray XT4 system architecture and a detailed discussion of its interconnection network.

Discussion

The physical sciences are increasingly turning toward computational techniques as an alternative to the traditional “wet lab” or destructive testing environments for experimentation. In particular, computational sciences can be used to *scale* far beyond that of traditional experimental methodologies; opening the door to large-scale climatology and molecular dynamics, for example, which encompass enough detail to accurately

model the dominant terms that characterize the physical phenomena being studied [2]. These large-scale applications require careful orchestration among cooperating processors to ply these computational techniques effectively.

The genesis of the Cray XT4 system was the collaborative design and deployment of the Sandia “Red Storm” computer that provided the computational power necessary to assure safeguards under the nuclear Stockpile Stewardship Program which seeks to maintain and verify a nuclear weapons arsenal without the use of testing. It was later renamed the Cray XT3 and sold commercially in configurations varying from hundreds of processors, to tens of thousands of processors. An improved processor, faster processor–network interface, along with further optimizations to the software stack and migrating to a lightweight Linux kernel prompted the introduction of the Cray XT4; however, the underlying system architecture and interconnection network remained unchanged.

System Overview

The Cray XT4 system scales up to 32k nodes using a bidirectional 3-D torus interconnection network. Each *node* in the system consists of an AMD64 superscalar processor connected to a Cray SeaStar chip [5] (Fig. 1) which provides the processor–network interface, and six-ported router for interconnecting the nodes. The system supports an efficient distributed memory message passing programming model. The underlying message transport is handled by the Portals [3] messaging interface.

This chapter focuses on the Cray XT interconnection network that has several key features that set it apart from other networks:

- Scales up to 32K network endpoints
- High injection bandwidth using HyperTransport (HT) links directly to the network interface
- Reliable link-level packet delivery
- Multiple virtual channels for both deadlock avoidance and performance isolation
- Age-based arbitration to provide fair access to network resources

Subsequent sections cover these topics in more detail.

There are two types of nodes in the Cray XT system. Endpoints (nodes) in the system are either

compute or system and IO (SIO) nodes. SIO nodes are where users login to the system and compile/launch applications.

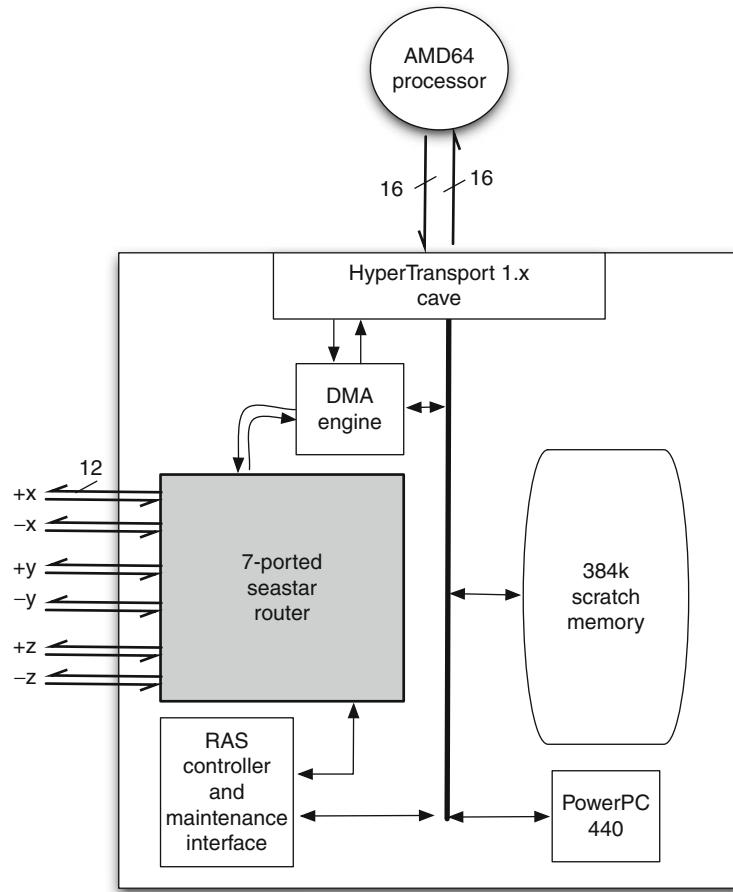

Topology

The Cray XT interconnect can be configured as either a *k*-ary *n*-mesh or *k*-ary *n*-cube (torus) topology. As a torus, the system is implemented as a *folded* torus to reduce the cable length of the wrap around link. The seven-ported SeaStar router provides a processor port, and six network ports corresponding to $+x$, $-x$, $+y$, $-y$, $+z$, and $-z$ directions. The port assignment for network links is not fixed, any port can correspond to any of the six directions. The noncoherent HyperTransport (HT) protocol provides a low latency, point-to-point channel used to drive the Seastar network interface.

Four virtual channels are used to provide point-to-point flow control and deadlock avoidance. Using virtual channels avoids unnecessary head-of-line (HoL) blocking for different network traffic flows; however, the extent to which virtual channels improve network utilization depends on the distribution of packets among the virtual channels.

Routing

The routing rules for the Cray XT are subject to several constraints. Foremost, the network must provide error-free transmission of each packet from the *source* node identifier (NID) to the *destination*. To accomplish this, the distributed *table-driven* routing algorithm is implemented with a dedicated *routing table* at each input port that is used to look up the destination port and virtual channel of the incoming packet. The lookup table at each input port is not sized to cover the maximum 32K node network since most systems will be much smaller, only a few thousand nodes. Instead, a hierarchical routing scheme divides the node name space into *global* and *local* regions. The upper three bits of the destination field (given by the destination[14:12] in the packet header) of the incoming packet are compared to the global partition of the current SeaStar router. If the global partition does not match, then the packet is routed to the output port specified in the global lookup table (GLUT). The GLUT is indexed by destination[14:12] to choose one of eight global partitions. Once

Cray XT4 and Seastar 3-D Torus Interconnect. Fig. 1 High-level block diagram of the SeaStar interconnect chip

the packet arrives at the correct global region, it will precisely route within a local partition of 4,096 nodes given by the destination[11:0] field in the packet header.

The tables must be constructed to avoid deadlocks. Glass and Ni [9] describe *turn* cycles that can occur in k -ary n -cube networks. However, torus networks are also susceptible to deadlock that results from overlapping virtual channel dependencies (this only applies to k -ary n -cubes, where $k > 4$) as described by Dally and Seitz [7]. Additionally, the SeaStar router does not allow 180° turns within the network. The routing algorithm must both provide deadlock-freedom and achieve good performance on benign traffic. In a fault-free network, a straightforward dimension-ordered routing (DOR) algorithm will provide balanced traffic across the network links. Although, in practice, faulty links will occur and the routing algorithm must route around the bad

link in a way that preserves deadlock freedom and attempts to balance the load across the physical links. Furthermore, it is important to optimize the buffer space within the SeaStar router by balancing the number of packets within each virtual channel.

Avoiding Deadlock in the Presence of Faults and Turn Constraints

The routing algorithm rests upon a set of rules to prevent deadlock. In the turn model, a positive first ($x+, y+, z+$ then $x-, y-, z-$) rule prevents deadlock and allows some routing options to avoid faulty links or nodes. The global/local routing table adds an additional constraint for valid turns. Packets must be able to travel to their local area of the destination without the deadlock rule preventing free movement within the local area. In the Cray XT, network, the localities are split with yz planes.

To allow both $x+$ and $x-$ movement without restricting later directions, the deadlock avoidance rule is modified to $(x+, x-, y+, z+ \text{ then } y-, z-, z+ \text{ then } z+, z-)$. Thus, free movement is preserved. Note that missing or broken X links may induce a non-minimal route when a packet is routed via the global table (since only $y+$ and $z+$ are “safe”). With this rule, packets using the global table will prefer to move in the X direction, to get to their correct global region as quickly as possible. In the absence of any broken links, routes between compute nodes can be generated by moving in x dimension, then y, then z. Also, when $y = Y_{\max}$, it is permissible to dodge $y-$ then go $x+ / x-$. If the dimension is configured as a mesh – there are no $y+$ links, for example, anywhere at $y = Y_{\max}$ then a deadlock cycle is not possible.

In the presence of a faulty link, the deadlock avoidance strategy depends on the direction prescribed by dimension order routing for a given destination. In addition, toroidal networks add *dateline* restrictions. Once a dateline is crossed in a given dimension, routing in a higher dimension (e.g., X is “higher” than Y) is not permitted.

Routing Rules for X Links

When $x+$ or $x-$ is desired, but that link is broken, $y+$ is taken if available. This handles crossing from compute nodes to service nodes, where some X links are not present. If $y+$ is not available, $z+$ is taken. This $z+$ link must not cross a dateline. To avoid this, the dateline in Z is chosen so that there are no nodes with a broken X link and a broken $y+$ link. Although the desired X link is available, the routing algorithm may choose to take an alternate path when the node at the other side of the X link has a broken $y+$ and $z+$ link (note the $y+$ might not be present if configured as a mesh), then an early detour toward $z+$ is considered. If the X link crosses a partition boundary into the destination partition or the current partition matches the destination partition and the current Y matches the destination Y coordinate, route in $z+$ instead. Otherwise, the packet might be boxed in at the next node, with no safe way out.

Routing Rules for Y Links

When the desired route follows a Y link that is broken, the preference is to travel in $z+$ to find a good Y link. If $z+$ is also broken, it is feasible to travel in the opposite direction in the Y dimension. However, the routing

in the node in that direction must now look ahead to avoid a 180° turn if it were to direct a packet to the node with the faulty links. When the desired Y link is available, it is necessary to check that the node at that next hop does not have a $z+$ link that the packet might prefer (based on XYZ routing) to follow next. That is, if the default direction for this destination in the next node is $z+$ and the $z+$ link is broken there, the routing choice at this node would be changed from the default Y link to $z+$.

Routing Rules for Z Links

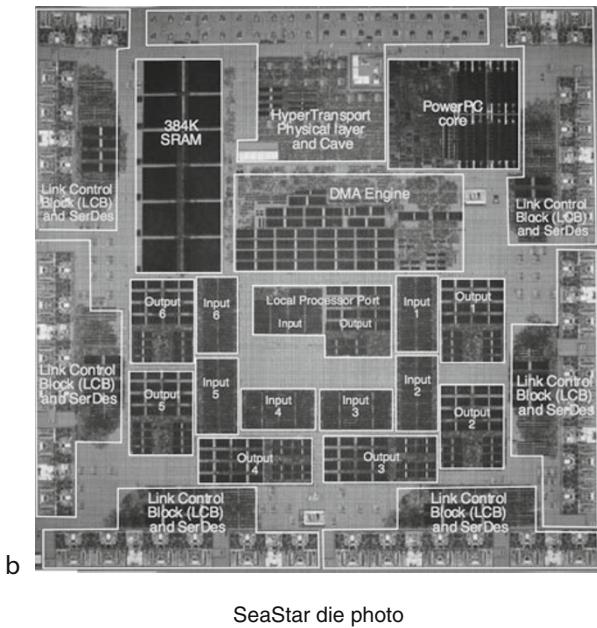

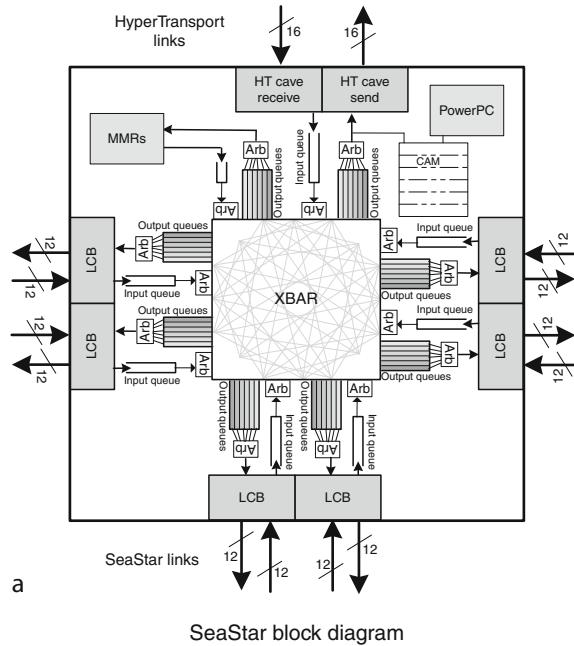

When the desired route follows a $z+$ link that is broken, the preference is to travel in $y+$ to find a good $z+$ link. In this scenario, the Y link look ahead is relied up to avoid the node at $y+$ from sending the packet right back along $y-$. When the $y+$ link is not present (at the edge of the mesh), the second choice is $y-$. When the desired route is to travel in the $z-$ direction, the logic must follow the $z-$ path to ensure there are no broken links at all on the path to the final destination. If one is found, the route is forced to $z+$, effectively forcing the packet to go the long way around the Z torus.

Flow Control

Buffer resources are managed using credit-based flow control at the data-link level. The link control block (LCB) is shown at the periphery of the SeaStar router chip in Fig. 2. Packets flow across the network links using virtual cut-through flow control – that is, a packet does not start to flow until there is sufficient space in the receiving input buffer. Each virtual channel (VC) has dedicated buffer space. A 3-bit field (Fig. 3) in each flit is used to designate the virtual channel, with a value of all 1s representing an *idle* flit. Idle flits are used to maintain byte and lane alignment across the plesiochronous channel. They can also carry VC credit information back to the sender.

SeaStar Router Microarchitecture

Network packets are comprised of one or more 68-bit *flits* (flow control units). The first flit of the packet (Fig. 3) is the *header* flit and contains all the necessary routing fields (destination[14:0], age[10:0], vc[2:0]) as well as a tail (t) bit to mark the end of a packet. Since most XT networks are on the order of several

Cray XT4 and Seastar 3-D Torus Interconnect. Fig. 2 Block diagram of the SeaStar system chip

Cray XT4 and Seastar 3-D Torus Interconnect. Fig. 3 SeaStar packet format

thousand nodes, the lookup table at each input port is not sized to cover the maximum 32k node network. To make the routing mechanism more space-efficient, the 15-bit node identifier is partitioned to allow a two-level hierarchical look up: A small eight-entry table identifies a *region*, the second table precisely identifies the node within the region. The region table is indexed by the upper 3-bits of the *destination* field of the packet, and the low-order 12-bits identifies the node within 4k-entry table. Each network port has a dedicated routing table and is capable of routing a packet each cycle. This provides the necessary lookup bandwidth to route a new packet every cycle. However, if each input port used a 32k-entry lookup table, it would be sparsely populated for modest-sized systems, and use an extravagant amount of silicon area.

A two-level hierarchical routing scheme is used to efficiently look up the egress port at each router. Each router is assigned a unique node identifier,

corresponding to its destination address. Upon arrival at the input port, the packet destination field is compared to the node identifier. If the upper three bits of the destination address match the upper three bits of the node identifier, then the packet is in the correct *global partition*. Otherwise, the upper three bits are used to index into the 8-entry *global lookup table* (GLUT) to determine the egress port. Conceptually, the 32k possible destinations are split into eight, 4k partitions denoted by bits destination[11:0] of the destination field.

The SeaStar router has six full-duplex network ports and one processor port that interfaces with the Tx/Rx DMA engine (Fig. 2). The network channels operate at 3.2 Gb/s \times 12 lanes over electrical wires, providing a peak of 4.8 GB/s per direction of network bandwidth. The link control block (LCB) implements a sliding window go-back-N link-layer protocol that provides reliable chip-to-chip communication over the network links.

The router switch is both input-queued and output-queued. Each input port has four (one for each virtual channel) 96-entry buffers, with each entry storing one flit. The input buffer is sized to cover the round-trip latency across the network link at 3.2 Gb/s signal rates. There are 24 staging buffers in front of each output port, one for each input source (five network ports, and one processor port), each with four VCs. The staging buffers are only 16 entries deep and are sized to cover the crossbar arbitration round-trip latency. Virtual cut-through [11] flow control into the output staging buffers requires them to be at least nine entries deep to cover the maximum packet size.

Age-Based Output Arbitration

Packet latency is divided into two components: *queueing* and *router* latency. The total delay (T) of a packet through the network with H hops is the sum of the queueing and router delay.

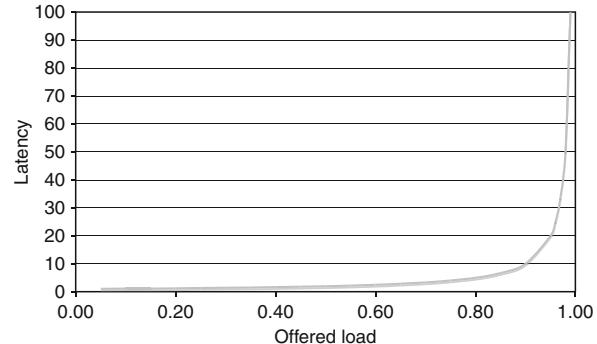

$$T = HQ(\lambda) + Ht_r \quad (1)$$

where t_r is the per-hop router delay (which is ≈ 50 ns for the SeaStar router). The queueing delay, $Q(\lambda)$, is a function of the offered load (λ) and described by the latency-bandwidth characteristics of the network. An approximation of $Q(\lambda)$ is given by an M/D/1 queue model (Fig. 4).

$$Q(\lambda) = \frac{1}{1 - \lambda} \quad (2)$$

When there is very low offered load on the network, the $Q(\lambda)$ delay is negligible. However, as traffic intensity increases, and the network approaches saturation, the queueing delay will dominate the total packet latency.

As traffic flows through the network it merges with newly injected packets and traffic from other directions in the network (Fig. 5). This merging of traffic from different sources causes packets that have further to travel (more hops) to receive geometrically less bandwidth. For example, consider the 8-ary 1-mesh in Fig. 5a where processors P0 through P6 are sending to P7. The switch allocates the output port by granting packets fairly among the input ports. With a round-robin packet arbitration policy, the processor closest to the destination (P6 is only one hop away) will get the most bandwidth – 1/2 of the available bandwidth. The processor two hops away, P5, will get half of the bandwidth into router node 6, for a total of $1/2 \times 1/2 = 1/4$ of the available

Cray XT4 and Seastar 3-D Torus Interconnect. Fig. 4
Offered load versus latency for an ideal M/D/1 queue model

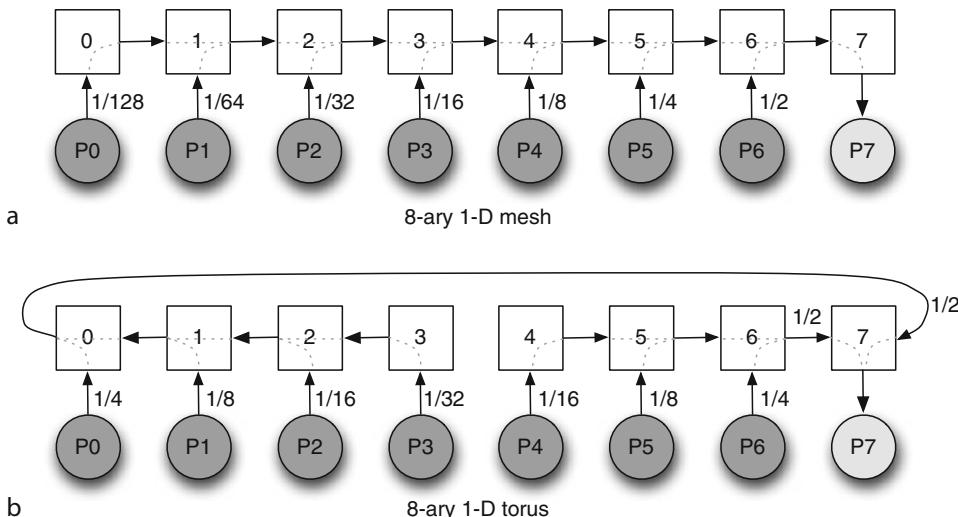

bandwidth. That is, every two arbitration cycles node 7 will deliver a packet from source P6, and every four arbitration cycles it will deliver a packet from source P5. A packet will merge with traffic from at most $2n$ other ports since each router has $2n$ network ports with $2n - 1$ from *other* directions and one from the processor port. In the worst case, a packet traveling H hops and merging with traffic from $2n$ other input ports, will have a latency of:

$$T_{\text{worst}} = \frac{L}{(2n)^H} \quad (3)$$

where L is the length of the message (number of packets), and n is the number of dimensions. In this example, P0 and P1 each receive 1/64 of the available bandwidth into node 7, a factor of 32 times less than that of P6. Reducing the variation in bandwidth is critical for application performance, particularly as applications are scaled to increasingly higher processor counts. Topologies with a lower diameter will reduce the impact of merging traffic. A torus is less affected than a mesh of the same radix (Fig. 5a and b), for example, since it has a lower diameter. With dimension-order routing (DOR), once a packet starts flowing on a given dimension it stays on that dimension until it reaches the ordinate of its destination.

Key Parameters Associated with Age-Based Arbitration

The Cray XT network provides *age-based arbitration* to mitigate the affects of this traffic merging as shown in Fig. 5, thus reducing the variation in packet delivery time. However, age-based arbitration can introduce a

Cray XT4 and Seastar 3-D Torus Interconnect. Fig. 5 All nodes are sending to P7 and merging traffic at each hop

starvation scenario whereby *younger* packets are starved at the output port and cannot make forward progress toward the destination. The details of the algorithm along with performance results are given by Abts and Weisser [1]. There are three key parameters for controlling the aging algorithm.

- AGE_CLOCK_PERIOD – a chip-wide 32-bit count-down timer that controls the *rate* at which packets age. If the age rate is too slow, it will appear as though packets are not accruing any queuing delay, their ages will not change, and all packets will appear to have the same age. On the other hand, if the age rate is too fast, packets ages will saturate very quickly – perhaps after only a few hops – at the maximum age of 255, and packets will not generally be distinguishable by age. The resolution of AGE_CLOCK_PERIOD allows anywhere from 2 ns to more than 8 s of queuing delay to be accrued before the age value is incremented.
 - REQ_AGE_BIAS and RSP_AGE_BIAS – each hop that a packet takes increments the packet age by the REQ_AGE_BIAS if the packet arrived on VC0/VC1 or by RSP_AGE_BIAS if the packet arrived on VC2/VC3. The age *bias* fields are configurable on a per-port basis, with the default bias of 1.
 - AGE_RR_SELECT – a 64-bit array specifying the output arbitration policy. A value of all 0s will select

round-robin arbitration, and a value of all 1s will select *age-based* arbitration. A combination of 0s and 1s will control the ratio of round-robin to age-based. For example, a value of 0101...0101 will use half round-robin and half age-based.

When a packet arrives at the head of the input queue, it undergoes routing by indexing into the LUT with destination[11:0] to choose the target port and virtual channel. Since each input port and VC has a dedicated buffer at the output staging buffer, there is no arbitration necessary to allocate the staging buffer – only flow control. At the output port, arbitration is performed on a per-packet basis (not per flit, as wormhole flow control would). Each output port is allocated by performing a 4-to-1 VC arbitration along with a 7-to-1 arbitration to select among the input ports. Each output port maintains two *independent* arbitration pointers – one for round-robin and one for age-based. A 6-bit counter is incremented on each *grant* cycle and indexes into the AGE_RR_SELECT bit array to choose the per-packet arbitration policy.

Synonyms

Communicating sequential processes (CSP)

Definition

Communicating Sequential Processes (CSP) is a mathematical notation for describing patterns of interaction. It has been used in the analysis of concurrent behavior in a variety of applications; it has inspired the design of concurrency mechanisms and primitives in several programming languages; it remains a focus for research and development in both academia and industry.

Process Language

In the CSP notation, *processes* are used to specify the behavior of components, to express assumptions about behavior, or to characterize behavioral properties. In each case, behavior is described in terms of the occurrence and availability of abstract entities called *events*: these are transactions, or atomic, multi-way synchronizations, between combinations of processes.

Processes may be combined using a number of operators, denoting choice, sequencing, and parallelism. The resulting language has a range of algebraic equivalences, and is often referred to as a *process algebra*. These equivalences help to explain the meaning of the operators, and support the automatic transformation of process descriptions into forms more convenient for analysis or implementation.

The alphabet of a process is the set of all events that require its participation. If an event appears in the alphabet of two or more processes in a parallel combination, then we say that this event is *shared* between

them. A shared event cannot occur without the simultaneous participation of all of the processes involved, and so each process added to a parallel combination represents a further constraint upon the order in which shared events may occur.

The simplest operator is *Stop*, which describes a process that can do nothing, and hence prevents the occurrence of any event in its alphabet. The prefix operator \rightarrow is used to introduce an event into a process description: if a is any event, and P is any process, then $a \rightarrow P$ is a process that is ready to engage in event a and, should a occur, will then behave as P . This choice of language is deliberate: a may be shared with other processes, and so $a \rightarrow P$ cannot simply “do” a ; indeed, if it is sharing a with *Stop*, then a will never occur.

A generalized prefix notation encompasses a process that offers the choice of a set of events: $?x : A \rightarrow P(x)$ is prepared to communicate any event $a \in A$ and then behaves like the corresponding process $P(a)$. You can think of A as being a menu of alternatives that the process offers.

This choice is further generalized to one between processes by the external choice operator $P \square Q$. This offers the first events of P and Q and behaves accordingly, so that

$$a \rightarrow P(a) \square b \rightarrow P(b) = ?x : \{a, b\} \rightarrow P(x)$$

In the case where P and Q have overlapping sets of initial events, $P \square Q$ acts *nondeterministically*: in $(a \rightarrow P) \square (a \rightarrow Q)$, once a has been communicated then the process can behave like P or Q , at its *internal* choice.

Because internal choices like this arise in CSP, both for this reason and others, there is an operator $P \sqcap Q$ that expresses internal, or nondeterministic choice. This process may choose to behave like either P or Q and neither the user nor other processes have any influence over which. Thus

$$(a \rightarrow P) \sqcap (a \rightarrow Q) = a \rightarrow (P \sqcap Q)$$

The sequential composition $P ; Q$ behaves as P until that process reaches a point in its behavior described by *Skip*, denoting successful termination; the subsequent behavior of the combination is then that of Q .

$$(a \rightarrow \text{Skip}) ; Q = a \rightarrow Q$$

for any event a and any process Q . *Skip* is distinct from *Stop*, which does not even terminate successfully.

In the parallel composition $P \parallel Q$, the two processes P and Q will evolve independently, while sharing in the occurrence of any event that is common to the two alphabets. If a and b are *not* shared between the two processes, then

$$a \rightarrow P \parallel b \rightarrow Q = a \rightarrow (P \parallel b \rightarrow Q) \sqcap b \rightarrow (a \rightarrow P \parallel Q)$$

that is, a and b may be observed in either order.

If P and Q can neither communicate independently nor agree on a shared event, then $P \parallel Q$ is *deadlocked*, and equivalent to *Stop*. For example, if a and b are shared between the two processes, then

$$a \rightarrow b \rightarrow P \parallel b \rightarrow a \rightarrow Q = \text{Stop}$$

the left-hand component of the parallel composition is able to perform b , but only after a has occurred; the right-hand process is able to perform a , but only after b has occurred; each event requires the cooperation of both processes, so no progress is possible.

The interleaving operator $P \parallel\!\!| Q$, on the other hand, allows each of P and Q to communicate freely: no communications are synchronized even when they belong to the alphabets of P and Q ; it follows that $P \parallel\!\!| Q = P \parallel Q$ when P and Q have disjoint alphabets.

The hiding operator $P \backslash X$ removes all actions in the set X from both the sight and control of the external environment. Thus

$$(a \rightarrow P) \backslash \{a\} = P \backslash \{a\}$$

It is frequently used to conceal the internal communications of a parallel composition as in $(P \parallel Q) \backslash (\alpha P \cap \alpha Q)$ where αP and αQ are respectively the alphabets of P and Q .

If R is a relation between the set Σ of all visible events and itself, then $P[R]$ is a process that can perform b whenever P can perform a for any pair (a, b) related by R . Sometimes, the special cases where R is either a function f or an inverse function f^{-1} are considered separately.

The language constructs above are usually considered the “core” of the notation. However, Hoare [7] also introduces interrupt: $P \triangle Q$ behaves like P until an initial event of Q occurs, after which Q takes over. This is typically used to handle externally occurring exceptions

as in

$$\text{resettable}(P) = P \triangle (e \rightarrow \text{resettable}(P))$$

where e is an event representing an external exception. Roscoe [19] introduces an operator for handling internal exceptions: $P \Theta_{\text{error}} Q$ behaves like P until the event error occurs, at which point Q takes over. Thus

$$(a \rightarrow P) \Theta_a Q = a \rightarrow Q$$

Process Semantics

The language of processes described above can be given a formal meaning, or semantics. Any process can be associated with a unique set of sequences, or *traces*, comprising every sequence of events, within its alphabet, that this process will allow. For example, the process *Stop* allows only the empty sequence $\langle \rangle$, while the prefix process $a \rightarrow P$ will allow any sequence in which the first event, if there is one, is a , and for which the remaining events could be performed by P .

The trace semantics is enough for many applications, but does not provide for an adequate treatment of nondeterminism. For example, the processes $a \rightarrow \text{Stop}$ and $(a \rightarrow \text{Stop}) \sqcap \text{Stop}$ have the same set of traces, the set $\{\langle \rangle, \langle a \rangle\}$. Yet the first of these *must* be ready to perform a , whereas all that can be said for the second is that it *may* be ready to perform a (or it may deadlock).

For nondeterministic processes, another level of semantic information may be required. Each trace of a process may be associated with a set of sets of events, or *refusal sets*, comprising every combination that may be blocked by the process once that trace has been performed. The combination of a trace and a single refusal set is called a *failure*: if the process, having performed that trace, were required to participate in one of the events from the refusal set, then no further progress would be made.

To provide a full characterization of the process language, the failures semantics must be augmented by an appropriate treatment of undefined expressions. Where the behavior of a process P is determined solely by an equation such as $P = P$, or even $P = P \sqcap (a \rightarrow \text{Stop})$, then there is not enough information to uniquely determine a set of failures; such a process is said to be *divergent*. Processes like $AS \backslash \{a\}$, where $AS = a \rightarrow AS$, are also divergent. In the definitive *Failures-Divergences* semantics, each process is associated with a set of failures and

a set of divergences: traces leading to a point where the subsequent behavior may be described by a divergent process. Besides traces and failures-divergences, there are a variety of other models. See [19] for details.

In analyzing the semantics of CSP, it is useful to have an additional form of choice: $P \triangleright Q$ may choose to offer the initial actions of P , but *must* offer the initial choices of Q . It is equivalent to $(P \square a \rightarrow Q) \setminus \{a\}$ for a an event that neither P nor Q performs.

Any finite CSP program (one whose traces are of bounded length) is equivalent to one written using only *Stop*, *Skip*, prefix-choice, internal choice \sqcap , sliding choice \triangleright , and a constant *div* representing a *divergent* process: one equivalent to $A\$ \setminus \{a\}$ that simply performs internal (τ) actions for ever. This fact tells us that, in some sense, the other operators are not language *primitives* and that every program is equivalent to a sequential one. The fact that this transformation can be accomplished using algebraic laws is the core of an *algebraic* semantics for CSP (see Chap. 13 of [19]).

Refinement and Abstraction

In applications of CSP, processes are used to describe components, assumptions, or properties, and then compared in terms of their semantics. The usual method of comparison is based on the notion of *refinement*, which corresponds to subsetting or containment of the semantics: a process P is a refinement of another process Q , written $Q \sqsubseteq P$, if every behavior of P – every trace, or every failure and divergence – is also a behavior of Q .

In the trace semantics, refinement can be used to check whether a particular sequence of interaction is possible, or to check whether every possible sequence of interaction is acceptable according to some specification. However, for nondeterministic processes, it cannot be used to demonstrate that a sequence *must* be possible: for this, refinement in the failures–divergences semantics is required.

Most comparisons will be made between processes described at different levels of abstraction: one of the processes will describe a design or implementation, the other a property or specification, using a smaller set of events. To effect such a comparison using refinement, the events not mentioned in the property description must be abstracted.

CSP provides a number of mechanisms for describing abstraction, including renaming, hiding and *lazy*

abstraction: $\mathcal{L}_A(P)$ describes now the process looks to a user who cannot see the events in A but assumes there is another user who can see and control them. This is identical to hiding in the traces model, but subtly different in other models since $P \setminus A$ assumes that the events of A become automatic and uncontrolled.

A key feature of the process language is that all of the operators are monotonic with respect to the refinement ordering: if $Q \sqsubseteq P$, then $C[P]$ refines $C[Q]$ where $C[\cdot]$ is any CSP context, namely, a piece of CSP syntax with a free process variable.

Tools and Applications

The multiplication of states and entities that is inherent in concurrent behavior means that (fully) manual analysis of process semantics is infeasible. Effective tool support is required: to examine the properties of a process through step-by-step rewriting, or to check whether or not one process is a refinement of another, through exhaustive exploration.

A *machine readable* syntax for the language has been defined, called CSP_M : process descriptions written in this syntax can be checked for type consistency using the *Checker* tool, and rewritten step-by-step using a tool called *ProBE*. A refinement checking tool called *Failures–Divergences Refinement* (FDR) is also available: the refinement of processes with millions of control states can be checked in less than a minute; designs with billions of states have been checked successfully. Processes with larger, finite state spaces can be checked using *compression* operators and related techniques.

A number of people, for example [9], have embedded theories of CSP into theorem provers such as Isabelle and PVS: such embeddings make it easier to prove general results such as language equivalences and healthiness conditions, but are not as effective as FDR at proving results about specific systems.

A key application area for CSP has been in the analysis of cryptographic protocols. Gavin Lowe discovered that these could be conveniently modeled in CSP and checked for security on FDR, and he and others developed tools – most notably a front end for FDR called Casper [14] – that can input a protocol in a natural notation and either find an attack on it or prove there is no such attack. The fact that Lowe, early on in this work, found a famous attack on a well-known protocol [13] led

to an explosion of work around the world on the formal verification of security protocols.

Apart from its use in security, CSP has been used successfully for the development of critical systems for avionics, automotive, military, and embedded systems. Some of these are based on modeling directly in CSP_M , and some, like Casper, rely on front ends that translate another notation to CSP_M .

Language Versions

There are several different versions of the process language, the best known being the mathematical notation used in Hoare's 1985 book *Communicating Sequential Processes* [7], used here. An extended version of that and the "machine readable" variant CSP_M are used in Roscoe's 1997 book *The Theory and Practice of Concurrency* [16]. CSP_M is a significant extension of the 1985 notation, with more powerful notions of sequencing and abstraction, as well as directives for expediting the checking of traces and failures–divergences requirement. CSP_M also contains a functional programming language related to Haskell [2] that is used both for building processes' events and parameters, and for laying out networks. These same two versions of CSP are used in Roscoe's 2010 book *Understanding Concurrent Systems*.

The main difference between the Hoare and Roscoe presentations is that whereas Hoare assumes that every process has an intrinsic alphabet for use in the parallel operator, Roscoe uses versions of parallel that specify alphabets explicitly: for example $P[|A|]Q$ (in the CSP_M syntax) runs P and Q with interface A .

Hoare introduced an early version of the notation in 1978, in the Communications of the ACM [6]. This was a language of programs rather than constraints or patterns of behavior; however, it embodied two of the characteristic features of the later notation: that the behavior of a process should be characterized entirely by its external interaction, and that parallel composition should be a primary means of adding structure to process descriptions.

The CSP notation in both its 1978 and process algebra versions was the inspiration for the programming language OCCAM [8], implemented on the INMOS Transputer: both the language and the processor are discussed elsewhere in this volume. It has inspired also the design

of concurrency mechanisms for the Java language [11] and the Go language released in 2009 by Google [5].

An account of the history of CSP up to the mid-1980s and its influences on OCCAM and the Transputer can be found in [10], a scientific biography of Hoare.

Timed, prioritized, and probabilistic extensions have been suggested for the CSP notation, and attempts have been made to integrate it with object modeling and state-based notations such as B [1]. Of these, there has been considerable industrial use of CSP for timed and state-based systems, but always by translation from the extended notation into CSP_M and then checking on FDR. For example, the passage of time can be represented by the regular occurrence of a *tock* event.

Discussion

Many other process algebras have been proposed for the study of concurrency, most notably Milner's CCS and its many derivatives, including the π -calculus. Among these, CSP is characterized by a rigorous adherence to a small, coherent set of design principles:

- Each event is an atomic, symmetric, multi-way synchronization, corresponding to an abstract transaction involving a fixed collection of processes.
- Each process gives only a partial account of when an event may occur: until closure is achieved through abstraction, other processes may further constrain its occurrence.
- Processes are characterized completely by their externally observable behavior: there are no "internal" or "hidden" events in the language.
- There is no explicit treatment of priority, timing, or degree of parallelism; these require more specific interpretations of interaction and communication.
- The semantics is captured by models which describe a process as one or more sets of observations of *linear*, as opposed to *branching* behaviors.

As a result, the language has certain properties not found in other algebras: most notably, processes describing components, assumptions, or properties at different levels of abstraction may be compared using notions of refinement.

In other languages, comparisons between processes are made only at the same level of abstraction, using various notions of simulation; analyses across different levels of abstraction are conducted using separate

formalisms, such as temporal logic. Such logics are often excellent at expressing succinct properties of systems, but using CSP descriptions as refinement specifications frequently has an advantage when capturing a more complete description of a system [12]. It is possible to express some subsets of Linear Temporal Logic in CSP, and aspects of fairness, but any property that can be checked over standard CSP semantics must be determined by a process's *linear* as opposed to branching behavior.

On a theoretical note, it can be shown that every *closed* property R of CSP models, and many others, can be characterized by refinement checks of the form $F(P) \sqsubseteq G(P)$ for CSP contexts F and G [17]. Here, R is closed if, whenever $R(P)$ does not hold, there is some n such that there is no Q which both satisfies R and is equivalent to P for the first n steps of its behavior.

Recent results (see Chap. 9 of [19]) have demonstrated that the CSP notation is in some sense a *universal* language for concurrency: every language whose operational semantics satisfies the conditions to be *CSP-like* can be simulated (at the level of strong bisimulation) by CSP. Any such language is automatically given compositional semantics over CSP models and a theory of refinement. One such language is π -calculus: see [18].

Bibliographic Notes and Further Reading

A comprehensive account of CSP is presented in Roscoe's book *Understanding Concurrent Systems*, published by Springer in 2010 [19], a significant update of his 1997 book *The Theory and Practice of Concurrency* [16]: this includes a guide to the latest version of the "machine readable" language, and a detailed account of tools, applications, and extensions. It explains the links with other ideas from concurrency such as shared variables, data-flow and buffered channels, mobility, time, and priority by showing how to model these

in CSP. The vision for the process language, and the failures-divergences semantics, is set out in Hoare's 1985 book, *Communicating Sequential Processes*; key stages in its development can be seen in Hoare's 1978 paper of the same name [6] and the 1984 paper by Brookes et al. [3]. Schneider [21] is a book on CSP that emphasizes the theory of Timed CSP (see also [4, 15]). The application of CSP to security protocols is covered in [20].

Cyclops-64

Definition

Cyclops is a targeted-purpose, highly parallel, massively multicore family of computers developed at the IBM T.J. Watson Research Center. The design is characterized by several novel architectural features and by an aggressive exploitation of ASIC chip technology. Machines under construction range in performance from tens of teraflops to a full petaflop.

Discussion

Introduction

Cyclops falls into the category of targeted high-performance computing systems. These machines are built with an intentionally unconventional balance of resources in order to optimize cost-performance for specific application domains. Cyclops was designed to target proprietary optimization codes for a select group of IBM clients.

Five observations of the execution of these codes on commercial machines motivated several of the key architectural decisions:

1. The majority of instructions were not used most of the time. This was true even for so-called RISC processors. Instructions were found that were never emitted by any compiler.
2. Much of the architectural, design, and implementation work that went into optimizing single-thread performance was wasted. Many processor resources were idle much of the time, wasting clock and leakage power.
3. Data caches consumed a large part of the silicon resources, but often increased the energy per operation and, in some cases, even decreased performance.

4. The traditional splitting of the general-purpose register file into fixed and floating-point components almost always resulted in the wrong balance. For applications without floating point data, all of the floating-point registers were wasted. For applications with very high floating point content, many of the fixed-point registers went unused.
5. When processors were running the same small program, the dedication of a large instruction cache to just one or two processors wasted silicon resources.

Thread Unit

The fundamental Cyclops computing element is the 64-bit general-purpose thread unit, the instruction set architecture for which was developed without any particular tie to previous machines.

The thread unit contains a 4-port (2 read, 2 write) 64×64 register file and a 32-KB SRAM (Static Random Access Memory). It executes one scalar instruction per cycle. Instructions and data are, respectively, 32 and 64 bits wide. There are only 60 basic instruction types.

Instructions are executed from a 32-element prefetch buffer (PIB). While execution is not speculative, instructions are prefetched using a 512-entry 2-bit branch history table (BHT).

The name thread unit is historical – a thread unit is actually a complete processor that can execute a fixed point instruction every cycle.

Processor

Two thread units and a shared floating-point unit constitute a processor. The floating-point unit can start one double precision add and one double precision multiply every cycle. Underflow is truncated to zero and overflow is forced to infinity – Cyclops has no interrupts on arithmetic exceptions. The multiply unit can also start a $64 \times 64 \rightarrow 136$ integer multiply-accumulate operation every cycle.

A processor also has 100-bit outgoing and incoming ports to the chip-wide crossbar described below.

Instruction Cache Group

Five processors (ten thread units) and a shared Instruction Cache constitute an Instruction Cache Group.

The 32-KB shared Instruction Cache is 8-way associative and has 64-byte lines. Replacement is Least-Recently-Used.

On each cycle the Instruction Cache can provide one 16-instruction line. These are aligned to 16-byte (4-instruction) boundaries. Requests to the same line are combined and satisfied simultaneously.

Crossbar

On-chip Cyclops communication is provided by a large pipelined crossbar. This avoids the locality constraints that accompany, for example, nearest-neighbor interconnects. A full crossbar ensures that programmers do not have to consider the particular positions of processors on the chip.

The crossbar has 96 ports, each approximately 100 bits wide. It is pipelined so that, in the absence of blocking, transactions can be initiated on every cycle. Transactions can encompass either single items or blocks of items. Forward and return transactions share the same wires, but otherwise have separate facilities in order to prevent deadlock.

Of the 96 crossbar ports, 80 connect to the processors, 4 to the Instruction Caches, 4 to the DRAM controllers, 6 to the 3D router, 1 to the combining router, and 1 to the parallel host interface.

Loads and Stores through the Cyclops crossbar have an important ordering property, which is best illustrated by example: If a processor stores data into global memory and sets a flag to indicate that the data has been written, then another processor observing that the flag has been set will subsequently read the correct data. Unlike most other multiprocessors, Cyclops does not require or have a synch instruction.

The unloaded crossbar latency is 10 cycles.

Storage

Each of the 160 Cyclops processors contains 32 KB of SRAM. The SRAM is partitioned at runtime into two parts. The first is local scratchpad, which is most often directly accessed by the owning processor, but which can also be explicitly accessed by any other processor on the chip.

The second is a contribution to global interleaved SRAM. This memory segment is interleaved across all participating processors, so that the first 64 bytes are in the SRAM of the first processor, the next 64 bytes in the

SRAM of the second processor, and so on. In order to enforce ordering, access to global interleaved memory is always done over the crossbar, even if a particular item is local to the accessing processor.

Attached to each Cyclops chip is one gigabyte of external DDR2 DRAM, implemented as four independent quadrants, each with its own port to the chip. Data is interleaved in 64-byte blocks, first across the quadrants, and then within the internal banks of the DRAM modules. The peak bandwidth into external DRAM is 16 GB/s.

Only the processors on a chip can directly address the memory associated with that chip. Remote access is handled by message routing hardware described below and SHMEM utilities.

Atomic Memory Operations

All levels of Cyclops storage support atomic memory operations. These include both fetch-and-add and fetch-and-logic with any 2-input logical operation. Alternative versions perform the update without returning data.

Signal Bus

The signal bus is a 16-bit wide 160-way pipelined OR tree used to support fast barrier operations. To preserve ordering, processors write to the signal bus over the crossbar, but read from it locally. Each processor observes the logical OR of the contributions of all 160 processors. Three bits are typically used to implement each barrier.

A-Switch

Each Cyclops chip contains a simple 6-port 3D router referred to as the A-Switch. Chips are physically connected in a 3D mesh. The petaflop version of Cyclops is a $24 \times 24 \times 24$ cube.

Each of the six external channels simultaneously sends and receives data at a rate of 4 GB/s, for an aggregate external data bandwidth of 48 GB/s. A small amount of additional bandwidth is present for control.

Each channel consists physically of 12 differential pairs (lanes), each running at 5 Gbits/s. Nine of the lanes are for payload, two for block error correction, and one is reserved as a spare. The block error correction is strong enough to allow total failure of any single lane.

There are four classes of traffic. Two are for normal forward and reply messages, and two are for forward and reply messages that must be rerouted to avoid a bad chip.

Messages typically travel first along the x -axis, then along the y -axis, and finally along the z -axis of the mesh. The number of hops along each axis is contained in the header.

If chip A cannot reach chip B because of a failing chip along the route, then chip C is found such that A can reach C and C can reach B. As the message passes C, its class is changed to the reroute class. This mechanism prevents deadlock.

In order for processors to collectively participate in the creation of messages, traffic injected into the A-Switch is mediated by six outgoing channel controllers, one for each direction. Processors assemble components of messages in memory, and then atomically queue a pointer to the appropriate channel controller.

Similarly, there are six incoming channel controllers responsible for dejecting data from the A-Switch. Data is written to FIFOs allocated in memory. Processors remove message pointers from an incoming work FIFO, process the corresponding data, and then notify a channel controller when done so that it can free the space.

B-Switch

In a machine with over 13,000 processor chips, collective operations such as floating-point reductions, global max/min, and barriers can, if implemented in software, negatively affect performance. The Cyclops processor chip incorporates a component referred to as the B-Switch, which accelerates these operations.

Traffic to and from the B-Switch uses the same physical links as the A-Switch, with B-Switch traffic always taking priority. Processors directly inject packets into and deject packets from the B-Switch. B-Switch transactions are strictly between neighbors in the 3D mesh.

Central to the unit is a set of 16 trigger tags. Each tag is programmed with criteria for activation based on B-Switch packets received from the six neighboring chips. The tag can either require that all members of some particular subset of the neighbors have sent B-Switch packets, or that any member of a particular subset has sent a packet.

In addition to the activation criteria, the tag also contains the location of an applet in a small instruction memory. When a tag is activated, it posts a notification of that event on an activation queue.

The B-Switch contains a simple embedded processor that is a subset of the primary Cyclops processor. Only instructions important for collective operations are implemented. For example, floating-point addition and comparison are supported, but multiplication is not.

The B-Switch processor executes, one by one, the applets on the activation queue. During execution, the processor typically sends new packets to adjacent chips and also notifies the sources that an operation is complete and resources are now free.

A typical B-Switch operation is to determine a maximum floating point value across all chips in a $24 \times 24 \times 24$ machine, and then to broadcast that value to all participants. This operation is done in two phases, each with an associated tag. First, the comparisons are done in a B-Switch tree that terminates near the center of the cube. Then, the chip at the root of the tree changes the tag and, in the reverse direction, broadcasts the maximum value to all participants.

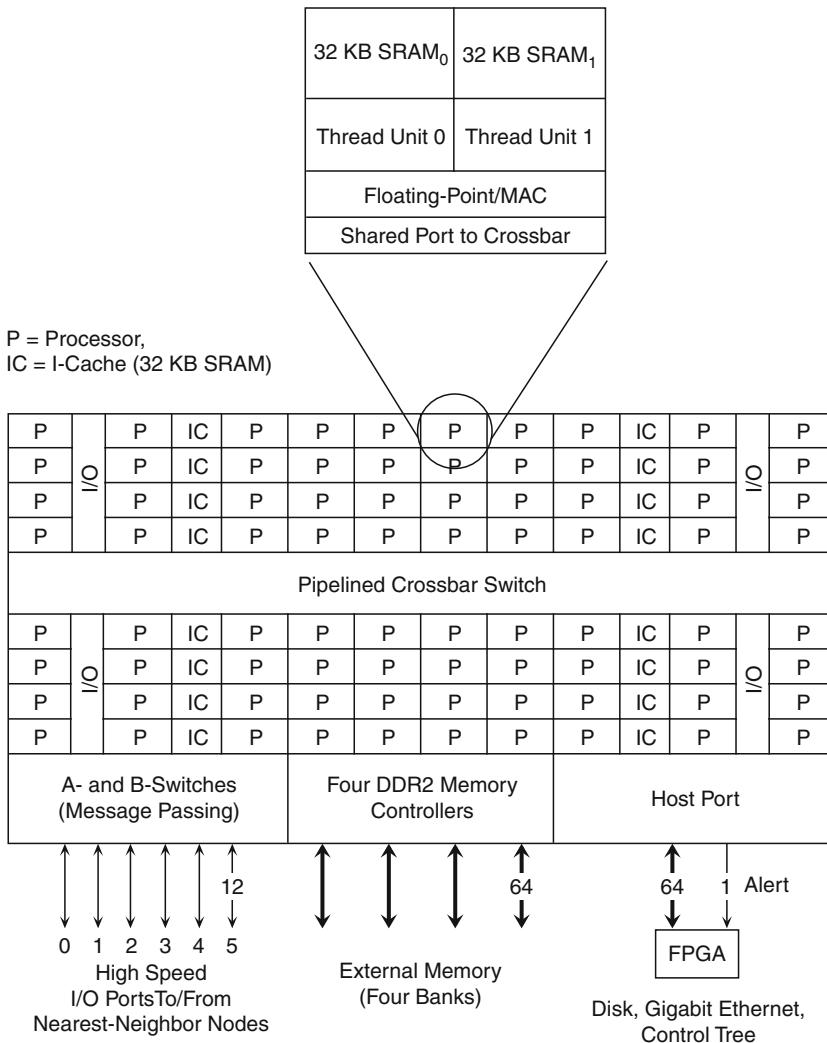

An overview of the Cyclops chip is shown below (Fig. 1).

Single-Step

Cyclops has a unique single-step property. It can be started from cycle 0, run M cycles, stopped and examined, then run an additional N cycles, and it will behave exactly as if it were run $M + N$ cycles without interruption.

Several mechanisms were required in order to enable single-step. There is a unique central oscillator, and the rising edges of the clock can be thought of as being numbered. All chips update their state in the same way on edge N , even though they may receive edge N at different times.

The major challenges to single-step were the DRAM and HSS (High Speed SerDes) subsystems. On any given cycle these can have transactions or data in flight. When the machine pauses, Cyclops sinks in-flight results to completion buffers. Upon starting again, the machine sources results from the completion buffers in such a way that they appear on the same clock cycles that they would have if no pause had occurred.

Cyclops. Fig. 1 Overview of the Cyclops chip

Processor Sparing

Cyclops was the first chip designed within IBM to exploit large scale processor sparing in order to reduce silicon costs. Even in a mature technology, yields of perfect die the size of the $21 \text{ mm} \times 23 \text{ mm}$ Cyclops die would not be high. A single failed logic transistor or wire results in the die being discarded.

The Cyclops ASIC can tolerate any number of failed processors, with the sole consequence being a linear reduction in performance and SRAM capacity. This is achieved by mapping out the failed processors and compressing the remaining interleaved memory space so that it appears to be contiguous.

The compression is done in two steps. First, fast arithmetic hardware divides the address by the number of good banks and produces the quotient and remainder. The quotient is the address in the target bank. Next, the remainder is used to index a remap table that lists, without gaps, the good banks. The output of the remap table is the target bank.

Mechanical Package

Each Cyclops ASIC is contained on its own $6'' \times 9''$ water-cooled blade. The blade contains one gigabyte of off-the-shelf DRAM, an FPGA for external Ethernet

access and hard disk drive control, power supply components, and support for an integral hard disk drive.

Water-cooling is implemented by means of a cold plate constructed from fused sheets of etched copper. The junction temperature of the ASIC is typically held to under 30 °C, enhancing reliability and improving system speed.

Twenty-four blades are mounted on each side of a midplane, and three midplanes make up a rack of 144 blades. The petaflop installation of Cyclops has 12 rows of 8 racks each.

Midplanes are connected within rows using high-performance flex. Row-to-row connections are made with 12X Infiniband cable.

Power consumption of the petaflop machine is under two megawatts.

Programming Model

Within a chip, Cyclops is a 160-way SMP. In the simplest mode of operation, a single program is loaded into shared memory. Processor identity determines which parts of the program to execute and on what data to operate. There is also a lightweight thread library similar to pthreads.

Between chips there are simple message-sending and Shmem-like shared storage libraries. There is no support for MPI.

The primary software for Cyclops was developed under the direction of Dr. Guang Gao at the University of Delaware.

Performance

While Cyclops was not designed for high floating point performance, it still achieves over 70 GFlops/s multiplying double-precision matrices stored in external DRAM. The corresponding power is 1 watt/GFlop.

The chip achieves approximately 0.09 GUPS (giga updates per second) to external DRAM.

Design

The Cyclops ASIC, a 500-MHz 90-nm design, was the largest die ever processed by the IBM ASICS division. It had the densest logic implementation of any ASIC, the highest content of low threshold voltage logic, the highest latch count, and the highest peak power. As a

result, it posed many unique challenges to the existing design methodology and tools.

Work on early versions of Cyclops began in the late 1990s to address first the challenges of raytracing, and later protein-folding. The ASIC was designed by very small teams at the IBM T.J. Watson Research Center, the IBM Burlington and Fishkill facilities, and by Dr. Gregory Chudnovsky at the Polytechnic Institute of New York University. Packaging and electronics were developed by Central Scientific Services at IBM Research under the direction of James Speidell.

Future Work

Aside from the expected improvements in speed and processor count resulting from the expected course of technology, the next generation of Cyclops will take advantage of two major advances. First, multiple processor and memory die will be tightly integrated on the same module, greatly increasing the bandwidth between them. Second, cost-effective optics and different topologies will enable a large increase in global long-hop bandwidth.

Probably the single most distinctive and valuable feature of the Cyclops architecture is the very large pipelined crossbar. This is expected to persist, with increasing size and bandwidth, through all future generations.

Appendix

The Cyclops die is shown in the photograph below (Fig. 2). Colors are due to diffraction. The photograph was taken before fabrication of the upper metal layers.

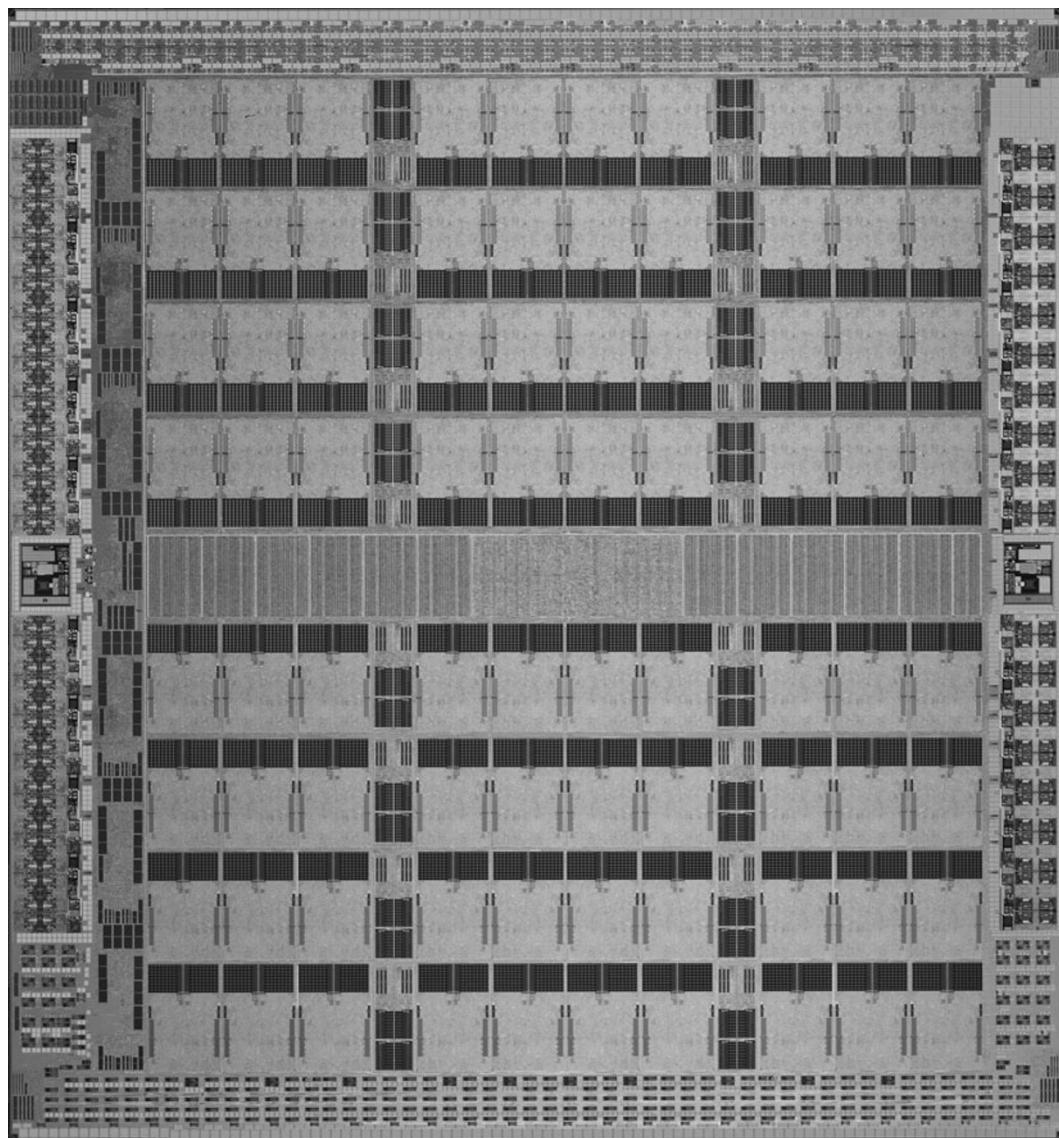

On the left edge are nine 8-bit HSS (High Speed SerDes) receivers, with a phase-locked loop in the center. On the right edge are the corresponding nine 8-bit HSS transmitters.

To the right of the HSS receivers are the A-Switch and B-Switch.

On the top and bottom edges are four DRAM controllers.

Running horizontally across the center is the 96-port pipelined crossbar.

The two thin columns approximately one-third and two-thirds of the way across the die are 16 Instruction Caches.

Cyclops. Fig. 2 The Cyclops die

Finally, most of the die is filled by the 8×10 array of processors, each of which contains two thread units and a floating-point unit. Two blocks of SRAM can be seen attached to each processor.

Cydra 5

MICHAEL SCHLANSKER
Hewlett-Packard Inc., Palo-Alto, CA, USA

Definition

The Cydra 5 was a mini-supercomputer designed by Cydrome and completed in 1987. The Cydra 5 heterogeneous multiprocessor consisted of a general-purpose shared-memory multiprocessor based on Motorola

68020 processors along with a numeric processor that used Cydrome's Directed Dataflow™ architecture. The numeric processor achieved about one half the performance of a contemporary supercomputer at about one tenth of the price.

Discussion

Introduction

Cydrome (originally known as Axiom) was founded by chief architect Bob Rau, along with Arun Kumar, Ross Towle, Dave Yen, and Wei Yen. The key design goal for the Cydra 5 was to provide near-supercomputer levels of computing performance at departmental prices. The Cydra 5 was designed to accelerate existing unmodified FORTRAN applications commonly used for scientific computing. Goals included providing 50 (25) MFLOPS of peak single (double) precision floating-point performance and achieving greater computation efficiency by sustaining a higher fraction of peak performance than competing vector and multiprocessor architectures.

System Architecture

A primary feature of the Cydra 5 was the Directed Dataflow architecture that provided specialized hardware for parallel loop execution. The Cydra 5 supported compiler-directed parallelization of a very general class of loops, thus providing greater flexibility for accelerating existing codes than competing vector and multiprocessor architectures. The architecture combined the MultiConnect register file, predicated execution, and a specialized branch to support software-pipeline loops without code replication needed by other hardware architectures. In addition to supporting traditional vectorizable loops, this architecture efficiently supported a very general class of loops with recurrences, conditionals, arbitrary fixed stride, and randomly scattered memory references.

Software pipelining [1, 2] exploits parallelism by overlapping the execution of a sequence of loop iterations. When loop iterations are executed sequentially, latencies between the operations within each iteration limit loop parallelism. This problem is alleviated by initiating subsequent loop iterations before the completion of prior iterations. Software pipelining executes identical copies of the loop body at periodic intervals. An optimized periodic schedule is identified to minimize

the delay between successive loop iterations. The time delay between successive loop iterations is known as the Initiation Interval (II). The II measures the throughput of loop execution as one new loop iteration is completed every II cycles.

VLIW processors evolved from earlier microprogrammed processors that employed complex data paths to carry operands from registers to and from function units. The processing efficiency was greatly reduced by a number of obstacles. A key obstacle was the need to develop operation schedules that jointly accommodate all resource. Complex schedules often required a distinct and coordinated schedule for both function unit use and register use. Processors often contained multiple specialized register files that held operands as inputs to and outputs from function units. A single bus often supported multiple register files or multiple function units. This increased scheduling complexity and reduced efficiency, limiting program parallelism. Such machines could not be effectively exploited by compilers and were best programmed by clever humans. Another key challenge is to accommodate register lifetimes that often limit parallelism by introducing bottleneck dependences arising from register reuse. The lifetime of a variable formalizes the need hold a value for an extended period of time and is the period of time starting when a variable is computed and terminating on the variable's last use. A register cannot be reused to hold a new variable until the end of the prior variable's lifetime.

The Cydra 5 architecture addressed above difficulties using the Context Register Matrix (CRM) or Multi-Connect as it was called inside Cydrome. The CRM provided a number of features to allow compiler technology to automate the construction of compact and efficient software pipelines for a broad class of loops. The CRM evolved from the earlier PolyCyclic interconnect [3]. The polycyclic interconnect required the shifting of data as new values were created. This required custom memory structures and could not be implemented using high-performance RAM. The CRM integrated standard RAMs with novel register addressing units to provide similar benefits.

The Cydra 5 system contained multiple General-Purpose Processors (GPPs) and a numeric processor (NP) integrated as a heterogeneous multiprocessor running the Unix System 5 operating system. While

the primary role of the NP was to accelerate scientific applications, the GPPs were used to run nonnumeric applications. This architecture alleviated troublesome limitations of specialized attached processors such as the Floating Point Systems AP 120b [4] that ran numeric programs with no general-purpose or I/O capability. Such architectures required careful rewriting of applications to stream data from a main program running on the host into numeric kernel programs running on an attached processor. Unlike these machines, the Cydra 5 appeared as a single processor that allowed applications to be compiled either for the GPPs or for the NP.

The general-purpose processors provided an extensible general-purpose computing capability based on 16.67 MHz Motorola 68020 processors. Up to seven GPPs could be added to expand the general-purpose computing capability. In addition to hosting compilations needed for the Numeric Processor, the GPPs supported a large variety of conventional computing tasks under the Cydrix operating system which was derived from AT&T System V Unix.

Cydra 5 Numeric Processor

The numeric processor was a Very Long Instruction Word (VLIW) [5] processor implemented in Emitter Coupled Logic (ECL) gate arrays for very high performance. The NP achieved its 25-MHz clock speed using simple hardware to perform performance critical tasks and, where possible, relied on compiler and runtime software to implement complex operations that could be performed in software without excessive performance loss.

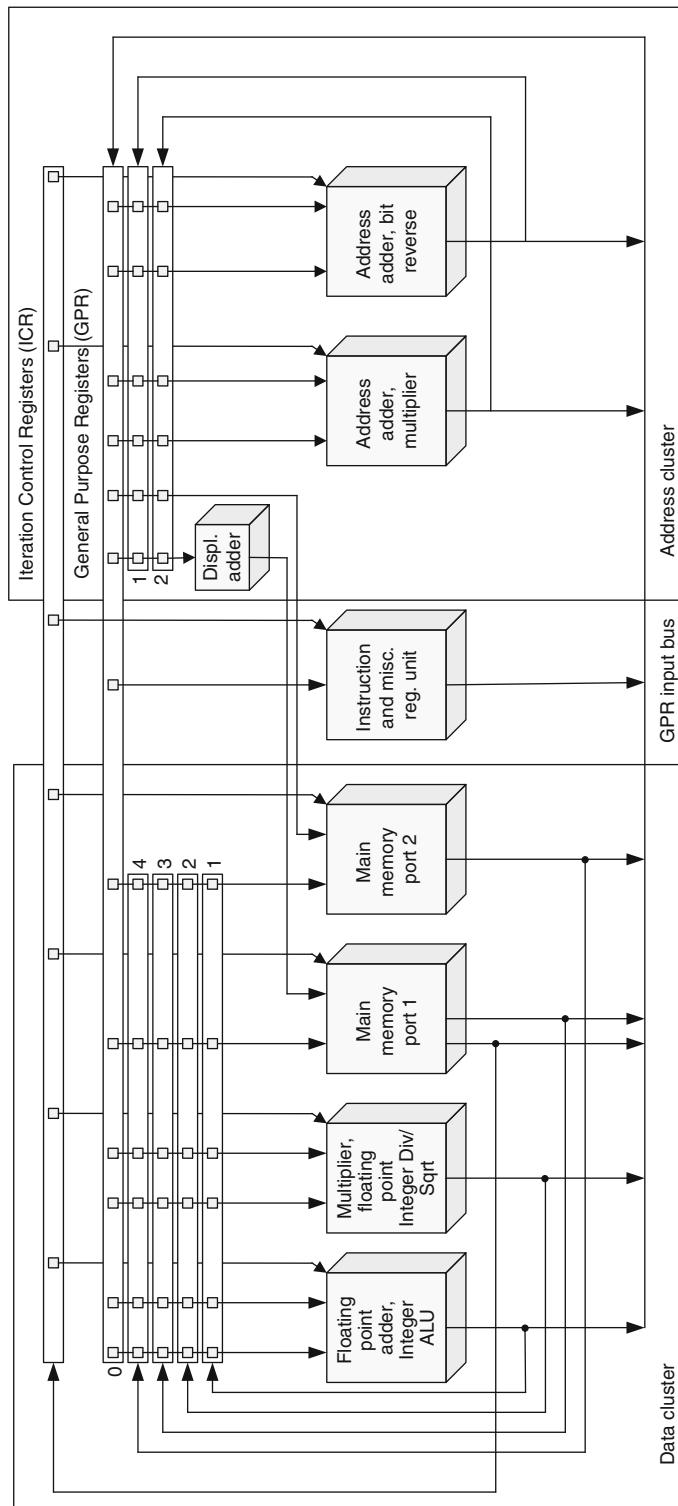

The numeric processor provided a 256-bit wide instruction container that was interpreted in either UniOp or MultiOP execution modes. In UniOp mode, the VLIW instruction was interpreted as six sequential instructions with explicitly encoded delays between those instructions as needed to satisfy interoperation dependences and resource constraints. The UniOp mode was used outside of high-performance loops and provided a relatively compact encoding for sequential code. In MultiOp mode the VLIW instruction was interpreted as a single instruction that allowed the issue of seven operations in a single cycle. Simultaneous operations included two arithmetic (floating or integer), two address, two memory, and one branch operation.

Multi-Op mode was primarily used to accelerate highly parallel innermost loop code but could also be used outside of accelerated loops when sufficient parallelism was available. The combination of the Cydra 5's wide instruction issue along with its deep pipelining produced large amounts of instruction-level parallelism. The total number of operations in flight (issued but not complete) could exceed 70 concurrent operations.

The Cydra 5 NP relied on explicit compile-time scheduling to eliminate complex hardware resource-dependence checking and arbitration. Hardware offered no instruction interlocks or ability to dynamically delay dependent operations, and the compiler was responsible for inserting explicitly encoded delays needed to enforce a correct program schedule. Instructions provided capabilities needed to program explicit delays. Resource usage was modeled with reservation tables [6] that encoded the pattern resources over a number of machine cycles relative to the time instruction issue. A machine description database formally defined the hardware's characteristics capturing both resource needs and latencies of all operations and precisely defined constraints that must be met for correct execution. This database was used by the compiler to ensure that all resource and dependence constraints are met.

The Cydra 5's NP datapath is shown in Fig. 1. This datapath was designed to sustain a peak bandwidth of two floating point operations on every cycle for important numeric loops. Two floating point units, two memory units, and two address units were needed to satisfy this goal. The machine executed six simultaneous non-branch operations each capable of reading two inputs and writing one output on each cycle. Twelve input ports and six output ports were needed to sustain full performance in parallel code regions. A single file with so many ports could not be constructed using available ECL gate arrays. In order to reduce complexity for providing needed register file ports, the Numeric Processor is divided into data and address clusters.

The CRM holds operands flowing into and out of all function units. Each row consists of cross-point registers that are replicated as a multiported file (indicated by small squares). When a value is written into a row, it is broadcast across the row so that cross-point registers hold identical values. Thus, each function unit has dedicated write access and can generate a new value

Cydra 5, Fig. 1 Cydra 5's NP datapath

into its dedicated row on every cycle. Columns provide distinct read access ports for two inputs from any row on each cycle.

Often, the length of variable lifetimes must be greater than the initiation interval. When a software pipeline is executed on a conventional horizontal architecture-computed operands are systematically overwritten, after looping to the next iteration, by the same operation that computed the operand on prior iterations. This overwrite often occurs even before the end of the operands lifetime. This problem can be alleviated by copying the operand before the operand is overwritten or by unrolling code and renaming registers. Each of these techniques has complex limitations.

The CRM addressed this problem using an Iteration Frame Pointer (IFP) that relocated loop-variant values on each iteration. Loop-variant register operands are addressed by adding a displacement from the instruction to the IFP modulo the register file size to determine the physical location of the selected register. The IFP is decremented every loop iteration to relocate subsequent register reads and writes. This allowed each operation in the loop body to generate overlapped sequences of register lifetimes that spanned multiple loop iterations. The compiler was responsible for allocating and tracking these values as loop execution progressed.

General-purpose registers (GPRs) were designed to solve a number of problems. Loop invariant values are values that are computed prior to loop execution and repeatedly referenced on each iteration. Loop invariants are supported using GRPs that are addressed as conventional registers and do not participate in register relocation. The use of separate address and data clusters limits the flow of operands between clusters. For example, a value loaded from memory and stored within its CRM row cannot be read directly by an operation in the address cluster. To provide flexible connectivity, all units can write or read the GPRs. GPRs are typically written outside of innermost loops and allow flexible communication between clusters.

Predicated Execution

Many loops have conditionals that preclude parallelization by previous vector and multiprocessor techniques. The Cydra 5 used predicated execution to allow the execution of nested if-then-else conditionals within a loop

body. If conversion is a code transformation that uses predicates to eliminate branches. After simple if-then-else code is if-converted, a compare computes complementary Boolean predicates for then and else clauses. Operations within each clause reference a predicate operand that provides the correct clause conditional. Each predicated operation executes only if its predicate input is true otherwise it performs no action. This correctly implements conditional actions without program branches. Predicated execution also allows the nested if-conversion of conditionals within conditionals. After if-conversion, conditional, and unconditional code is uniformly scheduled within a software pipeline. The execution of multiple if-then-else conditionals can be overlapped and scheduled as if the code were unconditional code.

Specialized Loop Control

Software pipelining produces code schedules that are periodic only after a prolog period during which the software pipeline is filled and before an epilog period during with the pipeline is drained [7]. Without specialized hardware, code replication is needed for both prolog and epilog code before a periodic kernel loop is reached. Efficient support for loops with small trip counts exaggerates the complexity of code generation and scheduling as prolog code may enter epilog code without ever reaching the kernel.

The Cydra 5 combined the CRM with predicated execution and a specialized branch to greatly simplify this problem. A *brtop* loop branch operation supported software pipelines. The *brtop* was itself a pipelined branch having two branch delay slots in which additional *brtop* operations might be scheduled. The *brtop* referenced a number of registers, including: the Loop Counter (LC), Epilog Stage Counter (ESC), the iteration frame pointer (IFP), as well as the Iteration Control Register (ICR) predicate file.

The structure of a software-pipeline loop executing on the Cydra 5 is shown in Fig. 2. Each row illustrates operations executed during II cycles of machine code execution. Operations from a single iteration of the original loop body are divided into lettered stages, each stage requiring exactly II execution cycles. The vertical (time sequential) execution of code within stages ABCD and E completes a single iteration of the source

Iteration number	Loop counter	ESC	Stages executed					ICR predicates		
initial	6	4						00001		
1	6	4	e	d	c	b	A	Prolog code	00001	
2	5	4		e	d	c	B	A	00011	
3	4	4		e	d	C	B	A	00111	
4	3	4			e	D	C	B	A	01111
5	2	4	Kernel code	E	D	C	B	A	11111	
6	1	4		E	D	C	B	A	11111	
7	0	4			E	D	C	B	A	11111
	0	3			E	D	C	B	a	11110
	0	2				E	D	C	b a	11100
	0	1				E	D	c	b a	11000
		0				E	d	c	b a	10000
									00000	

Cydra 5, Fig. 2 The structure of a software-pipeline loop

loop. These loop iterations are overlapped, and each subsequent copy of the actively executed loop body is displaced downward in time by II cycles. The example illustrates the execution of seven source iterations of a loop body having five stages in its software pipeline schedule. The execution of code stages is lettered and lower case indicates that a stage is nullified (executed with predicate 0). Upper case indicates that a stage is active (executes with predicate 1).

The number of stages measures the amount overlap among successive iterations. The kernel code region is shown in gray. In this region, horizontal (simultaneous issue) code from all five stages of the loop executes every cycle. Each kernel stage corresponds to a single loop iteration at the machine instruction level that executes the steady-state pattern in the heart of highly optimized loop. This is the period during which full parallelism is achieved.

Prior to entry in the kernel, the loop is in its prolog. New iterations are initiated every II cycles, but there are an insufficient number of prior iterations to fill the pipeline. In the first row or iteration of the machine code loop, only the first stage A of the first source iteration actively executes. In the second row, B from the first source iteration and A from the second source iteration execute simultaneously. As the pipeline fills, additional stages become active. The pattern of predicates shown on the right correctly enables corresponding stage code. During the epilog, old iterations continue to finish but no new iterations are initiated. Again the epilog pattern

is controlled using the pattern of ICR stage predicates shown on the right.

The brtop operation implements all actions needed to control such loops. Each execution of the brtop decrements the iteration frame pointer in order to relocate all register values (including predicates) to allow overlap of lifetimes. The brtop operates on both loop count (LC) and epilog stage count (ESC) registers to correctly calculate the branch decision and stage predicate needed for the next II cycles. While the LC counts the number of source loop iterations, the ESC counts additional iterations needed to fill the software pipeline. A newly calculated stage predicate shifts into view from the right-hand side every II cycles. Operations within each stage reference a corresponding stage predicate. Using this architecture, a single copy of the loop body executes highly optimized software pipelines.

Cydra 5 Memory

Instead of relying on a data cache for high bandwidth, the Cydra 5's NP provided full bandwidth to DRAM-based main memory. A 64-way interleaved memory provided up to 512 MB of storage, and two access ports allowed two memory operations on every cycle. Memory module collisions, memory refresh, and other difficult-to-predict events introduced nondeterministic delays in performance. However, the numeric processor provided no register interlocks to stall dependent operations for tardy input operands, and memory operands

needed to return at a statically scheduled time. This was accomplished using the memory collating buffers and the memory latency register (MLR).

Memory collating buffers allowed operands to return from memory early and out of order within the memory subsystem while those operands are delivered on time and in order to the NP. The collating buffer holds returning memory operands until the exact delivery time. The memory latency register allowed the programming of the latency time at which results from memory were delivered. If a memory result could not be delivered within the requisite time as defined by the MLR, the NP was stalled until that operand was available. From the viewpoint of the NP, all memory operands are delivered exactly on time.

A key memory system goal was to support the efficient access to data for programs having arbitrary stride or complex scatter-gather access patterns. Conventional interleaved memories suffer a large performance loss when the stride of the access pattern and the degree of memory interleave have common factors. For a worst-case stride 64 access into a 64-way interleave memory, only a single memory module is used and memory bandwidth drops significantly. The Cydra 5 uses a pseudo random address transformation [8] that randomizes the memory access pattern so that common address patterns appear as a random pattern to the memory. The memory is designed to deliver full bandwidth for such random patterns.

The lowest possible latency for The Cydra 5 NP memory is 17 cycles. For scalar code, the MLR was set to 17 to minimize the wait time for scalar operands arriving from underutilized memory that occurs out of loop. Within loops, the this minimal MLR value leads to reduced performance as collisions from memory reference sequences resulted in delayed memory access. An optimal value for loops was selected as 26 cycles which balanced needs for high bandwidth and low latency, especially for short trip count loops.

Exception Handling

The Cydra 5's exception handling followed the philosophy of relying on software rather than hardware for complex operations that not critical to performance. The Cydra 5 provided a Program Counter History Queue (PCHQ) to record the recent history of instruction addresses. Exceptions are not generated at the time

of instruction issue but instead occur a number of cycles after issue at specific exception latencies. For example, a memory exception is reported after a failed address translation, three cycles after operation issue. Hardware directs execution a software exception handler that provided a direct indication of the unit on which the exception occurred and the cause of the exception. However, hardware does not directly indicate the actual operation that caused the exception. This operation issued a number of cycles in the past and may have been followed by one or more intervening branches. Exception-handling software processes the PCHQ and uses known exception latencies to identify the exact operation that caused the exception. If needed, software recovers input operands from the input registers for the exception causing operation. This provides all inputs needed to process exceptions in software and resume execution.

Cydra 5 Compiler Technology

A large burden was placed on the compiler to identify and exploit large amounts of parallelism. After classical optimizations, the compiler was responsible for identifying all interoperation dependences to expose parallelism as a program graph. The graph was transformed to enhance parallelism in order to providing adequate parallelism for the NP. Then the compiler's scheduler created a schedule that packed operations into instructions and time. Specialized compiler technology for software pipelining was developed to exploit the NP hardware. While the Cydra 5 compiler also utilized specialized VLIW compilation techniques for scalar code, this is beyond the scope of this discussion and can be studied in more detail in [9, 10].

The Cydra 5 software-pipelining technology demonstrated optimal sustained performance for most numeric loops. Specialized loop optimization was applied to software-pipeline loops to transform code into an optimized form for software pipeline execution. The compiler used an intermediate form to represent loops in various optimization stages. The intermediate form used the concept of Expanded Virtual Registers (EVRs) to reference operands that have been computed in the current iteration or in previous iterations that may still be available for use in the current iteration. Thus, while an operand "t" represents a temporary computed in this iteration, t [1] represents the value of the same operand

as computed in the prior loop iteration. This intermediate form was used to express a number of loop optimizations, including load/store elimination, common sub-expression elimination, and height-reducing transformations needed to produce optimized code. Each of these optimizations reused values computed from prior iterations and EVRs precisely define this operand reuse.

Optimization is followed by scheduling for software pipeline execution. Performance bounds on the maximal execution rate were calculated and used to assist in loop scheduling. For most loops, loop schedules were identified that exactly match those bounds achieving optimal program schedules for long trip count loops. The Initiation Interval II measures the minimal time delay in cycles between successive iterations in a software pipeline. The II may be limited either by insufficient hardware resources or by the latency between dependent operations in successive iterations.

The limited availability of hardware resource provides a bound known as ResMII. Assume that a loop body has a number of operations n_t of a given operation type t (e.g., four operations of type memory in the loop body). Assume that hardware provides a number f_t of function units that execute operations of this type (e.g., two memory units). For operation type t , $res_t = n_t/f_t$ provides a resource bound for that type. This bound provides a lower bound on the initiation interval and an upper bound on the throughput for this loop. In this example, a loop body having four memory operations that executes on a processor having two memory units has $\Pi \geq 2$. For multifunction VLIWs, the largest res_t over all resource types provides the worst-case ResMII bound. The initiation interval measures a number of clock cycles as an integer quantity. When the ResMII resource bound is fractional, loop unrolling can often achieve the fractional bound. For example, if the ResMII = 2.5, two unrolled loop iterations may be executed every five cycles.

Dependences between operations in adjacent iterations also limit parallelism. A bound known as RecMII is calculated directly the program intermediate form. The intermediate form represents a program graph that captures dependences both within a loop iteration and between loop iterations. Inter-iteration dependences are marked with a distance that captures the number of iterations spanned by the dependence. Legal program graphs contain cycles that describe dependence

```

initialize:
a[1]
s[1]

do N times
    a = a[1]+4
    t1 = read(a)
    s = fadd(s[1],t1)

enddo

s = s[1]

```

enddo

u = fadd(s[1],s[2])
s = fadd(u,s[3])

```

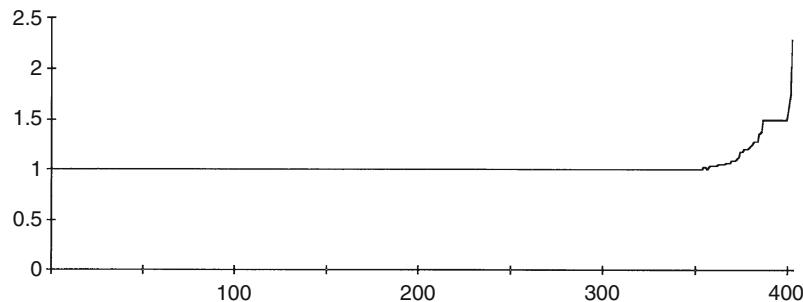

Cydra 5. Fig. 4 Height-reduced code

Cydra 5. Fig. 5 Loop graph for height-reduced code

relationships between operations within a single loop iteration as well as between iterations.

The Cydra 5 compiler applies height-reducing transformations to alleviate the performance limiting effects of inter-iteration dependences. Figure 3 illustrates vector sum pseudo code for the Cydra 5. To simplify the example, latencies of 2 for address add, and 3 for floating add replace actual Cydra 5 latencies of 3, and 4. Each operation in the loop body can be executed as a single

Cydra 5. Fig. 6 Achieved performance for over 400 loops

machine operation on the Cydra 5. The EVR references provide an iteration distance as a register reference $r[i]$ indicates the register value r from the i 'th prior loop iteration. A value produced in the current iteration $r[0]$ is abbreviated as r . In this non-height-reduced form, the floating point sum recurrence limits loop performance to one iteration every three cycles.

Figure 4 shows code after height reducing transformations [11] are applied to alleviate limitations from recurrences. First-order recurrences are replaced by second- and third-order recurrences for address and floating sums, respectively. While summation terms are reordered, a correct final value is reproduced as the same terms are finally summed. Figure 5 illustrates the program graph for the height reduced loop. Two recurrences are shown, and each limits performance by its path length divided by the iteration distance. After height reduction, a new loop iteration is initiated every cycle and, in the final loop schedule (not shown), all three operations are scheduled in a single machine instruction that executes every cycle.

The Cydra 5 loop scheduler relied on an accurate estimate of the desired II to begin the scheduling process. ResMII and RecMII bounds are calculated, and the larger of the two is used as the starting II for loop scheduling. The actual procedure to calculate RecMII is somewhat complex and beyond the scope of this discussion. After an initial II is determined, the scheduler uses a branch and bound search algorithm to explore the placement of operations within a cyclic schedule. Each newly scheduled operation is placed to satisfy both resource availability and interoperation dependences from previously scheduled operations. The scheduler backtracks when new operations cannot

be scheduled. Typically, the scheduler finds an optimal schedule in this process. However, sometimes, when all scheduling choices are exhausted or after excessive compile time is expended searching for a schedule, the II is raised to search for a lower performance loop schedule.

Figure 6 illustrates the performance of over 400 loops taken from Numerical Recipes, Linpack, and the Livermore FORTRAN Kernels. The performance each loop is plotted as a ratio of the II for the achieved loop schedule divided by the II that is estimated using the MAX(ResMII, RecMII) bound. Thus, a value of one indicates the loop scheduler has achieved optimal performance. Loops are sorted on order of increasing ratio of (achieved II)/(estimated II) and plotted. Note that over 350 of the loops achieve optimal performance. On the right, a single worst case loop having unusually complex resource patterns and dependences achieves a throughput 2.5 times slower than the desired bound.

Bibliographic Notes and Further Reading

At the time Cydra 5 was introduced, scientific computing was dominated by Cray corporation's vector processors [12]. Other key contemporary processors included the Alliant multiprocessor and the Convex vector processor. VLIW architectures were explored in research by Fischer [5], and this work resulted in the Multiflow architecture and compiler [13] that was contemporary with the Cydra 5. The Multiflow architecture relied on Trace Scheduling to identify and replicate important program code regions.

Definition

A Data Center is a facility hosting large collections of servers that are physically co-located to facilitate one or more combinations of Internet connectivity, operation infrastructure (such as power delivery and cooling), management, and providing access security.

Discussion

Introduction

Large organizations (e.g., enterprises, governmental agencies, research and academic institutions) have historically used machine rooms to host and operate a collection of server- and supercomputer-class computing platforms. The machine rooms were designed to leverage the cost of building, hosting and operating a collection of high-performance computers.

The exponential growth in information technology made possible by advancements in semiconductor fabrication for the past several decades has been met or surpassed by the growth in demand for computing. The net result is that computing platforms hosted in machine rooms have become denser (e.g., have a higher computational and storage capability per occupied unit volume), and machine rooms have been growing in size, increasingly hosting large collections of server-class machines referred to as clusters or server farms.

Today, information technology is an indispensable pillar for a modern society in general and industry in particular. Companies from start-ups to multinationals all have IT departments which are large organizations with many machine room installations that provide computing as a service internally to the company. Because most of the activity within an IT department is centered around processing and storage of data belonging to an organization, machines rooms have evolved into entities that are increasingly referred to as Data Centers.

Today, Data Centers range in size from installations that have about thousands of processing cores and a few petabytes storage dissipating a few hundred kilowatts of electricity to hundreds of thousands of processing cores, hundreds of petabytes, and tens of megawatts of electricity.

Physical Layout

As in machine rooms, a Data Center typically refers to a physical site. A site can be a shipping-container-sized entity, a room, one or more floors of a building, or a number of collocated buildings. The minimal physical unit to which network connectivity, power, and cooling are delivered to is referred to by some vendors as a POD. A POD is a collection of racks of hardware that are collocated and sit adjacent to each other.

Containers are PODs that are optimized for transport and mobility and are sized exactly to be the size

of a shipping container. PODs in a room are sized for maximum energy efficiency.

Servers

The IT equipment in a Data Center consists of compute nodes or compute clusters (for processing), storage nodes or storage clusters (for storing), the network nodes (for communicating both within and to the outside), and a tape library (for backup). Compute, storage, and network hardware today appear in the form of rack-mounted platforms. Tape libraries often appear in the form of tightly integrated collection of tapes that are operated internally by robots. Nodes of the same type are often collocated due to the diverse cooling and reliability requirements of the node types. Node form factors continue to evolve based on improvements in fabrication technology, server density, and power/cooling delivery.

Hosting Infrastructure

Hosting infrastructure includes outside network connectivity, power delivery, cooling, and security (including both fire protection and secured access). The site must provide network connectivity commensurate to its size. Fortunately, with advances in communication technologies in line with improvements in processing speed and storage capacity, network bandwidth has kept pace with the demand on IT installation sites. Cooling and power delivery account for a substantial fraction of electricity in Data Centers. Power Usage Efficiency (PUE) is a metric that expresses the energy efficiency of a Data Center. PUE is the total electricity used by a site divided by the electricity used only by the IT equipment. PUEs in today's Data Centers can be as high as two indicating a 100% overhead in electricity to deliver cooling and power. Vendors are now marketing installations with PUEs as low as 1.3.

Historically, machines in a room have been air-cooled with computer room air conditioning (CRAC) units that cool the room and consequently the equipment. As Data Centers have become denser through the years and semiconductor technologies are reaching their limits in energy efficiency, designers are resorting to CRAC-less cooling technologies that are more energy-efficient. Modern PODs are airtight from all sides and have access panels/doors from the sides to

allow for serviceability. Today's low PUE installations circulate chilled water over rack tops and use forced air down to cool the racks. Modern cooling infrastructure and POD installations also obviate the need for raised floors which played a central role in air circulation in more conventional setups.

Power accounts for the second largest source of overhead after cooling. To prevent a single point of failure, all elements of the electrical system are replicated. This replication dramatically adds to the cost and electricity usage of the power delivery system. There are provisions for backup power that consist of universal power supplies and diesel generators.

Tiers

Data Centers have diverse reliability and availability requirements based on usage. As such, they are categorized into "tiers" ranging from Tier 1 with the least stringent reliability requirements to Tier 4 with the most stringent reliability requirements. Even within the same organization, applications may demand the usage of Data Centers from varying tiers. For instance, a telecommunications company may use a Tier 4 data center for high availability in their data network service and a Tier 1 data center with less stringent availability for bill processing. The various tiers' availability requirements are 99.671% for Tier 1, 99.741% for Tier 2, 99.982% for Tier 3, and 99.995% for Tier 4. The difference in the infrastructure (power delivery and cooling) cost between Tier 1 and Tier 4 can be a factor of two or higher [1].

Energy

The main scalability impediment to Data Centers in the future is energy, with both economic and environmental implications. Demand for Data Center scalability has shot up through the years, resulting in an unprecedented level of electricity usage in Data Centers. On the one hand, the demand for ubiquitous computing and data access by all computer users has skyrocketed. On the other hand, the cost of owning and operating IT equipment has caused many start-ups and smaller enterprises to buy processing and storage of data as a utility. The latter is loosely referred to as Cloud Computing. Cloud Computing is leading to unprecedented growth in server-side computing and Data Centers.

The Energy Star report to the US government indicates that Data Center electricity usage in the USA doubled from 2000 to 2006, and is slated to double again by 2011. The net result is that in 2012, operation cost in terms of electricity over the lifetime of volume servers will cost 50% more than the capital cost of purchasing the server in 2012. The carbon footprint of Data Centers in the USA in 2012 is slated to equal that of the airline industry.

While projections of conventional semiconductor fabrication technologies indicate scalability in chip integration levels and cost for another decade, chip energy efficiency has dramatically slowed down. The net result is tokened “the economic meltdown of Moore’s law” for servers and datacenters by Kenneth Brill of the Uptime Institute.

There are a number of short-term solutions to mitigate the Data Center energy efficiency problem. Idle power is quite high in servers, reaching up to 70% of peak power. Virtualization helps avoid idling by consolidating multiple servers into a single physical platform. Virtualization is quite effective in eliminating idle power, but soon reaches diminishing returns as utilization reaches 100%.

Cooling efficiency is another low hanging fruit. Modern installations use cold-isle rather than the conventional hot-isle setup where the racks are cooled inside the air-tight POD and the hot air is circulated out. Cooling efficiency can dramatically reduce electricity consumption. Improvements in overall energy consumption can come about for installations (e.g., in Europe) that tightly integrate outdoors air/water at cooler temperatures to help reduce cooling costs, and use the generated heat to warm buildings.

Microprocessors are increasingly incorporating a larger number of simpler processing cores. The latter are more energy-efficient but require an increase in the degree of parallelism in the software. A number of conventional server softwares are highly parallel and as such amenable to such organizations. Low parallelism in code and the diminishing returns on how simple cores can get will eventually limit energy efficiency in conventional microprocessor organizations.

Solid-state disks (SSD) are emerging as a cost- and energy-effective approach to augment the storage hierarchy. A layer of SSD between memory and disks can serve as an effective cache for the storage, filtering much

of the traffic to disks, requiring lower bandwidth disk configurations, and saving energy at the same time.

Future Directions

With regards to energy efficiency, there are a number of opportunities to exploit to scale Data Centers. As voltages in semiconductors chips have leveled off, while chip integration continues, designers must pursue solutions that minimize the number of joules per operation in a computing stack. To scale energy for another 10 years, the solutions must achieve two orders of magnitude of improvement in energy efficiency.

Mobile platforms historically have been designed for low power due to battery usage concerns. Servers must incorporate such technologies to minimize power without sacrificing the multitude of abstraction layers in modern server software. Specialization and vertical integration of lower-level software and hardware for common services in a server (e.g., OS, databases, web, search) are likely candidates to achieve such orders of magnitude in energy reduction.

Air cooling is highly inefficient as air is not an effective medium in absorbing heat. Conventionally, supercomputers have used liquid cooling to achieve much higher cooling efficiencies at albeit higher technology costs. Technologies, such as two-phase liquid cooling, are promising approaches to improve Data Center PUE’s to levels below 1.1.

To achieve optimal temperature and minimal cooling, thermal sensing, management, and cooling must be coordinated. Modern servers include internal knobs (e.g., voltage/frequency scaling) for thermal/power management. As servers are overprovisioned (to provide performance guarantees), modern servers do not exploit these mechanisms. Moreover, modern platforms include crude temperature sensing and management technologies that do not lend themselves well to accurate thermal management. There are proposals for integrated and accurate thermal management and cooling.

There are a number of proposals to reduce replication levels in the electrical system and power delivery while not compromising the availability. Such proposals dramatically reduce the electricity usage in the power delivery.

Data Distribution

SAMUEL MIDKIFF

Purdue University, West Lafayette, IN, USA

Definition

Data distribution refers to the process of spreading the elements of a data structure, typically an array, across two or more processors of a distributed memory machine. This is done to enable parallel computation on the distributed structure. Distributing an array across multiple processors leads directly to the problems of how to address the elements of the array within a processor, how to determine the processor on which some element of an array has been placed, and the related question of what elements a given processor owns. Topics related to distributing non-array data structures are not covered in this article. Moreover, the discussion is

restricted to arrays whose subscripts are affine expressions, and to distributions that can be described as affine expressions in one or two variables. These restrictions are important because they allow the problems above to be targeted with Diophantine equations while handling common data distributions and program idioms.

Overview

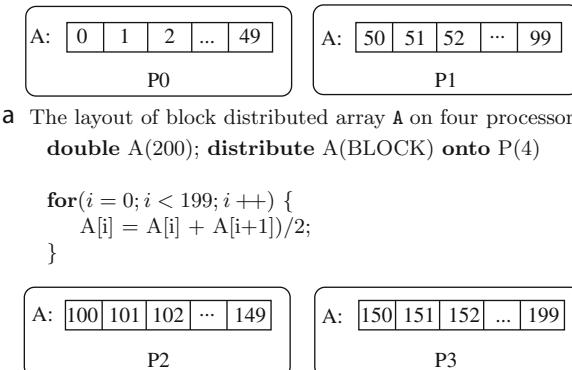

Computational Model and Notation

Figure 1a shows the array A *block* distributed across four processors. The distribution results in the block of elements 0...49 being placed on the first processor, elements 50...99 on the second processor, elements 100...149 on the third processor, and elements 150...199 on the fourth processor.

Given a set α of array elements whose values will be computed by a processor p , it is often the case that values not distributed onto p are needed to perform the computation. A popular way of determining the elements in α is the *owner computes rule* [11], i.e., each processor computes new values for the array elements that reside on it, i.e., that are *owned* by it. To compute the new values of array elements in α , it is necessary for the processor to receive from other processors the input values that reside on these processors. Thus in Fig. 1a, to compute A[49], processor p_0 must acquire the value of A[50] from processor p_1 . Because values are typically communicated via two-sided MPI primitives, it is also necessary for the processor that owns the needed values to know that it must send them. Thus, in the example, it is necessary for p_1 to send the value of A[50] to processor p_0 .

Notation Needed by Data Distribution

Let A be an array of rank D_A , that is A has D_A dimensions. For every dimension d , $0 \leq d < D_A$, the lower bound of A in dimension d will be zero, and the upper bound will be denoted U_{A_d} . The processors performing the computation can also be arranged as an array with rank D_P , using a similar notation. Individual processors will be described as elements in the processor grid, i.e., $p_{j_0, j_1, \dots, j_{D_P-1}}$ is element $P[j_0, j_1, \dots, j_{D_P-1}]$ in the processor grid P. For simplicity, in this article, one-dimensional processor grids will be assumed unless otherwise stated.

- a The layout of block distributed array A on four processors
double A(200); distribute A(BLOCK) onto P(4)

```

for(i = 0; i < 199; i++) {
    A[i] = A[i] + A[i+1])/2;
}
  
```

- b A loop performing a computation on A that is not distributed.

Data Distribution. Fig. 1 An example illustrating data distribution and related problems

References to arrays are typically contained in loop nests. The loops within a nest are subscripted by index variables named i_1, i_2, \dots, i_n , where the i subscript is the nest level of the loop, i.e., i_1 is the outermost loop. The index variable for an entire loop nest is called I , i.e., $I = [i_1, i_2, \dots, i_n]$. For each dimension d of array A, there is an affine index or subscript function $\sigma_{A_d}(I) = c_1 * i_1 + c_2 * i_2 + \dots + c_n * i_n + c_0$.

Upper (lower) bounds will be referred to as $U(L)$, respectively, with a subscript indicating the program structure (e.g., a loop, or a data array or processor grid) and the dimension whose bounds are being represented. Thus, U_{i_1} is the upper bound of the loop whose index variable is i_1 , L_{A_d} is the lower bound of dimension d of an array, and L_{A_d, p_j} is the lower bound of dimension d of the portion of the array A on processor p_j . The number of elements in an array (processor grid) dimension is $U_{A_d} + 1$ ($U_{P,d} + 1$).

The *block size* B_s is the number of elements of a block of an array dimension that is either block or block-cyclic distributed. As with upper and lower bounds, subscripts can be used to further identify the block being described. For each distribution, there is an affine function $\Delta_{A_d}(\cdot)$ in one or two variables that describes the distribution of elements of dimension d of array A onto a processor grid. A function $\sigma(\cdot)$ is an affine subscript function for some dimension of an array reference. Subscripts on σ (and other quantities) may be dropped if the meaning is clear from the context.

Local and Global Spaces

The literature often refers to the *local* and *global* spaces of an array. In the example of Fig. 1, the global space of the array contains all of the elements of the array, and valid index values are 0...199. The local space varies with each processor. Thus the local space of the array on p_0, p_1, p_2 , and p_3 is 0...24. In languages like Fortran 90 that support nonzero lower bounds and array sections, the distributed array elements on some processor can be addressed in the global space. In languages like C, C++, and Java, they must be accessed in the local space, and a translation analogous to what Fortran 90 does going from a reference in global space to accessing a locally distributed element must be performed by the programmer. For simplicity, in this article, it is assumed that all accesses are in global space, i.e., $A[25]$ is used to access the first element of the A array on processor p_1 in Fig. 1a.

Data Distributions

This section describes what elements of an array are placed on what processors, and how this placement can be represented by an affine function in one or two variables.

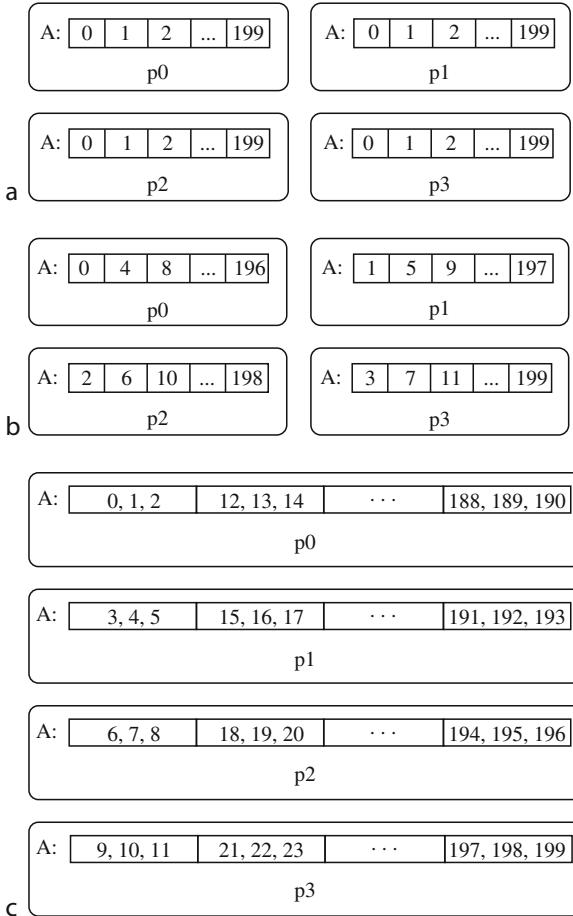

After discussing the simple one-dimensional case, the case of multidimensional data arrays being distributed onto multidimensional processor grids will be considered.

Replication of Data

The simplest form of data distribution is to *replicate* the structure across the different processors [8]. Thus, a copy of the distributed array is placed on each processor as shown in Fig. 2a. The function $\Delta(e) = 0 \leq e < U_A$ describes the elements of A contained on each processor.

Block Distribution
